We must now, however, return to the spiked collar. The impression produced by this instrument is never effaced; so much so, that a smooth-haired, high-bred pointer will not refuse to go into a river in the coldest and severest weather in winter, although he will, perhaps, shiver on the bank at the very sight of it, before plunging in. We have heard of dogs of this description, which had been thoroughly broken by compulsory means, and they never refused to go into the water, although they might sometimes hesitate in frosty weather; but the instant the magic words "Collier de force" were uttered, they plunged in with all the alacrity imaginable. Such dogs, however, ought not, as a rule, to be taken out on such occasions. It may be further questionable whether pointers ought to be taught to retrieve; and as a rule it is perhaps wrong; but, in a country where snipes are abundant, and are the principal objects of the sportsman's pursuit, it is, we think, advisable that all his dogs should be taught to fetch and carry, in case of accident to the regular retriever; because it will occur every day that some few snipes will fall in places not easily, and sometimes not safely, accessible to the sportsman; and all sportsmen know how vexations it is to lose a bird after he has been killed, and how tantalising it is to see him lying almost within reach, and yet be obliged to leave him. This will occur even in grouseing, in the case of a towering bird falling into a fresh-water loch; and where there is no retriever the bird must be left and lost. This, however, is a rare occurrence; but in snipe-shooting, in most marshes, it will happen often to the sportsman, if he has not a retriever with him: in fact, no sportsman of any experience will either go out snipe or duck-shooting without being accompanied by a first-rate retriever; and even then he must make up his mind to lose some few birds, if he is shooting in the immediate vicinity of the sea, as both widgeons and ducks will occasionally fly some distance when they are wounded, and drop dead; and, if they happen to fall in a strong outward current, they are soon carried beyond the power of any retriever. Indeed, sometimes blackcocks, which have towered after being shot, and fallen out a good distance at sea, have been lost; and woodcocks also (as these birds tower sometimes) are apt to be lost in the absence of retrievers.

Leaving this incidental digression, we now return to the system of training. The two great advantages arising from the compulsory system, when it has been carried thoroughly into effect by a first-rate hand, consists, in the first place, in the complete obedience and thorough docility exhibited on all occasions on the part of the dog, as he never refuses to search for and bring his game when ordered to do so, either on land or from the water, irrespectively of the weather; and, in the next place, which is an important feature characterising this system, he invariably picks up his game at once, without mouthing it, and returns to his master immediately. The reverse of this, it is said, is the case with dogs taught by gentle means—even with the spaniel and Newfoundland; and some very good ones, excellent in every respect, with the one exception of not returning directly and promptly with the game they had in their mouths to their master, have been known.

With regard to dogs instructed by children to fetch and carry, a writer says, he had the ill-luck to be the purchaser of one through the instrumentality of a friend; and the result is so much to the purpose, that he relates some of the circumstances connected with the purchase, possession, and trial of the said dog. Having taken up quarters for a little snipe and duck-shooting, in a favourite locality, he found himself much in want of a good retriever, and applied to a friend resident in London, giving him carte blanche as to price. The friend shortly replied, stating that he had purchased a first-rate retriever for £10—a beautiful Newfoundland, warranted to retrieve perfectly on land and from the water. He
observed that, although the dog's teeth were somewhat damaged, he was perfectly young and fresh, the teeth having been injured in consequence of his recent instructors—the children of the family from whom he was procured—having given him considerable practice in fetching up stones from the bottom of a river which passed through their garden. Broken teeth in a retriever were, of course, not objectionable. When the dog arrived, the purchaser was certainly very much pleased with his appearance, as he was as handsome a Newfoundland as he had ever seen, and fancied he would answer the purpose exactly; which favourable opinion of him was confirmed after the two or three first days' duck-shooting, as he brought all his birds perfectly; but it so happened, that every duck killed fell on the near side of the river; and on going out on the fourth day, some ducks were killed, which fell on the opposite side, nearer to the farther bank, when, greatly to the sportsman's astonishment and annoyance, the retriever, after taking the water in his usual gallant style, and possessing himself of his bird, swam out on the other side of the river, where, after depositing his bird, he commenced rolling himself on the grass, and, after having well shaken himself and performed a variety of gambols, returned very quietly, leaving his bird behind him, as doubtless he had been in the habit of doing with the stones thrown into the river by the children, whenever accident or caprice induced him to go out on the reverse side. He tried his utmost to persuade him to go back and fetch his bird, but without success, the bad habit acquired from the children being ineradicable; as, on every occasion of a bird falling near the opposite bank, he acted in a similar manner. As a temporary remedy, during the short time he retained possession of this dog, he made his game-carrier take a long cord with him, which he fastened to the dog's collar whenever any bird fell into the river at a distance, so that his attempt to go out on the further side was not only checked, but he was conveyed safely to the proper shore. This plan was pursued for some time, thinking it might, perhaps, break him of his bad habit; but this was not the case, as, on relinquishing the cord by way of experiment, he immediately committed his first offence; and, finding him incorrigible, he was presented to a family, where he afforded the greatest satisfaction, being a safe playfellow for the children by day, and a faithful and vigilant guardian by night.

Dogs taught by children generally acquire a variety of bad habits, which totally unfit them for sporting purposes. We have no doubt, however, that there are exceptions, and that some few sportsmen may possess dogs so instructed, which are perfect; but these neither establish a rule, nor militate against the one on which we insist. Dogs generally are so docile, that we are predisposed to believe anything which may be related of any one particular dog; but still, when animals are to be trained for specific purposes, it appears to us to be judicious to adopt that system which has been pursued with unqualified success by those who have devoted all their time and attention to it, purely as a matter of business; as it must be recollected that dogs, like human beings, vary much in temper and disposition. It is, therefore, presumable that those who break the largest number of them are more likely to discover the best mode of proceeding with, and treating them, than those whose practice and experience have been confined to a few, and those, perhaps, of one particular breed. A French dog-breaker will undertake to break, and will succeed thoroughly with, any breed or race of dog, provided he be about twelve months old. It therefore appears to us that it must be conceded to them that their system is a good one. "We speak advisedly on this point," says a writer, "as we have seen various cross-breeds of dogs, which had been taught by French breakers, bringing their game perfectly; and, on one occasion, on our questioning one of these heroes of the *collier de force* on this particular point, his reply was—"*N'inporte quelle race; aussitôt que je mets mon collier il faut cela marcher, sauver et aller nom de chien.*' We have shot to several pointers and setters broken by the same man, all of which brought their game perfectly, never disturbing a single feather, and always returning the instant they picked up their birds. This latter result is produced by giving the spiked collar a sharp jerk in the first instance, the moment the dog under instruction picks up whatever is thrown out.
for him to fetch, in the event of his not returning with it immediately, omitting this infliction when he returns promptly, so that the fear of receiving this punishment produces an alacrity which is never abandoned, and which is so agreeable to the sportsman. When setters have undergone the ordeal of the collier de force, they give the sportsman comparatively little trouble when he wishes to instruct them to back and stand. Having been made docile and obedient, more than half the difficulty is overcome."

As some of our readers may not be aware as to what sort of an instrument the collier de force is, we may explain that, in France, it may generally be obtained at the shops of the gunmakers and saddlers. It is composed of thick but pliable leather, stout nails of about three quarters of an inch in length, and two semi-circular pieces of iron. "The collar may be two inches in breadth; length, about three inches shorter than the circumference of the dog's neck, for whose use it is intended; having at each end the semi-circular piece of iron firmly secured by the broad end of it; its strength being that of an ordinary buckle of a dog's collar, and being an inch and a-half in length; so that the extreme ends, when drawn tightly by one of the cords, will meet. As there must be two cords, one to lead the dog by; the other to inflict punishment—the former will be fastened to both rings; the latter only to one, but passing through the other; so that, when it is pulled, the collar is of necessity contracted, and the nails forced into the dog's neck. The two pieces of leather of which the collar is formed, are of similar size and shape, the under one being rather the thinner of the two. It is through this that the nails are introduced, the flat heads lying compactly between the two, and kept steadily and firmly in their position by strong sewing. The cord used is generally from twenty to thirty yards in length."

With the above implement, the dog under instruction is forced gradually to do whatever his instructor requires of him. Several objects are thrown out to be fetched and carried—sometimes, a piece of wood, of about nine inches in length, in the shape of a rolling pin, with two small pegs passed through at each end, so as to facilitate the dog's picking it up; at other times, either a stuffed bird or an old hare skin, tied up in a bundle; but the piece of wood is generally made use of in the first instance. The first difficulty is to make the dog pick up whatever is thrown down; when this, as it were, premier pas, is accomplished, the subsequent instruction is easily, although only gradually imparted, as continuous daily lessons must be persevered in for the space of a month, before the dog will be thoroughly taught to fetch and carry on land, without the risk of disappointment; and after this is accomplished, as we have already intimated, the second course of education, which consists in forcing him to take water without plunging, and bringing his game instantly from it, will occasion quite as much trouble as has been previously incurred, and occupy about the same length of time; a shallow piece of water being selected for the necessary manoeuvres, and during the summer months—this season being most suitable, as the obstinacy and resistance of the pupil will frequently necessitate the entrance of the instructor into the water. "As we have frequently witnessed dogs under this species of instruction," says the anonymous writer to whom we are indebted for the information contained in this part of our subject, "we are well aware of all the difficulty and trouble involved in it; but when it is once thoroughly carried out, the sportsman will have the satisfaction of possessing a dog on whom he can invariably depend, without the slightest fear of disappointment; and we do not believe that this can often be said of dogs that have been taught by gentle means."

We will now direct our remarks to the various methods of breaking and training pointers and setters to stand, back, down charge, and conduct themselves properly in the field and on the hill; and if we have spoken highly of the French system of breaking retrievers, we cannot say much in behalf of their method of training pointers and setters, as it is radically bad—repudiating the very first principle of the strict adherence to which the success of all subsequent sound instruction must depend; namely, that of down charge and dropping to hand; as these are not only not taught in France, but universally discouraged, inasmuch as every dog is expected
to run in immediately after a shot is fired, pick up and bring whatever game is killed; and in the case of a hare being shot at and wounded, to chase and do his best to catch the hare; and, if he is absent half an hour, provided he returns with the hare, his master is highly delighted, and considers him a first-rate dog. We have seen some hundred pointers and setters—at least what are called so—and never saw one that either went down to charge, or that did not invariably chase. As all dogs are naturally disposed to chase, the highest bred ones as well as mongrels, it is not to be wondered at that when they meet with constant encouragement they should accomplish this feat to perfection.

There are various methods of breaking pointers and setters, recommended by different sportsmen and gamekeepers; and although there is some difference of opinion as to which are most advisable to be employed, there is none as to what the results ought to be. A good dog is expected to go down to charge, drop to hand, stand, back, carry his head high, range well, and quarter his ground in the most advantageous manner.

The natural requisites in pointers and setters are good breeding, perfect symmetry, and fine nose. The two latter qualities are generally consequent on the first, as it is rare to find a well-bred dog that is not well made and has a good nose. Admitting this position to be correct, attention to breeding becomes important; and, supposing a sportsman to have a first-rate female, either setter or pointer, we should recommend him to spare no trouble or expense in procuring or sending to the best dog he can find; and if he selects a dog that is unexceptionable in every respect, there will be little liability to disappointment. Differing from opinions given by some excellent sportsmen, we should say that it is best not to breed constantly in-and-in with dogs used in the sense of breeding from dogs nearly related one to another, as we have good reason to believe that the produce of such connections would be physically degenerate, and most probably deficient in sagacity. We cannot explain the physiological reasons for this result, as these, like many other operations of nature, we fancy are beyond our intellectual range; but we think we may safely affirm that the law of nature is universal in this respect, and therefore should not be disregarded. Herdsman, farmers, shepherds, gardeners, and breeders of horses and cattle, are all well alive to the fact that breeding in-and-in produces degeneracy: it is discernible in plants and seeds as well as in animals—in potatoes and wheat as well as in sheep. No good farmer will sow two years consecutively wheat in the same soil that produced it; and intelligent gardeners seek for change of seed. Shepherds, also, who have the care of large flocks of sheep, make changes every two years, too obvious to be more than hinted at, and find these necessary to avoid degeneracy. We refrain from going further into the particulars of this law of change, compliance with which is manifestly universally required by nature for the maintenance and advancement of our general interests, inasmuch as the subject, in all its various bearings, however interesting and important, is not likely to be settled by us. In support of these views, some very valuable information has been advanced on the subject of breeding fowls, not for the purpose of exhibition, but for the more important object of utility, where it is stated that, by following the law of change (i. e. crossing), heavier, finer, and more marketable fowls are produced; and it should be remembered "that the exhibition of birds is only a secondary consideration when compared with their commercial utility."

In proceeding with the method of training and breaking pointers, and setters, we will assume, for argument’s sake, that a young dog is well bred, of good shape and make, and about twelve months old, and just brought home from his walk to be taught everything which a pointer and setter ought to learn. The first thing to be done is to make him thoroughly docile and obedient, to know his name, to come immediately when called, to drop to hand, and not to move till he is allowed to do so. To produce these results, some use a collar with a cord; some the spiked collar with the cord also; and others exert moral influence aided by the whip. The merit and success of each plan will depend much upon a dog’s temper, as there is much difference in this respect; so that what would produce success with one dog would entirely fail with another. The breaker must, therefore, be
in a great measure, by circumstances. If a dog be of mild temper and naturally docile, neither collar nor cord will be required, and he may be made to go down without having recourse to severe means; in which case it will be merely necessary to place him at a particular spot, and keep him down with the hand, pronouncing audibly at the same time the words "Down, down!" giving a stroke or two with the whip, in the event of his evincing a disposition to move; and, when he is thus far obedient, his instructor must retire from him, like a courtier after kissing hands, keeping his eye upon him till he reaches a distance of forty or fifty yards, holding one hand up, and not permitting him to move till either calls, whistles, or makes a movement with his arm. In the event of his moving before he is ordered, he must be taken back to the precise spot where he was first placed, and made to lie down; and this lesson must be repeated till it fully succeeds—by which we mean, until the dog goes down at all times the instant the words "Down, down!" are pronounced, the hand being invariably simultaneously held up. The object of this is, that the dog may ultimately go down and back at all times on his seeing the hand raised, without its being necessary to call to him, as speaking would be disadvantageous when birds are wild; it being expedient, when having a brace of dogs at work, to make one dog stop instantly by a silent signal when his companion may have suddenly made a point unperceived.

When the above means are found insufficient, the collar with a cord may be used; and some think the spiked collar will prove more effectual than the plain one, with a cord of about five yards in length, the end of which can either be held by a boy, or fastened to a stake. When this first lesson is imparted, the efficacy of this plan will soon be perceived, if the dog is at all unruly or obstinate, by his gradual and progressive obedience. In the first instance he may resist; but when he discovers that he can neither escape nor avoid punishment if he disobeys, he will yield to his instructor, and go down when required. The greater the difficulty, the more certain and implicit will be the obedience, when the former is once thoroughly vanquished. Should the dog rise without permission, or move, he must be forced back to the precise spot, and made to go down, receiving at the same time several sharp jerks with the cord, and the same method of instruction adopted as we have just suggested. This mode of inflicting punishment is preferable to the use of the whip, as following immediately any act of disobedience; it is more intelligible to the dog, and makes a more lasting impression, consequently is more effective.

When this lesson has been thoroughly and completely inculcated, so that the dog is under perfect command, and will go down instantly he is called to, or on the hand being raised, then he ought to be taken out and taught to range his ground. The day should be fine and suitable; a slight breeze would be all in the dog's favour; more than that would be prejudicial. In the first instance, it will be better to go where game is thin; and, when he is somewhat fatigued, to where it is more abundant, especially if he has evinced symptoms of progress. It must be expected that he will chase in the first instance; but if the collar and cord be on him, as they should be, these will check him considerably; but, on each occasion of his committing any offence, by either running in or chasing, he must be caught and spoken to sharply, and receive a few smart jerks with the cord—"Down, down!" being several times simultaneously repeated. A steady old dog, taken out with the young one, will afford considerable facility in imparting instruction, particularly if they are acquainted with each other, as the young dog will naturally look to the old one, watch his movements, and go to him when he makes a point. On these occasions, the breaker must get up as promptly as he can, in order that he may exercise all his influence in encouraging his pupil if he is doing right, and in restraining and punishing him if he is disobedient. The chances are in favour of a dog's running in the two or three first times, although he should make a short temporary point, in which case he must, on each occasion, be caught, spoken to sharply, and receive punishment; and, should he continue to run in without showing any visible signs of amendment, then it will be advisable to take a boy out to hold the cord, so that he may receive prompt and immediate punishment, if he attempts to dash forward, either on his
seeing the old dog point, or on his perceiving birds rise, or on their falling if a gun be used. Three days' perseverance in this system have been known to succeed in making a dog perfectly staunch in backing, as well as pointing. It is advisable, especially if dogs are very high couraged, to let them have a little liberty, and not to be too severe for one or two days, and to allow the wire edge to be somewhat taken off, before stringent measures are had recourse to; the highest couraged dogs are generally the wildest at starting, but, when once broken, prove the best and staunchest. After one good point has been made, and a disposition evinced to yield to sound discipline, the progress is rapid; then no single fault must be overlooked, however trifling, and every care and attention is demanded of the breaker.

An indispensable requisite to all good dog-training is, to begin early. There is likewise another valuable ingredient in the art, namely, that the words of encouragement or reproof be always uniformly adhered to. The following is a kind of catalogue of phrases, or dictionary words usually connected with the subject. The word Steady! ought to be used when all dogs enter a field, especially young ones. Take heed! implies the same thing. When a dog is seen very busy and active with his nose and tail, feathering as he hunts, then the word To-ha! in a mild, but sufficiently marked and loud tone for the animal's hearing should be used, to cheer as well as to inspire caution. Down! or Down Charge! is a command to the dogs to crouch, or drop the birds. Back! brings the dogs back again to your feet. Seek out! sends them off again in quest of game; but a wave of the hand is considered much better where it is expected birds are near. Hie on! gives a spur to the timid dog to leave your feet; and Seek out! orders him to hunt. Go seek! should be impressed on a dog's memory as a command to look out for something considered as lost, or wanting; and the term is distinguished from seek out, by dogs that are properly trained. Hold up! is used to prevent the dropping of the nose to the earth to catch the scent, which, although the odorous particles may not have disappeared from the spot the birds stood on, are chiefly floating in the air; conse-

quently, by holding up his head down wind, he comes in contact with the scent of the birds almost immediately. The puzzle peg is used as a last resource when Hold up! is not attended to.

Ware! is a word of caution; and Ware Here! is to check the animal from running after the hare, when partridges, grouse, or pheasants are at hand. It is a good device to accustom a dog to attend to signs as well as words; for a wave of the hand will often do more execution than loud shouting.

The pairing season is a good time to break young dogs, as birds lie well; and this is an important point, and not to be disregarded. It would not only be detrimental to make the attempt with wild birds, but, in all probability, end in complete failure, and give the breaker considerable additional trouble on a future occasion. If a dog is not intended for the moors, and only for the marsh and field, then snipes are excellent birds to introduce to his notice, especially the Jack snipe, as he lies remarkably close, and a few of these shot on the ground, before the dog's nose, make him remarkably staunch.

When dogs are commenced to be taught to range, give them the wind as much as possible, but never persevere long in one direction; but, on the contrary, change your course constantly, alternately right and left, so as to induce your dog to watch your movements, without its being necessary to speak to him, by which means, if you are successful, he will subsequently beat his ground exactly as you desire, being influenced by your movements, which is a great advantage.

When a dog is beginning to learn his business and becoming steady, it is not a bad plan to go at right angles to the wind, as, in the event of his picking up a bird or two, and being merely scolded and made ashamed, he will be more careful and carry his head better when he goes partially down wind; and, moreover, when he points, will give you an opportunity of heading him, whereby you can put his patience and staunchness to the test, and will, at the same time, cure him of "blinking," if he has ever shown any disposition to do so, which means leaving a point after it has been made, and coming back to the gun—not a common fault, but one which sometimes occurs.
The very best of dogs will sometimes put up a bird; therefore a dog must not be condemned on his first trial if he commit a fault, but be rather judged by his general conduct. In grouse-shooting sportsmen like to give their dogs the wind as much as possible; but when birds are wild there is sometimes an advantage in going down wind with one old steady cunning dog, who will "sink" the wind, and get beyond running birds and head them, in which case even wild old cunning cocks, on finding themselves between two enemies, will allow the sportsman to get within shot. We are aware that this is not the regular mode of proceeding; but it is one of the many expedients which may be resorted to when birds are wild at the end of the season.

Setters and pointers may be either broken in the shooting season, or out of it, with, or without the gun; if without the gun in the pairing season, the breaker must take with him a horse-pistol, which he can discharge on the rising of birds, in order to accustom the young dog to the sound of the report, and also to make him down charge. The shooting season we think is the best time to complete the education of a dog; provided the sportsman is disposed to take the trouble on himself, and has patience to pay the requisite attention; a few shots may be lost at starting, but the progress of the dog is rapid, if he is well tired down each day, and plenty of game found and killed to him. At the commencement much work and little game is best for a young dog; but when he begins to behave well, he requires the encouragement of more game, but without diminution of work. There is little difficulty, we apprehend, in breaking a well-bred dog, provided the proper preliminary measures which we have suggested be strictly attended to. Well-bred pointer, and setter puppies, have frequently been seen to back and stand instinctively; and most sportsmen who have resided much in the country, we have no doubt, have constantly witnessed young dogs in a farmyard pointing all sorts of poultry.

Before concluding these remarks, we must notice one fault occasionally to be found in puppies, which must be counteracted—it is that of carrying their heads low, and endeavouring to make out scent as a spaniel would do. The remedy for this is an implement called a puzzle, made of iron, fastened in such a manner that the dog is obliged to carry his head high. The above fault is rarely found in high-bred dogs; they almost invariably carry their heads well—an advantage which the experienced sportsman appreciates; his legs are saved, and he procures good sport, where second-rate dogs would have completely failed.

The other dogs, more especially of the spaniel kind, are the Cocker, the Springer, the Blenheim Spaniel, and the King Charles' Spaniel. They are all, more or less, adapted for the field.

THE COCKER.

This dog is like a small land-spaniel, but with a shorter muzzle, a more rounded head, and longer ears. He is a lively little animal, and is used to spring woodcocks and pheasants in copses and thickets, where larger dogs cannot enter. He is very hardy, and never seems to tire at his work. He may, therefore, be hunted for days together; but he is difficult to keep under command, and he gives tongue loudly.

THE SPRINGER.

Is only a larger-sized cocker, heavier in make, and neither so active, nor so lively as the other.

THE BLenheim SPANIEL.

"Blenheim Palace, near Woodstock, Oxfordshire," says Mr. Richardson, "was formerly the estate of King Ethelred, and since that of Henry II., as also the birthplace of several princes of the royal line of England; subsequently the prison of Queen Elizabeth, during a portion of Queen Mary's reign; and afterwards granted by Queen Anne to John Duke of Marlborough, with the present palace, for his great victory over the French and Bavarians, at the village of Blenheim, in Sunbia, A.D. 1704. In this superb mansion has been preserved, for the last century and a half, the small red-and-white spaniel, or companion, the "Pyrame" of Buffon—the Blenheim spaniel of the present day. Except for their beauty and attachment, they are of but little use, although some of the breeds bring a long price. From their restlessness, and proneness to give tongue on the least alarm,
THE DOG, AND ITS VARIETIES; [BLENHEIM SPANIELS.

they make excellent watch-dogs inside a house.”

THE KING CHARLES SPANIEL.

This breed is distinguished by the shortness of the muzzle—the round and bullet-like shape of the head—the prominence of his eye—the length of his ears—and his colour, which must be black and tan. The Suffolk Sportsman says—“the cocking or gun-spaniel of true perfect breed is of one general or whole colour; either black, or black and tan, commonly called King Charles’s breed, or red in different shades, paler and deeper;” and concluding with “legs short and breeches behind.” This diminutive animal was the favourite of King Charles II., who had some of this kind constantly with him in his walks, and who was more partial to his dogs than to his duties as the sovereign of a great people. The breed is preserved in the family of the Duke of Norfolk, at Arundel Castle, where they are fondled and petted, we believe, in such a manner, as to lift them to the dignified position of being regarded as members of the family. James II., of unfortunate memory, was, also, extremely partial to these dogs, hence they have received the title of “the royal race,” and are now generally regarded as such.

In London, where these dogs are bred with great care, and to the highest degree of perfection, the Blenheim is frequently crossed with the Charles, so that the variety of colour on which the difference of nomenclature depends often appears in the same litter; the black and tan being denominated “King Charles,” and the red and white “Blenheim.”

Several “spaniel clubs” have been formed, with a view to promote the careful breeding of these dogs; and of some of these His late Royal Highness the Prince Consort was patron, both her majesty and the prince being enthusiastic admirers of them. His Royal Highness had, at no sparing outlay, erected a superb kennel for them at Windsor.

The members of the spaniel clubs subscribe a small sum each, and, with the amount contributed, a handsome collar of silver, with gold entablature, is purchased; a particular day is then named, and judges are appointed, when each member brings to the club-room a dog of his own rearing, and that dog adjudged to possess the greatest number of good points attains the collar as a prize.

King Charles and Blenheim spaniels have been known, in London, to fetch the price of from 150 to 200 guineas!

The affection of these dogs for their owners is extreme; and their general intelligence is such, that they would seem almost to participate in the pleasures of a quiet drawing-room conversation, when carried on by those who are attached to them. They are capable of serving in the field, but their continual yailing is very apt to mar the sport. They, however, like other dogs of the species, could undergo the process of training, and be made of considerable use in some kinds of hunting. In England, however, they live for other purposes—for admiration and a couch in the lap of a lady, where we will leave them to make the following extract from Mr. Blaine:—

“The old Marquis of Granby was the owner of a very celebrated breed (of Spaniels); and, in later times, the Duke of Marlborough, and his descendants, have been famed for what was known as the Blenheim breed; and the late Lady Charles Spencer, with whom we were on terms of intimacy, kept numbers of them, and was so devoted to their welfare, that, we believe, she never wore a pin in any part of her dress, fearing that it might be accidentally the means of wounding one of these favourites. They were, one and all, red and white, zealous hunters in the field, but required much trouble to break. A still more notorious variety, was the black and tan spaniel of King Charles, which continued to be cultivated with such jealous care, by the late Duke of Norfolk, that no interest could obtain one without a strict injunction from the owner, and almost a solemn promise from the receiver, that he or she would not breed from it in the direct line. The late Duchess of York, who honoured us with much condescending notice, by sending for us frequently to Oatlands, either to consult us on the ailments of the poor around her, or on her brute favourites, of which, it is well known, she had a varied assemblage, afforded us a striking proof of what we have stated. On one occasion, when we were accompanying her royal highness to her menagerie, with almost a kennel of canine favourites behind her, after drawing our attention to a jet black
pug pup she had just received from Germany, she remarked, that she was going to show me what she considered a present of much greater rarity, which was a true spaniel of king Charles's breed, sent to her by the Duke of Norfolk. 'But,' she observed, 'would you believe he could be so ungallant as to write word, that he must have a positive promise, not from myself, but from the Duke of York, that I should not breed from it in a direct line?' It would almost seem that the word of ladies of high rank was not in equal estimation with that of the gentlemen of the same rank, at least that Norfolk's duke did not think it so; for it happened, a very little time after, when professionally waiting on the Princess Sophia of Gloucester, her royal highness, also, showed us a very fine young spaniel of the Norfolk breed, which she, likewise, observed was only presented by the duke on an understanding guaranteed, not by herself, but by her brother, the Duke of Gloucester, that it should not be bred from in the Charles's line. Whatever view we take of these restrictive attempts," adds Mr. Blaine, "we may, however, be assured that Nature will frustrate them; for not only is the Norfolk breed, but the Blenheim also, sufficiently common at the present time; and they ought to be, for both are great ornaments to the race, and make very many springers. We think it our duty, likewise, to observe, that however some ladies might not think themselves strictly bound by an agreement on such a subject, we feel assured that neither of those we have noticed on this occasion would have done other than strictly abide by the compact; and we are confident that those who were much better acquainted with them than we could possibly be, would bear us out in our assertion.'

**THE NEWFOUNDLAND.**

The Labrador and Newfoundland dogs are often confounded together. The Labrador dog exceeds the Newfoundland animal in point of size, and is often of extraordinary dimensions. A fine specimen, measured some time since, gave the following particulars:—Total length, including the tail, six feet three inches; height at shoulder, two feet six inches; length of head from occiput to point of nose, eleven inches; circumference of chest, three feet one inch. In Labrador, these powerful and intelligent dogs are used for drawing sledges, and are of great service to the settlers.

Newfoundland dogs are of less stature, but more compactly built, and are muscular and sagacious. These animals are also used for drawing sledges, and little carriages laden with wood, fish, and other commodities, and are very valuable in their native country. Both the Labrador and Newfoundland breeds are admirable water-dogs, and make excellent retrievers. Their fidelity and attachment to their masters are well known, and all are familiar with instances in which human beings, about to perish in the water, have owed their life to the courage and exertions of these devoted creatures. Mr. Blaine classes the Newfoundland dog with the spaniels—a classification from which Mr. Richardson disents. He makes a distinct group of the Newfoundland, which he denominates a wolf-group.

"I am compelled," he says, "thus arbitrarily to give, perhaps, an undeserved name to the present group; but it is the only one by means of which I can accurately indicate the family of dogs to which I refer. The individuals of which this group is composed, all bear a greater or less resemblance to the wolf, in erect, or semi-erect ears, in long and shaggy coats, and bushy tails. The Newfoundland dog is fully entitled to be placed at the head of the group; from his being better known than the others, from his greater beauty, his sagacity, his nobility of nature and disposition, his utility to mankind, and the high degree of estimation in which he is held in every part of the world where he is known. Those who have grouped these dogs with the spaniels, are in error, for they possess none of the characteristics of that group.

"The true breed of Newfoundland," he continues, "is a dog of moderate stature, seldom exceeding twenty-six or twenty-seven inches in height; long-bodied, broad-chested, a shaggy coat, a pointed wolfish muzzle, ears small, and inclined to the semi-erect; colour usually black, with a shade of brown through it, and occasionally some white. There is another breed of dog peculiar to Newfoundland; short-coated, and sharp-nosed—an excellent water-dog, by some mistaken for the true Newfoundland breed.
"The large dogs usually known as Newfoundlands in this country, are evidently the result of a cross with the mastiff. They are a fine, showy animal; but less sagacious, less active, and more apt to display irregularity of temper than the original breed; they often attain the height of thirty inches. These large dogs are rapidly becoming the peculiar breed of Newfoundland; and dogs of this sort are gladly imported there, whereas our Newfoundland friends have now little or nothing but curs to offer in return.

"The origin of this dog is questionable; but I am disposed to trace him to a large European variety, still in use among the Norwegians, for the chase of the bear and wolf. It is now well known that the original discovery of Newfoundland is to be attributed to the Norwegians, who, before the year 1,000, sailed from Greenland on a voyage of discovery, and that the same people discovered North America some time between the tenth and eleventh centuries."

Mr. Blaine says, "that although this dog was, without doubt, first introduced to general notice from Newfoundland, there is reason to suppose that it was originally derived from the large dogs of Spain, introduced by the early discoverers of the American continent, which, intermixing with the native breeds, produced an increase of size and power in the future races. These would be encouraged by the natives, because the use they made of them as beasts of draught were thereby better fulfilled. Such, we have reason to believe, was the first improvement made in the native dogs of those countries, which, as far as a factitious breed can continue its like, seemed, but in limited numbers, to have remained a standard among them until English importations had drained almost all of them. Another variety forms the smaller, smooth aquatic dog of Newfoundland. When the English settled there, they, without doubt, carried some of the largest and most powerful of the water spaniel breed, to assist them in the hunting and the shooting of wild fowl; and there is little reason to doubt, that an intermixture with these also assisted in perfecting a breed, whence our admired specimens of the large Newfoundland dog arose; the breeding of which, however, was never carried to any great extent in that country. The rigours of the climate, and the difficulty of procuring food for it during some seasons of the year, were unfavourable to both the production of numbers, and the full development of the frame. The splendid animal we now see has been greatly increased in size, since its residence among us. We have cultivated it so as to make it now an English breed; while in Newfoundland it is at present so nearly extinct, that a writer, in a new series of the Sporting Magazine, states that he could not find a single dog of the kind at St. John's. If this be so, it is a mistake when naturalists assert that the dog we possess is the same with that which is employed 'in their native districts in place of the horse.'"

Of all the species of the canine race there is none exhibits so much dignity, such a nobility of nature as the Newfoundland. He is majesty itself, and seems to be conscious of the power and appearance of which he is possessed; whilst he rarely descends to the level of other dogs in combating in the streets. This does not arise from cowardice, but from the excellence of his disposition, and the high intelligence with which he is endowed. As an aquatic dog, he is second only to the water-spaniel; his feet being webbed, and that element seeming to him as natural as the terra firma upon which he walks. Some time ago, ten of these animals were imported into Paris, for the purpose of watching the banks of the Seine. They were overlooked by regular trainers, whose duty it was to teach them to draw from the river figures stuffed, so as to have a close resemblance to those of children and full grown persons. Commodious kennels were erected for them on the bridges, and they were not long before they became adepts at plunging into the water, and rescuing from the grave many unfortunate drowning individuals.

The sagacity of the Newfoundland is almost human; and the variety of his accomplishments are such as to place him at the very head of all the canine races. In the various capacities of watch-dog, companion, water-dog, pointer, and retriever, he has been successful; whilst the pliability of his temper, and the docility of his nature, renders him capable of
being taught anything almost, but to read and speak. His courage is great; and, as the safe-guard of a household, there is much more dependence to be placed upon him than upon the mastiff. On the authority of the Boston Traveller, we give the following example of the sagacity of this kind of dog, in performing some of the duties of civilised life:

Our neighbour of the Evening Gazette has recently referred to a sagacious dog of the Newfoundland breed, owned by Mr. Hawes, of this city, who comes regularly to the Traveller counting room, every afternoon, and putting his paws upon the counter, receives his master's paper, and is off to his store. This same dog has other ways of his own, which are often amusing, though occasionally a little troublesome. Like his biped associates in this world of bustle and hurry, he requires to be waited on with the least possible delay; and if he is not attended to, he is quite likely to help himself, often making reprisals on us for our inattention, by taken from the pile of papers a mouthful, perhaps half a dozen. He seems to have very imperfect ideas of the distinction between meum and tuum—as much so as any person on 'Change. If, therefore, on coming to our counter, he finds it bare of papers, he casts an inquiring look around the room, and if a luckless boy loiters with a paper in his hand, to watch the movements of the sagacious animal, the dog will seize the coveted paper, and be off before the astonished boy has time to rescue his stolen property. We are often reminded by the movements of this intelligent quadruped of the favourite saying of a certain queer old fellow:—"There is a great deal of human nature in beasts."

There are innumerable anecdotes illustrative of the intelligence of the Newfoundland, which, when full grown, and of pure breed, should measure upwards of six feet from the point of the nose to the tip of the tail. This may seem an extraordinary length; but the beautiful proportions of this animal, with the general upward curve, or bend of the tail, has an apparent effect in lessening this measure. Over the shoulders, from one fore foot to the other, the measurement is upwards of five feet and a half; round the head, and across the ears, about two feet; the length of the head, about fourteen inches; and the upper part of the leg, about ten inches. This is the measure of an animal when full grown and in his prime. His body is covered with long curly hair; his legs are also well-clothed; and his tail, likewise, is abundantly covered.

According to Mr. Richardson, the Newfoundland is of comparatively recent introduction to this country. "From the great share of emulation which nature has given him," says that gentleman, "to be surpassed, or overcome, would occasion great pain. On every emergency he is active, the friend of all, and is naturally without the least disposition to quarrel with other animals. He seldom, or ever offers offence, but will not receive an insult or injury with impunity. Such is the capacity of his understanding, that he can be taught almost anything that man can inculcate, of which his own strength and frame are capable. His sagacity can only be exceeded by his energies, and he perseveres with unabated ardour in whatever manner he is employed. While he has a hope of success, he will never slacken in his efforts to attain it. The amazing pliability of his temper peculiarly fits him for man's use; and he never shrinks from any service which may be required of him, but undertakes it with an ardour proportional to the difficulty of its execution. He takes a singular pride in being employed, and will carry a bundle, stick, or basket, in his mouth, for miles, and to deprive him of either of these is more than a stranger could, with safety, accomplish. Sagacity, and a peculiarly faithful attachment to the human species, are characteristics inseparable from this dog, and hence he is ever on the alert to ward off impending danger from his master, and to free him from every peril to which he may be exposed. From the astonishing degree of courage with which he is endowed, he is ever ready to resent an insult, or to defend his friend, even at the hazard of his own life. Inclined habitually to industrious employment, such dogs are as useful to the settlers of the coast, from which they are brought, as our galloways and ponies are to us. It is easy to accustom them to daily labour. From three to five of them are harnessed to a sledge, or other vehicle, containing a load of wood, or lumber, amounting to twenty or thirty stones, which they will draw very steadily for miles,
with ease, and will do this without the aid of a drayman, when acquainted with the road; and having delivered their burden, they return home to their masters, and receive, as a reward for their labour, their accustomed food, which generally consists of dried fish, of which they are said to be extremely fond.”

THE LABRADOR DOG.

This is an animal considerably larger than the Newfoundland, with a shorter muzzle, a more pendulous upper lip, a coarser coat, and altogether exhibiting marks of greater athletic power than are presented in the form of the Newfoundland. He stands from twenty-eight to thirty inches high.

The following are the measurements of a dog of this breed, given in Knight’s Weekly Volume:—“Total length, including the tail, six feet three inches; height at the shoulder, two feet six inches; length of head, from occiput to point of nose, eleven inches; circumference of chest, three feet one inch. In Labrador, these large dogs are used in drawing sledges, loaded with wood, and are of great service to the settlers.”

A fine specimen of this dog belonged to Lady Bellew, of Barameath. It stood about twenty-nine inches high at the shoulder. This animal, although used for purposes of draught in his native country, might be applied to hunting purposes, as his scent is very keen.

THE LABRADOR SPANIEL.

In point of size, this dog stands between the Newfoundland and the land-spaniel. It is remarkable for its aquatic predilections, and, as a diver, is unrivalled. In reference to this animal, Mr. Richardson gives the following anecdote, on the authority of Saunders’s News-Letter, a Dublin newspaper, where it appeared on the 1st of September, 1846. If true, it places the sagacity and disposition of this kind of dog, in a very favourable light:—

“Peeler, the Dog of the Police.—During a recent investigation relative to the manner in which the policeman came by his death at Kingstown, a little active and inquisitive dog, of the Labrador breed, was seen, from time to time, during each day, running in and out of the room, as if he took a personal interest in the inquiry. The dog was admired, and a gentleman in the police establishment was asked to whom it belonged. ‘Oh,’ said he, ‘don’t you know him? we thought every one knew Peeler, the dog of the police.’ The gentleman then proceeded to give the interrogator the history of this singular dog. It appeared from the story, that, a few years ago, poor little Peeler tempted the canine appetite of a Mount St. Bernard, or Newfoundland dog, and was in peril of being swallowed up by him for a luncheon, when a policeman interfered, and, with a blow of his baton, levelled the assailant, and rescued the assailed. From that time Peeler has united his fortunes with those of the police; wherever they go, he follows; whether pacing with measured tread the tedious ‘beat,’ or engaged in the energetic duty of arresting a disturber of the public peace. He is a self-constituted general superintendent of the police, visiting station after station, and, after he has made his observation in one district, wending his way to the next. He is frequently seen to enter a third-class carriage at the Kingstown Railway, get out at Black Rock, visit the police station there, continue his tour of inspection to Booterstown, reach there in time for the train as before, and go on to Dublin to take a peep at the ‘metropolitans;’ and having satisfied himself that ‘all is right,’ return by an early evening train to Kingstown. He sometimes takes a dislike to an individual, and shuns him as anxiously as he wags his tail at the approach, and frisks about the feet of another, for whom he has a regard. There is one man in the force for whom he has this antipathy; and, a day or two ago, seeing him in ‘the train,’ he left the carriage, and waited for the next, preferring a delay of half an hour to such company; and when the bell rang, with the eagerness with which protracted joy is sought, he ran to his accustomed seat in ‘the third class.’ His partiality for the police is extraordinary; wherever he sees a man in the garb of a constable, he expresses his pleasure by walking near him, rubbing against, and dancing about him. Nor does he forget him in death: for he was at his post at the funeral of Daly, the policeman who was killed in Kingstown. He is able to recognise a few in plain clothes; but they must have been old friends of his. Wherever he goes, he gets a crust, a piece of
meat, a pat on the head, or a rub down upon his glossy back by the hand of a policeman; and he is as well known amongst the body as any one in it. We have heard of the dog of Montargis, the soldier's dog, the blind beggar's dog, and the dog of the monks of St. Bernard, and been delighted by stories of their fidelity and sagacity; but none are more interesting than 'Peeler, the dog of the police,' 'whose heart, enlarged with gratitude to one, grows bountiful to all.'

**THE CALABRIAN OR PYRENEAN WOLF-DOG.**

This is the shepherd's dog of the Abruzzo, standing about twenty-nine or thirty inches high at the shoulder. He is usually of a white colour, with one or two patches of buff or tan on the head or sides; the ears are not hairy, and are half erect; the tail is bushy, and is carried in a curl, close over the back; the nose is pointed, and the general aspect of the head wolfish. They fill the position of the Scotch collie, or that of the English sheep-dog, to the Spanish and Italian shepherds, but are rather guardians than herders of the flocks. Their great value is to protect the sheep from the attacks of wolves and other ferocious animals.

**THE POMERANIAN DOG.**

This is a small dog, and usually of a white colour. It is not twenty inches high at the shoulder; its ears are perfectly erect, like those of a fox, with an unfringed tail, bushed all round like that of the fox. It is often called the "fox-dog," from its resemblance to that animal.

There is a small Chinese variety of dog, so closely resembling the Pomeranian (except in colour, being usually yellow or black), that they cannot be distinguished from one another.

"These are the dogs used as food by the natives. There are regular dog-butchers in most of the Chinese towns; and dog's flesh, especially roasted, is held in high esteem. It is not long since, that not only was 'roasted dog' regarded as the very quintessence of good living, but that, like 'living turtle' among us, its promised appearance at the board was regularly announced as an attraction to the invited guests."

**THE HARE-INDIAN DOG.**

This dog was first described by Dr. Richardson, and found by him on the Mackenzie river. It is of small size, and slenderly made, with broad, erect ears, sharp at the base, the tail is pendulous, with a slight curve upward, near the tip. One which Dr. Richardson had was killed and eaten by one of his Indian guides, who stated that he mistook it for a fox. The feet of this animal are large, spread, and abundantly covered with fur, in consequence of which he can run up the snow with rapidity and ease, without sinking. In their native country, these dogs never bark; in confinement they do.

**THE EQUIMAUX DOG.**

This dog is as large as the Newfoundland, with long, coarse hair, and his tail curling over the back. Its ears are pointed and erect, and, in his general appearance, bears a strong resemblance to the wolf. He has a considerable share of intelligence and good temper. In his native country he is harnessed to the sledge, and generally performs the work of a draught animal. He is capable of undergoing great fatigue, and is both active and swift.

Besides this last dog of the north, there is the Siberian dog, a powerful animal; the Kamtschatka dog; the Iceland dog; the Green- land dog; and the Lapland dog; of which last, Mr. Clarke, in his work on Scandinavia, has given a description. He says—"We had a valuable companion in a dog, belonging to one of the boatmen. It was of the true Lapland breed, and in all respects similar to a wolf, excepting the tail, which was bushy and curved, like those of the Pomeranian race. This dog, swimming after the boat, if his master merely waved his hand, would cross the lake as often as he pleased, carrying half his body and the whole of his head and tail out of the water. Wherever he landed he secured all the long grass by the side of the lake, in search of wild fowl, and came back to us, bringing wild ducks in his mouth to the boat; and then, having delivered his prey to his master, he would instantly set off again in search of more."

These animals are also employed in a similar capacity to that in which our Drover's dog is employed. They herd the reindeer. A gentle
man who visited a Lap encampment, thus writes:

"While I sojourned on the Island of Tromso, learning that on the neighbouring mainland some Laplanders were encamped, I resolved to pay them a visit. Procuring a boat, I rowed over to the opposite shore, where I met with a Nordlander, who informed me that the Lap encampment might be found somewhere toward the extremity of Tromsdal—a magnificent ravine commencing at no great distance from the shore, and running directly inland. He stated that the Laps had a noble herd of reins (the name universally given to reindeer), about eight hundred in number, and that, when the wind blew from a certain quarter, the whole herd would occasionally wander close to his house, but a rein-hund (reindeer-dog) was kept by him to drive them back. * * * * *

"Onward we went, driving the herd, in which I gleefully helped, the three little dogs at times barking and fetching up stragglers. The Laps occasionally gave a short cry or urging shout to the reins, and I burst forth with my full-lunged English hallo, to the evident amusement of my companions. The scene was most exciting. The brilliant sunlight, the green grass, the sparkling, murmuring Elv, the picturesque glen, the figures of the Laps, the moving herd of reins—the novelty of the whole was indescribably delightful. I found the reins did not make such a 'clicking' noise as most travellers have asserted. Here were hundreds of reins striking their hoofs together, and yet the noise was certainly anything but loud from their cloven feet and hairy fetlocks, and would hardly have been noticeable had I not particularly listened for it. But another thing, of which I had never read any notice, struck me much—the loud, snorting noise emitted by the deer at every step. Unpoetical as my fancy may seem, it reminded me most strongly of the grunting of swine, but was certainly not so coarse a noise, and, at the same time, partook much of the nature of a snort. The cause of the noise is this: when the deer are heated, they do not throw off their heat in sweat—their skin is too thick for that; but, like the dog, they emit the heat through the mouth. The size of some of the reins astonished me. In many instances they were as large as Shetland ponies, and some had most magnificent branching antlers of a very remarkable size. This is the only animal of the deer genus which invariably has a horizontal branch from the main antlers, projecting in a line over each eye. These antlers are covered with a short grey hair. Some of the herd in question had broken pieces off their antlers, which hung down, bleeding, by the skin. The does also have antlers, but very small, and generally straight, which, when skinned and dried, can be distinguished from those of the male by their whiteness. All the herd were casting their winter hair, and consequently their coats looked rather ragged and parti-coloured—the new colour being generally a dark, and the old a light grey. In some cases, however, the deer are white; and, in winter, all are more or less of a light colour. There were many pretty young does running among the herd."

THE GREAT ROUGH WATER-DOG.

This dog has a long and curled coat; a large and round head; well covered ears; somewhat short legs; and is generally of a black, black-and-white, or brown colour. His sagacity is considerable, and he has sufficient courage to attempt anything when backed by his master. The water is his element. Here he delights to move in; and when swimming, he seems rather to float, and make his way without either motion or exertion of the limbs. He is capable of being made a good retriever, but his training would require to be conducted with great care, as he is apt to mangle his bird, from the severity with which he uses his teeth.

The water-dog is a very different animal from either the German or French poodle, and has an originality of his own. Regarding this dog, Mr. Richardson gives the following anecdote:—"I recollect a singularly large dog of this breed, about ten years ago, in possession of Mr. Grierson, of North Hanover-street, Edinburgh, near the foot of the Mound, which was possessed of unusual intelligence. Amongst other eccentricities, this dog followed the profession of mendicancy, and regularly solicited the charity of the passers-by. On receiving a halfpenny, his habit was, if hungry, to proceed at once to the shop of Mr. Nelson, at the corner of Rose-street, and purchase a biscuit; but it sometimes happened that he put by his halfpence until the calls of appetite
THE POODLE

Has a coat of wool rather than of hair, and bears a strong resemblance to the great water-dog, of the habits of which he partakes, in reference to his partiality for the element from which the other derives his distinction. This animal is as remarkable for his sagacity as many more of the race to which he belongs. He is extremely useful to persons engaged in the pursuit of water-fowl. He swims well, is very hardy, and is an excellent retriever. The French poodle may be referred to the spaniels. He appears to be very nearly allied to the rough water-dog figured by Bewick; the "grand barbet" of Buffon, of which there is a smaller variety, termed "le petit barbet."

In a paper, entitled "Sketched of Burschen Life," published in The Dublin University Magazine, appears the following ludicrous anecdote of a poodle and a short-sighted professor:

"There was a story, when we were in Heidelberg, going about, of a certain student who had a remarkably fine white poodle; the intelligence and sagacity of the animal were uncommon; and, as he used daily to accompany his master to the lecture-room of a professor, who was not very remarkable for the distinctness of his vision, he would regularly take his seat upon the bench beside his master, and peer into his book, as if he understood every word of it."

"One wet morning, the lecture-room, never at any time remarkable for its fulness, was deserted, save by the student who owned the poodle. The dog, however, had somehow happened to remain at home."

"'Gentlemen,' said the short-sighted professor, as he commenced his lecture, 'I am sorry to notice that the very attentive student in the white coat, whose industry I have not failed to observe, is, contrary to his usual custom, absent to-day!""

THE LITTLE BARBET.

This is nothing more than a smaller variety of the poodle, the head being covered with straight and silky hair—the rest of the body having a curly and woolly coat.

THE SILKY DOG—CHIEN DE SOIE.

Like a very small poodle, but covered with a long and silky coat. It is a great favourite with the French females.

THE LION DOG

Has a mane like a lion, the rest of the body being covered with short hair. It is supposed to have sprung from a cross between the small barbet and naked Turk. It is of no use as a dog, but interesting as a variety of the species to which he belongs.

CHAPTER VII.

MASTIFTS

We now enter upon a group of dogs distinguished by the shortness of the muzzle and the breadth of the head; this latter character resulting, not from a corresponding development of the brain, but from the magnitude of the temporal muscles, which are attached to a
bony ridge passing down the median line of the skull. The expression of the eyes is lowering and ferocious; the jaws are very strong; the lips pendulous; the general form is thick-set and robust; and the limbs are muscular.

This group comprehends the mastiff, the bulldog, and their allies. In sagacity and intelligence these dogs are not to be compared to the Newfoundland, the spaniel, or the shepherd’s dog. They surpass all, however, in determined courage and prowess in combat.

THE BRITISH MASTIFF.

This is the doogue of Buffon, who considers it an offset from the bulldog; but this opinion, in the judgment of Mr. Blaine, is erroneous. In early times the English mastiff was celebrated for his strength and resolution, characteristics which did not fail to attract the attention of the Romans when this island formed a part of their widely-spread empire. To a people in whom a partiality for scenes of bloodshed and slaughter, and in whom the sanguinary games of the amphitheatre was a ruling passion, dogs so fitted to gratify their taste were peculiarly acceptable; and accordingly we find that they were bred and reared by officers specially appointed, who selected such as were distinguished for combative qualities, and sent them to Rome for the service of the amphitheatres, where they were matched in fight with various beasts of prey. Dr. Caius, a naturalist of the time of Elizabeth, states that three were reckoned a match for a bear, and four for a lion.

Though the mastiff has by no means the keen sense of smell which the hound possesses, he seems to be either an offset from that branch, or a cognate branch from the same root. The mastiff, however, has a finer scent than persons are generally aware of, and his hearing is very acute. A dog of this breed, chained to his kennel, and never suffered to wander about the premises, nor treated as a friend and companion, affords but a poor example of what the animal really is. Confinement spoils his temper, and cramps the development of his better qualities.

The mastiff has a very wide geographical distribution; and wherever he is found he presents nearly a similarity of outline in his make, and evinces the same qualities whether in Sweden, the Alps, Poland, Spain, Italy, or the Levant. As he approaches warmer climates, however, his strength degenerates. He becomes more slender, and rather resembles the old Spanish pointer than the full-bodied European animal. This dog is considered by Grotius as one of the indigental of Britain; but in this he has not been satisfactorily corroborated.

Mr. Richardson attributes his origin to a mixture of the bulldog of ancient Britain with the old Talbot hound, and gives us the following characteristic anecdotes:

"The disposition of the mastiff is characterised by courage, generosity, and forbearance; even the midnight marauder will be held by him unjured until human aid arrives, provided he refrain from struggle or resistance. The attacks of puny antagonists are despised; but if they become intolerable, the noble mastiff is satisfied with showing his contempt, or inflicting chastisement of rather a humiliating than a painful nature. The story of the mastiff, which, when greatly annoyed by the incessant barking of a little cur, took him by the back of the neck, and dropped him over a quay wall into the river, is well known; but I recollect an instance of this nature, when the mastiff, standing for a moment contemplating the struggles of his late tormentor, and perceiving that the current was likely to carry him away, actually sprang into the water, and rescued him from his dangerous position."

Henry VII. ordered a mastiff to be hanged, because he had singly coped with and overcome a lion! And in the reign of Queen Elizabeth, when Lord Buckhurst was ambassador at the court of Charles IX., a mastiff is said, alone and unassisted, to have successfully engaged a bear, a leopard, and a lion, and pulled them all down. Slow relates an engagement which took place, in the reign of James I., between three mastiffs and a lion. One of the dogs being put into the den, was soon disabled by the lion, which took him by the head and neck, and dragged him about. Another dog was next set loose, which shared the same fate; but the third, on being put in, immediately seized the lion, and subdued him.

THE CUBAN MASTIFF.

We have said that the mastiff is allied to the hound: the Cuban mastiff, is, indeed, often...
termed a bloodhound. The pendulous ears, so large in the mastiff as in the hound; the thick hanging lips, the broad moist nose, brindle markings, and the general figure, attest the affinity. The mastiff is larger and stronger than the hound, and useless for the chase; this latter circumstance, however, is no proof of diversity of origin. It must be remembered that particular instincts and quantities are acquired, and that the excellence of the hound are the result of long-continued and judicious culture. We do not say that the mastiff can be converted into the hound, but merely that two branches from the same root may be so cultured as to assume, to a given point, diverse characteristics. This animals is by no means to be confounded with the Cuban bloodhound. He is quite a different dog. Nor is the Cuban bloodhound and the British bloodhound the same, although Sommerville seems to have thought them identical.

"Save the sagacious brute, his curling tail
Flourished in air, bow-bending, plus around
His busy nose, the steaming vapour sniffs,
Inquisitive, nor leaves one turf untried.
Till conscious of the recent stains, his heart
Beats quick; his snuffing nose, his active tail,
Assists his joy; then, with deep-opening mouth,
That makes the well-in trumble, he proclaims
The illustrious felon; foot by foot he marks
His winding ways, while all the listening crowd
Applaud his researchings. O'er the wat'ry ford,
Dry, sandy heaths, and stony barren hills;
Of human paths, with men and beasts desdined,
Unerring in pursuit, till at the spot
Arrest'd, and seizing by his guilty throat
The culprit, redeems the captive prey."

"The Spanish or Cuban mastiff," Mr. Richardson says, "is a very powerfully-built dog, and is supposed to be a breed between the mastiff and the pointer. He stands from twenty-six to twenty-eight inches high, with extraordinary development of bone and muscle. His head is of prodigious size, even apparently too large in proportion to his body; his eyes are placed very far apart; his upper lip pendulous, but not so much so as in the British mastiff; the ear is small, and not perfectly pendulous, being erect at the root, but the tip falling over; colour usually tawny or light russet; the under jaw is also undershot: and I do not think I can give my readers a better idea of the dog, than by describing him as a gigantic bulldog, occupying precisely the same position with regard to the mastiff as in the noble of the Alps, which our own British bulldog does in reference to the English mastiff." This animal is a dog of great courage; in Spain he is used in the combats of the amphitheatre, and is commonly known on the continent as the "Spanish bulldog." Colonel H. Smith conceives this race to have been identical with the broad-mouthed dogs for which Britain was celebrated during the Roman era.

THE DOG OF TIBET.

The huge Tibet watch-dog belongs to the present group. This dog (Canis familiaris, var. Molosus Tibetanus) is kept by the natives of the Tibet range of hills as a guardian of their flocks and their villages. It is very fierce, and its bark is loud and terrific. The colour is generally black.

His head is large and broad. His lips are very full and pendulous; and the skin, from the eyebrows, forms a fold towards the outer edge of the eyes, ending in the jowl; the neck is remarkably full, and the chest is furnished with a

drup. This species was originally noticed by Marco Polo, who described them as being "as large as asses," a description contradicted by some subsequent travellers, but since amply confirmed.

The probable cause of these varying accounts is, that the Tibet mastiff rapidly degenerates if removed to a milder climate; and several inferior, though similar breeds, exist in different portions of the Himalayan chain of mountains. Colonel Smith refers to this dog as the typical mastiff—the Canis Ursinus described by Oppian.

THE DOG OF ST. BERNARD, OR ALPINE

Mastiff.

This dog is placed under the spaniel group by Mr. Baine, and Mr. Richardson classes it with the mastiffs. We have adhered to the arrangement of the latter.

Colonel Smith classes it with the wolf-dog group. He, however, says that more than one description of dog is trained by the monks of the Great St. Bernard, with the view of rescuing the unfortunate from the horrors of death amid the dreary depths of Alpine snows. One sort he describes as having a long coat, with
the appearance of the Newfoundland; and the other as having a short one, and bearing a resemblance to the great Dane, both in the character of its hair and the colour.

Referring to the origin of the pious act of the monks of St. Bernard, in having dogs trained to the humane purpose of saving human life, Mr. Richardson says, that "the dog originally trained to this service was a large and powerful mastiff, short-coated, deep-jowled, of a yellow colour, with a long, fine tail. L'Ami, who was brought, in 1820, from the convent on the Great St. Bernard, was of this description. He was exhibited in both London and Liverpool to many thousands of people, at the charge of one shilling admission. I was favoured by Mr. Clark, of Holborn, with a full account of the true dogs of St. Bernard, obtained by him from the very best authorities. A good many years ago, a pestilence made its appearance amongst the dogs of the convent, and all were destroyed save one single specimen. Under these circumstances, the monks had no alternative but to cross the breed, which they did with the Spanish or Pyrenean wolf-dog—the most likely cross to which they could have resorted; hence arose the race of dogs ordinarily known as St. Bernards. Some of the true race have now been restored; but they are very scarce, and are not to be possessed under enormous prices; in fact, not to be had from the convent at all; Mr. Clark being acquainted with a nobleman who offered one hundred guineas for a brace of puppies, without success. Hence the mistakes arising from spurious dogs, supposed to be original, merely because they came from the mountain.

In Dublin these dogs used to be common. They were introduced by a Frenchman, named Casserane, in Ormond Market. He had a male and female, and their whelps were eagerly purchased at five guineas each, as soon as weaned. W. Flood, Esq., of Stillorgan, possessed a noble specimen; and there was, also, a beautiful specimen, named 'Donna,' in the possession of John Richardson, Esq., of Newington Terrace, Rathmines. Donna was celebrated as a water-dog. She was gentle, but very wild and playful, and her tremendous size rendered her romping caresses anything but agreeable. Mr. Richardson went, on one occasion, to bathe, accompanied by Donna, who watched the progress of unrobing with much apparent curiosity. No sooner had her master plunged into the water, however, than she sprang after him, and, doubtless uneasy for his safety, seized him by the shoulder, and dragged him, in spite of all his resistance—and he is both a powerful man and a capital swimmer—with more zeal than gentleness, to land; nor could he ever enter the water in Donna's presence."

THE BRITISH BULLDOG.

Of all the dogs of this group, none surpass in obstinacy or ferocity the bulldog. This animal is smaller than the mastiff, but more compactly formed; the chest is broad and deep; the loins narrow; the tail slender and arched up; the limbs short and robust; the head is broad and thick; the muzzle short and deep; the jaws strong, the lower jaw often advancing, so that the inferior incisor teeth overshoot the upper; the ears are short and semi-erect; the nostrils distended; the eyes scowling; and the whole expression calculated to inspire terror. This dog is distinguished by tenacity of tooth, and indomitable resolution. In all his habits and propensities he is essentially gladiatorial: he is a fighting dog, and nothing else. His intelligence is very limited; and though dogs of this breed are attached to their masters, they exhibit in the demonstration of their feelings, unless when incited to combat, a perfect contrast to the Newfoundland dog or spaniel. These latter delight to accompany their master in his walks, and scour the fields and lanes in the exuberance of delight; the bulldog skulks at his master's heels, and regards, with a suspicious glance, everything and everybody that passes by; nor, indeed, is it safe to approach the animal, for he often attacks without the slightest provocation. A cross between the bulldog and the terrier is celebrated for spirit and determination.

"The British bulldog," says Mr. Richardson, "is, when a good dog, perhaps one of the most courageous animals in existence. I am obliged to qualify my meed of praise, however, as I have myself seen bulldogs, not merely of very doubtful courage, but absolutely cowardly. I attribute this moral degeneracy to the prac-
BULLDOG.]
FOR MOUNTAIN, FIELD, AND FARM. [BAN-DOG.
tice of too close, or in-and-in breeding—a practice certain to prejudice the mental qualifications, even though external or physical conformation remain apparently the same."

The bulldog needs little description: he usually stands twenty inches in height—if smaller, he is so much the more highly esteemed—his head is large and round; his eyes small, and far apart; ears small, and partly erect; muzzle short, truncated, and turned upwards; under jaw projecting beyond the upper, displaying the lower incisor teeth; colour usually brindled, but white is the fancy colour; party colours, as black-and-white, &c., are to be condemned; his tail must be fine as a rush.

The bulldog is not wholly destitute of good qualities, as some writers have represented him to be. Besides his courage, he possesses strong attachment to his master. Mr. Jesse relates an anecdote of a bulldog which, having been accustomed to be his master's travelling companion in his carriage for several years, on his place being allotted to a new favourite, refused to eat, sickened, pine'd, and died.

THE PUG-DOG.

It has been usual to consider the pug-dog as a degenerate variety of the bulldog, but the correctness of this theory has been doubted. It has, indeed, somewhat the aspect of the bulldog, on a miniature scale; but the similarity is more superficial than real. The pug is a little round-headed, short-nosed dog, with a preternatural abbreviation of the muzzle, and with a tightly-twisted tail. Like the Gillaroo trout, it is a specimen of hereditary malformation. Not so the bulldog, in which the bones of the skull and the temporal muscles are finely developed, and in which the muzzle and head are in perfect harmony.

The pug-dog is snarling and ill-tempered, but cowardly, and by no means remarkable for intelligence. Formerly it was in great esteem as a pet, but is now little valued, and not often kept.

THE BAN-DOG.

The Ban-dog is a term applied to any of the fierce animals of which we have just been treating, and which are, in ordinary cases, kept chained or secured in kennels. Bewick, however, applies it to a dog, of which he gives an excellent figure, and which, he states, differs from the mastiff in being lighter, more active and vigilant, but not so powerful or so large; his muzzle, besides, is not so heavy, and he possesses, in some degree, the scent of the hound. His hair is described as being rather rough, and generally of a yellowish grey, streaked with shades of black or brown. He is ferocious and full of energy. Bewick says that this dog is seldom to be seen at the present day. Varieties, however, of the mastiff have been noticed, agreeing so closely with Bewick's figure and description, as to convince one that both of them were taken from nature.

In taking a review of the various breeds of the domestic dog, it must be observed, that they are endowed respectively with qualifications or habits certainly not innate, but the result of education, at least originally; which education, continued through a series of generations, has produced permanent effects. For example, no dog in a state of nature would point with his nose at a partridge, and then stand like a statue, motionless; for he would gain nothing by such a proceeding. Man, however, has availed himself of the docility and delicacy of scent peculiar to a certain breed, and has taught the dog his lesson; and the lesson thus learned has become second nature. A young pointer takes to its work as if by intuition, and scarcely requires discipline. Hence, therefore, must we conclude that education not only produces impressions on the sensorium, but transmissible impressions, whence arise the predispositions of certain races. Education, in fact, modifies organisation: not that it makes a dog otherwise than a dog, but it supersedes, to a certain point, instinct, or makes acquired propensities instinctive, hereditary, and, therefore, characteristics of the race. The effect of this change of nature is not to render the dog more independent, nor to give it any advantage over its fellows, but to rivet more firmly the links of its subjection to man.

It is not to the pointer alone that these observations apply. All our domestic dogs have their own acquired propensities, which, becoming second nature, make them, in one
way or another, valuable servants. No one, we presume, will suppose that the instinctive propensities implanted by nature in the shepherd’s Colley, could make it, not a destroyer, but a preserver of sheep. On the contrary, this dog, like every other, is carnivorous, and nature intends it to destroy and devour. But education has supplanted instinct, to a certain point, and implanted a disposition which has become an hereditary characteristic, and hence a Colley of the true breed takes to its duties naturally. But a shepherd’s dog could not, delicate as its sense of smell is, be brought to take the place of the pointer in the field, even though it were subjected to training from the earliest age; nor, on the other hand, could a pointer be substituted with equal advantage for a shepherd’s dog, as the assistant of the drover. Each is civilised, but in a different style; and education has impressed upon each a different bent of mind, and a different class of propensities.

CHAPTER VIII.

DISEASES OF THE DOG.

The diseases to which dogs are subject are numerous, and their treatment various. In the highly artificial state in which they are forced to exist, in order to serve the purposes of man, they require the utmost attention, especially such as are kept to assist in the sports of the field and the forest. These, like the race-horse and the hunter, require what is technically called “conditioning” before they are fit for use. Colonel Cook observes, that he lost three of his best dogs, wholly by inattention to their state in this particular, which caused him afterwards to pay double attention to that most material point—condition. “A dog, to be in condition, should be neither too fat nor too thin. His ribs should be visible, and the flanks moderately hollow; but the loins must be well filled up in a dog in perfect condition. When dogs exhibit general fulness and too much flesh,” observes Colonel Cook, “commence by physic and a regular course of exercise, which should be mild at first, but increased until it is severe. Avoid too great a privation of food, otherwise the conditioning process will be retarded.” As a general rule, hounds, greyhounds, pointers, setters, spaniels, and all sporting dogs, require to be put into a proper state for their work. They must be conditioned, by either lightening their bodies of flesh, or hardening that flesh to such a degree as to give firmness to its whole texture.

The physic necessary for this purpose is variously formed. “Julap,” says Mr. Blaine, “is a favourite purge with some sportsmen; but it is uncertain in its action. Gumbo is very drastic. The submuriate of mercury (calomel) is likewise very irregular in its action on dogs. We have known eight grains fail to open the bowels of even a small one; while, on the contrary, we have, ourselves, seen a pointer totally poisoned by ten grains. It forms, however, a useful auxiliary to purgatives in doses of three or four grains; and, as it not unfrequently acts upon the stomach, so it may be used with advantage as an emetic in some cases, particularly in conjunction with tartarised antimony (tartar emetic). When, therefore, a purgative is brought up again in which calomel was a component part, it may be suspected to arise from this source; and if it be necessary to repeat the purge, the mercury should be omitted. Epsom salts are used in some kennels; but they are bulky; and if attempted to be given in the food, are often refused. Syrup of buckthorn has long been a favourite purge with dog-fanciers. Mr. Beckford recommends it, but mixes with it sulphur and antimony, in the proportions of two pounds of sulphur, one pound of crude
antimony, and a pint and a-half of syrup of buckthorn, which answers for thirty couple of hounds. Aloe, in our opinion, form the best general purge for dogs; and such are the peculiarities of their bowels, that while a man can take, with impunity, as much calomel as would kill two large dogs, a moderate-sized dog will take a quantity of aloe sufficient to destroy two stout men. The smallest dog can take fifteen or twenty grains; half a drachm is seldom too much; but the smaller dose had better be tried first. Medium-sized dogs usually require a drachm; and some large dogs have taken more than two drachms. We have ourselves given three to a strong Newfoundlander dog without extreme catharsis; but, as before observed, dogs differ much in their different habits, and it is, therefore, the most prudent plan to begin with a dose too small, than too large. Hundreds of dogs are, every year, destroyed by temerity in this particular."

The alternative medicines for dogs are butter-milk and whey, which are good for cutaneous affections. The nitrate of potash (nitre), in cases of from four to ten grains, for heat of the blood or redness of the skin. Cream of tartar may also be given in large doses in the same cases. As dogs are easily salivated, all the preparations of mercury should be very cautiously given. Sulphur affects dogs but slightly. Where, however, there are diseases of the skin, it may be given in combination with a moderate quantity of cream of tartar.

Emetics have been questioned as good remedies in dog diseases. The best, in cases of distemper, is tartarised antimony; which may be given in milk or soup, or as a ball, rolled up in a piece of meat or butter. The quantity must be proportioned to the size and strength of the dog; from one grain, as the smallest, to five as the largest dose. As a cleansing emetic, calomel, of from four to six or eight grains, is good.

**Rabies, or Canine Madness.**

Hydrophobia—a term expressing fear of water—is, when used to mark this madness in the dog, quite incorrect; for a dog labouring under rabies will drink water, not only willingly, but greedily, to the very last. Where rabies exists, dogs never have fits. A knowledge of this fact may be the means of saving the life of many a poor animal.

"One of the earliest symptoms of rabies in a dog," says Mr. Richardson, "is restlessness. He is constantly turning round and round before he will lie down; his countenance becomes anxious; his eyes bloodshot; he fancies that he sees objects around him which have no real existence, and he snaps at the empty air; his fondness for his master increases, and with it his propensity to lick the hands and face—a filthy practice at any time, and one most dangerous; for the virus generated under the influence of rabies is deposited on the surface, and acts as if the person had been inoculated by it. Children should never be suffered to indulge dogs in this filthy habit. In a state of confirmed rabies, the appetite becomes depraved; his natural food is neglected, and, at the same time, every sort of filthy trash is greedily devoured. Eating his own excrement is an early symptom, and so sure a one, that the moment a dog is seen doing so, he should be destroyed, or, at all events, carefully confined.

"Rubbing the paws against the sides of the mouth. If this be done to remove a bone, the mouth will remain open; but when it takes place as the precursor of rabies, the jaws close after the rubbing ceases.

"Soon follows an insatiable thirst; so insatiable that the poor animal often plunges his whole muzzle into the water; and here you may observe sputum left upon the surface. Soon the dog falls, or staggers, and sometimes, but not invariably, becomes delirious. Death speedily ensues under these symptoms."

The origin of this terrible disease is, by the most experienced veterinarians, assigned to inoculation; but the first animal that indicated its symptoms must have generated it spontaneously. It was long supposed that heat was a prolific cause; but this has been proved not to be the case. The disease is hardly known on the continent of South America: it is entirely unknown in Egypt; and Syria has never been visited by it. Neither is extreme cold favourable to its generation, for it has never made its appearance in Greenland. M. Audry, a French writer on this subject, says, that January, the coldest, and August, the hottest month, furnish the fewest instances
of rabies. The quality and quantity of food has been assigned as a cause; but in dogs which, by chance, have been placed in situations where it was impossible for them to obtain food, though on the precincts of actual starvation, the disease has never yet been discovered. Experiments innumerable have been made to discover the real origin of this disease, which, in various years, has proved itself to be nothing less than a scourge in different European countries. Spain, Germany, France, and England have all been visited by its ravages; and there is, perhaps, no pain, no disaster, no disease, so terrifying to the human mind, as that which is supposed to succeed the bite of a rabid dog. Amongst other experiments, made with the view of tracing the origin of canine madness, one performed at the veterinary school of Alport is, perhaps, the most striking:—Three dogs were chained and placed in such a situation that the heat of the sun might fall, with all its power, upon them. To one nothing was given but water; to another nothing but salted meat; and to another neither food nor drink was allowed. The whole three died; but not one of them exhibited the slightest symptoms of rabies; which we take to be a strong argument in favour of its being generated only by inoculation. Repletion has never caused it; feeding on putrid meat does not cause it; nor does the want of water. Its real origin, therefore, must be supposed a kind of puzzle, which all experience has yet been unable to solve to the entire satisfaction of those who have been the most active in experimenting upon it.

Considering the fearful consequences which frequently result to those who have had the misfortune to be bitten by rabid dogs, the symptoms of the disease cannot be too clearly explained, or too widely disseminated. Both Mr. Youatt and Mr. Blaine have given much attention to this subject; and both had much experience in its treatment, in the canine as well as in the human species. It is a common belief that dogs have a horror of water when affected by the disease; but this is by no means the case. "A mad dog," says John Hunter, "can swallow solids and liquids through the whole disease." "A rabid dog," says Dr. Hamilton, "never avoids water, and laps whatever liquid food is set before him, long after the poison can be communicated by his bite;" and Mr. Meynell says, "that mad dogs will even lap it the day before they die from the effects of the disease." The most eminent veterinarians concur in these opinions—a circumstance which we hope will have the effect of completely eradicating from the minds of all those who peruse this book, the baleful prejudice that dogs, when labouring under an affection of rabies, will not drink water. Of the danger of entertaining a prejudice of this kind, Mr. Blaine produces a striking example. An eminent physician having been consulted on the propriety of employing some prophylactic means, in consequence of three persons of the family of a well-known horse-dealer having been bitten by a dog under disease, satisfied himself with inquiring whether the animal could drink while under the complaint? Being informed that he did so, freely, throughout the whole of its duration, he unhesitatingly declared that no precautionary means whatever were necessary, and that he would, therefore, suggest none. Fortunately, the bitten parts of each of these persons were, notwithstanding, excised at the suggestion of Mr. Blaine, and the result proved the correctness of his judgment in the performing of such an operation; as a horse and dog, both known to have been bitten by the dog alluded to, died rabid in three weeks afterwards.

We have given the symptoms of rabies, as described by Mr. Richardson; and we will now give those, as described by Mr. Blaine, whose extensive practice and experience of this disease, place him in the very highest position as a safe guide and authority. Before closing this subject, we would entreat all our readers who keep a dog or dogs, whether as domestic pets, watchers, coursers, hunters, or for any other purpose not implied by these terms, to have, at all times, a vigilant eye upon the condition of their animals. "The symptoms of madness are very variable; but, as the early ones are not very active, they are apt to be overlooked in sporting dogs; and it is only in such as are kept immediately about our persons, and within doors, that they show themselves. In these cases of close domestication, the approach may be observed by some slight alteration of manner and habit. In some of its approaches are marked by unusual dullness; in others by increased vivacity, accompanied with restlessness or
earnest attention to slight noises and minute objects. In one instance we foretold the approach of the disease by the uncommon attachment of a puppy to a kitten, which he was continually licking, as well as the cold nose of another pup that was with him. Deane, Earl Fitzwilliam's huntsman, has observed that, among hounds, he regarded the smelling and licking of the penis and fundament of another dog, as a most suspicious symptom. It is a curious circumstance that sexual excitement is frequently an early symptom in all the subjects of rabies; in dogs it is common; it has been remarked in the human species also. Sheep and pigs becoming rabid, are usually observed to show the disease first by riding their fellows. Lapping their own urine is a very common precursor to more active symptoms in the rabid dog. The eyes, even in the early stage of the disease, are often singularly bright, sparkling, and red; occasionally a slight tendency to distorted vision, or squinting, is apparent; and such alterations in the usual appearance of the eyes, are generally followed by mischievous propensities in the animal. Nevertheless, in some less frequent cases, the eyes are even less bright than natural, and a slight discharge of mucus, and sometimes of real pus or matter, escapes from their inner corners, and now and then flows from the nose also, which has frequently occasioned madness to be mistaken for distemper. But we would impress on the reader, that a moderate attention only to the manner of the dog and to the morbid symptoms here laid down, will enable any one readily to distinguish between these diseases, provided the observer does not allow himself to be swayed by prejudice or foolish counsel. In some instances, an early rabid symptom is a continual licking, scratching, and sometimes even biting of some part of the dog's own body; and this very part is often proved to be that by which the infection was received; and we believe, if a true history of every attack could be obtained, this would turn out to be the case in nine out of ten cases. Costiveness is very common; and vomiting also, although much less so, does occasionally occur; but intellectual efforts to vomit are by no means unusual. The appetite is not always affected, in either early or continued rabies; on the contrary, food is not only eaten, but digested also, during the first stages; and vomit will ext almost to the last; but with such subjects the food is seldom digested. That no disinclination to liquid exists, will be readily acknowledged by all who observe the disease with common attention; from the first to the last, no aversion to water is observed. We state this as a general fact; one or two instances in as many thousands may occur of constitutional indisposition, where liquids are refused; and of the many hundred rabid dogs we have seen, not one has shown any dislike to water. In the early stages, liquids of all kinds are taken as usual, and some continue to take them throughout the complaint; nor can we press too strongly on the recollections of persons engaged about dogs, that no manifest dread of water is either a pathognomonic, or at all a usual symptom in mad dogs. Neither does an active spasm attend the efforts to swallow water; and however the paralysis of the parts may render the attempt ineffectual, the sight and contact occasion no pain whatever; but, on the contrary, the desire for drink is urgent, and unceasing attempts to take it, mark a majority of rabid cases; it is true that paralysis of the parts prevents deglutition in some, while others drink freely throughout the disease; but certainly there is not one in a thousand that does not seek water."

As this is a most important subject, we think it cannot be too fully treated; accordingly we have collected as many opinions as we have been able upon its different modes of treatment, as well as the different characteristics of the disease.—When a dog is affected with rabies, the symptoms are, in the first place, restlessness, turning round before he will lie down, blood-shot eyes, an anxious countenance, and a continual snipping at fancied objects. All these, in most cases, exhibit themselves some days before he gets very bad. A dog in a fit is generally taken suddenly, and merely knocks about and froths at the mouth. It is the opinion of most country people, that a dog affected with rabies is afraid of water; and if they see a dog drink, or go near water, they conclude he is not mad, no matter what they may have seen before; but we have seen a mad dog that followed a man through a stream, and when he got into it he
stopped to drink, and tried to find the man again when he got over. As a matter of course, it will be asked, how do we know the dog was really mad. And it would have been well if it had never been proved, as it cost the life of one fellow-creature, besides a great number of sheep, dogs, and some beasts. That the dog was mad, therefore, there could not be the smallest doubt, and yet he had no dread of water whatever.

The symptoms of rabies, however, deviate greatly in accordance with the different temperaments of dogs. Such as are subject to fits will be at one moment scouring the fields in apparently excellent condition, but all at once will make a dead stop, gaze intently and wildly at some fancied object, then suddenly fall into convulsions, from which (if a little water is dashed in the face) they will soon recover, and be as well next day as if nothing had happened.

With a rabid dog, however, it is quite different. There are always premonitory symptoms, the most prominent of which are a depraved appetite, the animal ravenously devouring its own, as well as human excrement, sticks, cinders, mud, and all kinds of filth, which, in a healthy state, it would avoid. In some breeds of spaniels, however, there have been exhibited exceptions to this rule.

The next important symptom, and one which may, perhaps, be considered as the most demonstrative, is an insatiable thirst, and an eager craving after its own and other dogs' urine, searching in every corner, and, wherever one dog has wetted, greedily licking it up. This disgusting act is never found in the healthy animal.

We think this symptom so decided a proof of rabies, that we should at once have the animal destroyed, however valuable it might be.

For a disease so terrible, no efforts should be spared to find out the means of either preventing or counteracting its effects. In accomplishing this, even the labours of science have, in a great measure, been unavailing; for a curative agent has, we believe, not yet been discovered.

The following singular account of the discovery of a supposed antidote, however, appeared some years ago in several continental newspapers, as an extract from the Berlin State Gazette. We give it as it appears in the small work of Mr. Richardson:

In the year 1813, when Maraschetti, an operator in the Moscow hospital, was visiting the Ukraine, fifteen persons applied to him for relief on the same day, all having been bitten by a rabid dog. Whilst the surgeon was preparing such remedies as suggested themselves, a deputation of several old men waited upon him, with the request that he would permit a peasant, who had for some time enjoyed considerable reputation for his success in treating cases of hydrophobia, to take these patients under his care. The fame of this peasant, and his skill, were known to M. Maraschetti, and he acceded to the request of the deputation on certain conditions: in the first place, that he himself should be present, and made cognizant of the mode of treatment employed; secondly, that proof should be given him of the dog that had injured the sufferers being really rabid—and then that he, the surgeon, should select one of the patients to be treated by himself according to the ordinary course adopted by the medical profession. This might, at a hasty view, be deemed an improper tampering with human life on the part of the Russian surgeon; but, when the admitted hopelessness of all remedies is recollected, the reader will refrain from animadversion. M. Maraschetti selected, as his own patient, a little girl of six years old; the other condition was duly complied with: no doubt could exist of the genuine rabies of the dog, which perished shortly afterwards in extreme agony.

The peasant gave to his fourteen patients a decoction of the tops and blossoms of the broom plant (Flor. Genista lutea tinctoria), in the quantities of about a pound and a-half daily; and twice a day he examined beneath their tongues, where, he stated, small knots, containing the virus, would form. Several of these knots did eventually appear, and, as soon as they did so, they were carefully opened and cauterized with a red-hot wire; after which the patients were made to rinse their mouths, and gargle with the decoction. The result was, that all the patients—two of whom only, and these the last bitten, did not show the knots—were dismissed, cured, at the expiration of six weeks, during which time they had con-
tumed to drink the decoction. The poor little girl, who had been treated according to the
usual medical formula, was attacked with
hydrophobic symptoms on the seventh day,
and died within eight hours after the accession
of the first paroxysm. M. Maraschetti saw,
three years afterwards, the other fourteen
persons all living, and in good health.

In 1818, five years after the above occur-
rences, M. Maraschetti had another oppor-
tunity afforded him, in Podolia, of testing the
value of this important remedy, in the treat-
ment of twenty-six persons, all of whom had
been bitten by rabid dogs. Of these persons,
nine were men, eleven were women, and six
were children. He used the decoction of
broom, as before; and a careful examination
of their tongues gave the following results:—
Five men, all the women, and three of the
children, exhibited the knots—those most
severely bitten on the third day, others on the
fifth, seventh, and ninth; and one woman,
who had been bitten only superficially on the
leg, not until the twenty-first day. The re-
main ing seven showed no knots, but all con-
tinued to drink the decoction; and in six
weeks all the patients had recovered.

From these cases, M. Maraschetti was led
to the opinion, that the rabid virus, after re-
main ing a short time in the wound, becomes
absorbed, and, for a certain time, resides be-
neath the tongue, at the orifices of the sub-
maxillary glands, where it develops itself in
the small knots observed by him. The aver-
gage time for the appearance of these knots
would appear to be from the third to the ninth
day after the bite— that if not opened within
twenty-four hours after the first formation,
the virus is reabsorbed into the system, and the
patient is lost beyond all hope of cure. On
these accounts, Maraschetti recommended that
the patient should be at once examined be-
neath the tongue, which examination should
be continued for six weeks, during which
period they should take one pound and a-half
of the decoction of broom daily, or a drachm
of the powder four times a day. If, during
this time, no knots appear, there is nothing to
be apprehended; but if they do appear, they
should be freely opened and cauterised, using
the gargle afterwards, as already described.

Since the above statement appeared in the
Berlin State Gazette, an official report was
made to the Prussian government, and pub-
lished in a subsequent number of that paper,
representing that knots, similar to those de-
scribed by M. Maraschetti, had been formed
beneath the tongue of a rabid dog, in West-
phalia. It is possible that the above account
may be familiar to most, if not all, medical
readers, and that many of them may regard it
as resulting from either impatience or error;
but, as one and all of them admit that they
cannot cure this dreadful disease, surely any
suggestion is worth acting upon, if a melan-
choly opportunity should occur.

Instances of rabid dogs are numerous. One
much attached to its owners, on one occasion
returned home, covered with dirt, and hid
itself in a blanket, and would not obey the
commands of those it had hitherto been ready
to serve by all the means in its power. Mr.
Youatt, the veterinary surgeon, was sent for,
and when he arrived he found the animal lying
in the lap of its mistress, no doubt receiving
all those endearments which such animals are
so apt to draw from all those who are attached
to them; but it kept continually changing its
position, and starting at the least noise. Mr.
Youatt pronounced it rabid. The dog had
been licking the hands of its owner, and Mr.
Youatt urged a surgeon to be immediately sent
for. This was done, and the proprietors of
the animal were saved.

The habit of allowing favourite dogs to
lick not only the hands, but the face, as some
do, is not only abominable in itself, but in
the last degree dangerous, for there are com-
paratively few out of the multitudes who keep
dogs, that have the slightest idea of the
symptoms of rabies, even when they have
made their appearance. A lady's spaniel was
rarely out of her sight, and yet it became
rabid. She did not know of its having been
bitten by any other animal, and her servant
denied all knowledge of its having been so;
but the dog died; and, in a few weeks after-
wards, the man was taken ill. He now made
a confession that the spaniel had, on one
occasion, been attacked and rolled in the mud
by another dog, and that he had put it
through a process of ablation before he per-
mitted it to be seen by its mistress. The
dog which had behaved so unceremoniously to
Rabies.]  THE DOG, AND ITS VARIETIES;  [Rabies.

this pet spaniel, was mad, and some of the saliva which had fallen from its mouth, had remained on the coat of the spaniel, and by which the man had been inoculated.

Rabies, or hydrophobia, a few years ago exhibited itself to such a serious extent in Stainborough Park, near Barnsley, as to excite the alarm of the inhabitants of that locality, and to attract the attention of medical men. The disease first began to show itself on a small scale, immediately after a mad dog was said to have been roaming about the locality. Nearly one hundred deer in a short time fell victims to its effects. While in a state of disease, these otherwise innocent and playful animals foamed at the mouth, worried each other like dogs, and tore off each other's hair and flesh; and when placed in a state of confinement, bit at whatever came within their reach. Attention was drawn to the matter through a child belonging to one of the workmen on the estate having been bitten. This caused an alarm, which led to a medical gentleman (Mr. M. T. Sadler, of Barnsley) being called in. He issued a timely caution to the inhabitants, calling upon all to be on their guard, to protect themselves and their families from the infliction of so terrible a malady.

As canine madness suddenly changes the dog into an object of terror and a scourge, of course everything that may be esteemed a remedy for it should be tried. Among others already suggested, the "Berlin Drink" holds a prominent place. It was, and we believe still is, in the possession of a woman residing near Tunbridge. The recipe of it, it is said, is a secret, which has been handed down in the family from generation to generation; and its efficacy, in the counties around, is so well known and esteemed, that it has, at all times, proved a lucrative legacy to the family.

Among the numerous instances in which it is said to have been successful, we will adduce one which may excite some surprise.

The proprietor of a large pack of beagles had his kennel broken into by a rabid dog, and twenty of the pack bitten. He had known many cases successfully treated by the "Berlin Drink," and he determined to try its effect upon every one of his dogs that had been bitten. His brother, who had been brought up to the medical profession, laughed at the idea, maintained that nothing could save them if once the virus had entered the system, and proposed the total destruction of the whole pack. The other, however, opposed his experience to all the arguments of science. They therefore came to an arrangement which satisfied both parties. It was agreed that sixteen of the infected hounds should have a dose of the "Berlin Drink," and that the other four should take their chance.

The consequence was that, in less than six weeks, every one of the four died raging mad, and not one of the sixteen ever showed a symptom of the disease. As this fact has been pretty well authenticated, a more convincing proof of its power as an antidote to the virus could hardly be given. In colour and consistence the "Berlin Drink" resembles milk; and if administered to an animal not inoculated with the poison of rabies, it has no more effect than a cup of milk would have.

If, on the contrary, the poison has entered the blood, the effect of the antidote is very different: it seems to course through every vein like fire, to rack every nerve, and to convulse the system from head to foot. Human patients affirm the agony to be intense; and it is painful to witness its effect upon a dog. But the struggle is very short; and though, of course, the shock and excitement leave the patient a little weak and depressed, we are told that its administration has never been followed by any fatal result.

Besides the "Berlin Drink," there is another, called the "Hertfordshire Drink," or Webb's remedy. To this Mr. Blaine alludes in his Rural Sports. "The tree box," he says, "is one of the oldest reputed preventives made use of. Mention appears to be made of it in the writings of Hippocrates; Galen and Celsus likewise speak of it. It has continued to be used from their time to the present, and it forms the active principle in the remedy common in several counties, but in none more than in Hertfordshire, where it is known, as we stated, under the name of 'Webb's drink,' from the family name of the persons who prepare it. The rue which enters into it, in equal proportions, we have little dependence on. The bucus, or box, has long been known in India also; it is still used there as a preventive of rabies; but it is, we believe, the
dwarf box that is there used, and is usually united with a deoection of the horn of the rhinoceros. As from our own experience, and the testimony of others, we are inclined to place some dependence upon the preventive properties of the tree box, we shall introduce the original formula of ‘Webb’s Drink,’ as gained by ourselves from one of the family dispensers of it, whose oath was taken as to its being the genuine recipe:—‘Take of the fresh leaves of the tree box, two ounces; of the fresh leaves of rue, two ounces; of sage, half an ounce; chop these finely, and after boiling them in a pint of water to half a pint, strain and press out the liquor; beat them in a mortar, or otherwise bruise them thoroughly, and boil them again in a pint of new milk, until the quantity decreases to half a pint, which press out as before. After this, mix both the boiled liquors, which will make three doses for a human subject. Double this quantity will form three doses for a horse or cow; two-thirds of it is sufficient for a large dog, calf, sheep, or hog; half the quantity is required for a middle-sized dog; and one-third for a smaller one. These three doses are said to be sufficient, and one of them is directed to be given every morning fasting. Both human and brute subjects are treated in the same manner, according to the proportions specified.’”

Upon this specific Mr. Blaine places a considerable, but not a full reliance. He says, however, that whenever a very useful or a favourite dog was in question, he should make a trial of it; at the same time he would watch the animal with the utmost attention.

The opinions of experienced sportsmen upon rabies and its modes of treatment by practised veterinarians, are well worthy of an extensive diffusion amongst the people. Mr. Youatt, who had even more experience in the treatment of this disease than Mr. Blaine, remarks—“The veterinary surgeon, when operating on the horse, cattle, or the dog, frequently has recourse to the actual cautery. I could, perhaps, excuse this practice, although I would not adopt it in superficial wounds; but I do not know the instrument that could be safely used in deeper ones. If it were sufficiently small to adapt itself to the tortuous course of small wounds, it would be cooled and inert before it could have destroyed the deepest portions of the wound.” He states a case in which several horses had been bitten, and, on lunar cautie being applied to one, it was cured; the hot iron to the others, which were lost: mentioning other cases in which cautie was efficacious, and the cautery perfectly useless. Liquid and other applications of a soft or semi-fluid mass, have a tendency to aggravate the disease, by re-inoculating the injured parts; while, by the effects of lunar cautie, it being dry, hard, and insoluble, this danger is avoided.

M. Guerin-Meneville, some time ago, brought before the French Academy of Sciences a means of curing hydrophobia, which, he stated, is practised in Russia with success. A little insect, the golden cetonides, found in considerable quantities on rose-trees, is proved, when pounded to a powder, and administered internally, to produce a profound sleep, which sometimes lasts for thirty-six hours, and which has the effect, in many cases, of completely nullifying the hydrophobic affection. A distinguished entomologist of Russia, M. Motschouski, has tried several experiments with this insect, and in most cases with success.

Whatever virtue there may be in these specifics, we fear it will be a long time before they receive a very extensive application; therefore it is to the cautery or to the knife that recourse must be had to prevent danger, or, perhaps, death, resulting from the bite of a rabid animal. Mr. Blaine says, that three times his life had been endangered by the bites of mad dogs, and three times he had to suffer cauterisation, excision, and some mental agitation, as, doubtless, every one must suffer who has had the misfortune to be subjected to such an evil. What his experience suggested him to do to himself, we would recommend to be done to others, in the absence of other curative means, which may be less severe, and, we may add, probably less effective.

We have hitherto treated of this malady in its most acute form. We will now briefly consider its other state, which appears in what is called

**DUMB MADNESS.**

This kind of rabies is so called from the animal affected by it exhibiting an absolute
dumbness, which arises from the swelling in the pharynx being so great as to deny to the dog the power of barking. The symptoms of this complaint are, a dull, stupid look, accompanied with listlessness, and a constant rubbing of the jaws with the paws, as if he would dislodge a bone that had stuck in his throat. The disease causes death between the third and seventh days; generally on the fourth or fifth. A common symptom, and not altogether confined to this species of madness, but also to be found in the acute disease, is an inclination to pick up straw, hay, litter, and other materials, to make a bed with it, but more frequently to tear it to pieces. "It is likewise very common to observe dogs scratch the litter under them with their fore feet, not as when making their beds, but evidently to press the straw or litter to the belly." There is also exhibited a disposition to pick up substances which, when the dog is in health, are wholly averse to his nature. He gnaws the boards upon which he may be lying; is irritable, mischievous, and treacherous. This is, however, mostly before the disease has attained to that strength of character by which it is sometimes marked. When it has arrived at its height, neither irritation nor delirium are very apparent; on the contrary, there is displayed a peacefulness of disposition, which does not arise from the inability to bite, but from the really disinclination to do so. The jaws begin to lessen; increased paralysis takes place; and, like a drunken man, without consciousness, the animal begins to stagger about, until he tumbles, only to struggle to his legs again. He now seats himself on his rump, looks melancholy in the extreme, and in this position expires without an apparent pang.

There are other diseases to which the dog is subject, and which are not unfrequently confounded with madness. These it is important to know. "Thousands of valuable dogs," says Mr. Blaine, "have been destroyed as mad, which have laboured under other affections, as distemper, colic, epilepsy, &c. And also thousands of owners of dogs and others have been needlessly rendered miserable by having been bitten by dogs innocent of any rabid affection. On the other hand, it is even more important that the real criterion of rabies be set forth, that due precaution may be taken when necessary. Epileptic fits, whether occasional, or the consequence of distemper, are often mistaken for rabies; but it should be remembered, that there is no rabid symptom whatever that at all resembles a fit, whether in the irritable or in the dumb variety; we use these terms as being significant, although by no means scientific. An epileptic fit is sudden; it completely bewilders the dog, and, after a determinate period, leaves him perfectly sensible, and not at all irritable, but exactly as he was before; in rabies there is no sudden fit, no loss of recollection, no tumbling about wildly in convulsions; neither is there any marked bark in the natural irritability attendant on madness. If a dog in an epileptic fit should be so convulsed as to attempt to bite, it is evidently done without design; its attack is spasmodic, and pain may make him seize anything, and it is quite as likely to be himself as any person or thing besides. The irritability and mischievous attempts of the rabid dog have always method with them, and they evidently result from the mental purpose to do evil; he usually manifests a disposition to rove; the distempered dog never does so. A puppy in distemper, particularly if he have worms, may pick up stones, or eat coals; or he may, in a trifling degree, pick up other unusual matters as food; yet no dog but a rabid one will take in hay, or wood, coals, or rage, or will distend his stomach almost to bursting. Lastly, the mistakes likely to occur between rabies and other diseases, are, in some degree, attributable to erroneous pictures drawn by authors of such diseases. Thus, Dr. Jenner's account of the distemper, instead of deserving the praise his great name has drawn down upon it, is entirely calculated to mislead; indeed, it might be supposed, by his readers, that he was purposely describing rabies, and not distemper. We could produce many similar instances in other authors, as Dr. Parry, &c."

CANKER IN THE EAR.

This is a disease very common in all water-dogs, such as poodles, spaniels, and Newfoundlands, arising from the quantity of hair they usually have about their ears, retaining the moisture within their cavities, and causing an
afflux of humours towards them. The earliest symptoms show themselves by the animal shaking its head, holding it to one side, and violently scratching the ear. Immediately on these signs being perceived, a curative process should be entered upon; and what this is to be, and how proceeded with, must greatly depend upon the habit of the dog. If the animal is fat, his system must be reduced by purgatives and abstinence; he must have plenty of air, and plenty of exercise, that the fluids of the body may be diverted into another channel. If his skin is infected with mangy irruptions, causing him to itch, he must have a vegetable diet, accompanied with cleansing, alterative, and purging medicines. Mr. Richardson recommends the ears to be well washed with warm water and soap, and then syringed out with a solution of sugar of lead, in the proportion of about a teaspoonful of the lead to one pint of distilled water. If distilled water cannot be procured, use rain water. Besides this, the washing should be repeated twice or thrice daily, and the bowels of the dog kept open by a daily laxative; if these remedies fail, a seton must be run through the back of the neck, and strong doses of aloes given every second day.

Mixing of burnt alum with a little sweet oil, would, perhaps, be better than with water, in a case of canker, on account of the wax and the greasy nature of the inside of the ear, which throws off water. Cancer in the human frame has hitherto been found incurable when it cannot be got at; and when it can, cure has been considered very doubtful. Unless the roots are destroyed, the cancer will grow again, as is most frequently the case after cutting.

We have understood that canker in the ear has frequently been cured in little spaniels by the application of a solution of alum and water. It should be just warmed, so as to take off the chill; and a few drops poured into the ear, and worked about in it for a few minutes. The complaint generally shows itself by a white discharge of matter, which can be seen on examination far down in the ear.

We have also heard of a dog of six years old being cured by having put into his ear a piece of mercurial ointment, about the size of a horse-bean. Should the cure not be effected in the first instance, another bean should follow it shortly.

Mr. Blaine recommends, for external applications, first, the use of a wash, composed of half a drachm of sugar of lead, dissolved in four ounces of rose or rain water. "A small teaspoonful may be introduced, previously warmed to a blood-heat, to prevent surprise, night and morning, rubbing the root of the ear at the same time, to promote the entrance of the wash into the cavities. In more obstinate cases, it is prudent to add fifteen or twenty grains of vitriolised zinc (white vitriol) to the wash; or rather make two distinct articles, and alternate the use of each, which will prevent the chemical decomposition of these medicinal agents, as the suspending menstruum; and, likewise, instead of water, use a decoction of oak bark, which will greatly promote the end desired. Now and then acetate of copper (verdigris), mixed with oil, has proved beneficial, when introduced in the same manner. In others, calomel and oil have produced amendment, when applied in the same way. We have, also, seen a weak injection of corrosive sublimate succeed, when every other application has failed. A very mild injection of nitrate of silver, as one grain to two ounces of water, has benefited others; for in this, as in mange, and indeed in all skin affections, no one remedy is a universal panacea: happily, however, there are few cases but will submit to a patient trial of various means."

Canker on the outside of the flap of the ear, and abscess of the inner surface of the ear-flap, frequently afflict the smooth-cared dogs. For the former, an ointment, composed of equal parts of nitrate of quicksilver and calomine ceruse, is recommended. It should be applied once a day, and care taken, by making use of a sort of head-dress, not to have the ear injured by the dog shaking his head. If the canker prove obstinate, however, excision must be resorted to. For the latter, the tumour ought to be opened its whole length, and a pledget of lint introduced, to present too hasty a reunion of the edges of the ear; or a seton should be inserted, and allowed to remain in it for eight or ten days.

WORMS.

To the accumulation of worms in the intes-
tines dogs are very subject. They are of three kinds:—Ascarides, or small thread-like worms, not more than half an inch in length. The seat of these is principally in the rectum; and hence the common symptoms of their presence is the dog dragging his fundament along the ground. Puppies are frequently afflicted with them. The teres, but of a white colour, and having the form and appearance of an earthworm. The tawia, or tape-worm, several inches in length, and flat for nearly its whole extent.

Another description of worm, peculiar to very young puppies, and generated in their intestines in great quantities, is known to dog breeders. It is described as being from two to four inches in length, of a dirty-white colour, round, and pointed at both extremities. Sometimes this kind of vermes collect in balls or masses, to the number of a dozen or more in each mass. When puppies have them they usually fall away in flesh, until they actually reach the extreme of emaciation; when fits supervene, and death soon carries them off. The deaths are attributed to distemper; but worms are the true cause, and these of the description here described.

From the circumstance of hounds sometimes vomiting worms similar to earth-worms, it has been supposed that these have their seat in the windpipe. If this be the case, it has been recommended that they should have thirty drops of spirits of turpentine, suspended in a little castor-oil, every other day, for about a week; or they might be allowed to inhale chlorine gas for about half-an-hour, but not to have more gas in the kennel than a man can, without much annoyance, bear himself.

About a teaspoonful of ground glass mixed in lard has also been recommended for foxhound puppies afflicted with this malady. They take it without trouble when fasting; and in about twelve hours, some Glauber’s salts, in milk, after being dissolved in hot water, should be given to them. This they will lap up readily.

Mr. Richardson found the following mode of treatment efficacious, and, as he had great experience in rearing puppies, his advice is exceedingly valuable:—"Give, say on Monday, a small pill formed of Venice turpentine and flour, from the size of a very minute pea to that of a small marble, according to the size and age of the pup. The former will suffice for Blenheim or King Charles’ pups, Italian greyhounds, &c.; the latter for bloodhounds, Newfoundlands, mastiffs, &c. On Tuesday, give a small dose of castor-oil; a teaspoonful to the smaller, a tablespoonful to the larger breeds: in neither case, however, quite full. On Wednesday, give nothing; on Thursday, give the turpentine as before; on Friday, the oil; on Saturday, nothing; and so on.

"Keep your puppies’ beds dry, clean, and sweet. Do not feed them too often, or on food of too nutritious a quality. Puppies should not be fed oftener than three times a day. The morning and evening meals may be given at 9 A.M. and 7 P.M., and should consist of vegetables—potatoes, oatmeal, &c.—well boiled, and given with milk. At two, you may give meat with the mess, but not too abundantly. Between the meals give a drink of buttermilk, or milk and water."

The general symptoms of the presence of all or any of these worms are:—Putrid breath, staring coat, voracity, or total loss of appetite; violent purging, or obstinate constipation, with great emaciation, sometimes fits. Venice turpentine is a good remedy, and is effective in slight cases. Aloes are useful for dislodging worms from the rectum, as they pass down the intestines, almost unchanged; but powdered glass is the safest and most efficacious. Give it in pills formed with butter and ginger, and covered with soft paper.

THE YELLOWS.

This is the disease which Mr. Richardson treats under the head of Jaundice, and to which young dogs are very subject. It is often the precursor of distemper, and arises from an affection of the liver. Its symptoms are a general dullness, a disinclination for food, a yellowness in the whites of the eyes, as also over the surface of the skin; a dry and parched mouth; a general emaciation and debility, accompanied with vomiting greenish matter; loss of consciousness, often succeeded by death.

If taken in time it may be cured; but it makes its approaches so imperceptibly, that it has frequently fastened in the animal several weeks before it has been observed; and, in
such cases, death is the inevitable result. When perceived in time, Epsom salts, with mucilage of gum-arabic, or very well boiled gruel, are recommended. Should the disease have only just appeared, common salt will answer the purpose in the absence of the other articles. Calomel and coloehy in the form of a pill, and in small doses, administered at night, and succeeded in the morning by some opening medicine, will usually effect a cure; but, if there be much fever, bleeding must be resorted to. When the appetite returns, only small quantities of light food should be allowed.

As a tonic alternative, Mr. Blaine recommends the following:—Mercurial pill, one drachm; aloes, two drachms; gum myrrh, gum benjamin, balsam of Peru, of each one drachm and a-half; make into a mass, and divide into ten, fifteen, or twenty balls, according to size, age, strength, &c., of the dog: give one every evening, and, in a bad case, every morning also. Avoid bringing on active salivation, and active purging likewise, after the first purging dose recommended.

DISTEMPER.

This is the most fatal disorder, after rabies, to which the canine race is liable; and, we believe, it originated in France, where it is known by the name of La Chaladie. It is little more than a century since it was known in this country, and since that time it has played havoc among some of our best breeds of dogs. Some French authorities ascribe its origin to England; but others, better informed, and more candid in their sentiments, acknowledge that it originated in France. It is, however, of little consequence to us now where it was first known; of far more value would be the knowledge how to prevent it from affecting our dogs, how to check it, and how to cure it. Almost every dog, at some period of his life, is affected by it; and when it appears in an old one, there is little chance or hope of his recovery. The more excellent the breed, it would appear, the more susceptible is it of the disease. Animals of the inferior order have it often very slight, and the Colley of Scotland gets it without any medicines whatever in a few days. Dr. Darwin describes it as a debilitating catarrh; but, as he mis-took the character of the disease, or rather limited the seat of its operations, the rationale of his prescriptions was wholly unequal to compete with it. Dr. Jenner's description was worse. He was a great man, or rather, perhaps, a man with a great name; but he erred egregiously in reference to the dog-distemper. Mr. Youatt says, that his description of it was no more like the true disease than himself was like unto Hercules. "I have," Mr. Youatt continues, "again and again, put the power of his boasted preventive (vaccination, as in small-pox) to the test, and I can say, without the slightest hesitation, that it is altogether without effect. I know many gentlemen who have placed implicit faith in the power of vaccination, and their whole kennels have been submitted to the operation; the season has been favourable, and the disease either has not appeared, or has assumed the mildest type, and I have got into sad disgrace; but many years have not passed, before the distemper has broken out, and carried off the majority of those who were supposed to be exempted from its attack."

The symptoms of distemper are usually loss of appetite, fever, weakness of the eyes, dullness, a discharge from the nose, discharge from both the eyes and the nose, a short husky cough, emaciation, a fetid smell; sometimes fits. Dogs in a fit are sometimes mistaken for mad; but it should be remembered that fits are never an accompaniment of rabies.

The distemper is a disease of the mucous surfaces, and usually has its commencement in nasal catarrh. If it is detected in the first stage, bleeding copiously will do good. Give an emetic, and follow it up by a gentle purga-tive; if—as is generally the case when the above treatment does not effect a cure—inflam-mation of the lungs supervenes, more blood must be taken, and more aperient medicine, with occasional emetics, given. If the animal become weak, and is apparently sinking, mild tonics, as gentian or quinine, must be admin-istered; and if he will not eat, some strong beef jelly should be forced down his throat. A seton in the back of the neck is often useful, but should not be used indiscriminately. To save all this trouble, however, the best thing to do is to place the dog in the hands of a veterinary surgeon.
The causes of distemper are, generally, cold; suddenly throwing a domesticated dog into the water, or not properly drying his coat after being washed. They are, however, various, and, to a considerable extent, inscrutable; for any rearrangement of the system may bring it on. It is remarked in the *Encyclopædia of Rural Sports*, that the effects of distemper in different breeds of dogs used in rural pursuits, or those which live mostly in the open air, are comparatively slight; but, wherever man has interfered, and forced an artificial breed by educating them to artificial purposes, or closely confining them, in such, the disease acts with great severity. Hence it is so fatal to high-bred hounds, pointers, setters, and spaniels; and to terriers and greyhounds, as breeds even more artificial than the others, it is usually more so. Mr. Youatt observes, that few dogs imported into this country, as exotics, do well in it. In proof of this, it is known that the larger number of the northern dogs, brought here by Captain Parry, were swept away by it within twelve months. Some breeds have an hereditary predisposition to be affected in a far greater degree than others of the same kind. Litter after litter of some sporting strains, will hardly yield more than one or two survivors; and, in such cases, we would advise the breeder to cross the race. In crowded cities the disease is both severe and fatal. In London, those that are attacked by it have little chance of recovery compared to those that are attacked in the country, where the air is so much more pure, and where the lungs are less likely to suffer by it.

As in all diseases in which there is difficulty, in treating for distemper, various modes have been adopted. Some think it best, on its first appearance, to give their dogs emetics and purgatives. They begin by keeping the dogs warm, and then administering James’s powders and hot baths, if necessary.

It does not do to place a dog in an out-house, and to content yourself with looking at him, with your hands behind you, and saying “poor fellow” to him two or three times a day.

A gentleman of the old school, gave to his puppies, Scotch pills and James’s powders. The animals were then kept in an out-house, made as warm and comfortable as a lady’s parlour; and success generally resulted from this treatment. A great matter in this disease is promptitude of action. This same gentleman lost a most promising greyhound puppy, entirely through dilatoriness. The dog was out in the yard; and although the owner was told of his condition by one experienced in canine diseases, he did not take proper measures to check it. He was going out for a walk with his wife, intending “to see him when he came back;” and a few days afterwards the dog was dead. Knowing how soon some people tire of animals when any sickness or trouble comes, this does not surprise us; and the conduct of this gentleman is by no means exceptional, for there are hundreds like him. To such, however, the life of no valuable dog should be intrusted.

For the cure of distemper, one table-spoonful of castor-oil and a piece of garlic bruised, and given every day, has been found extremely effective. It has been repeatedly tried, at the same time keeping up the dog, or not allowing him to get low. We have known a dog perfectly paralysed from the distemper; but by giving the above for ten days or a fortnight together, and then, when it seemed, in some degree, to have lost its effect, Benbow’s Alternative Mixture, for a few days, afterwards returning to the castor-oil and garlic, completely restored him.

Every sportsman has his own specific for this disease; and the following will be found, we think, as excellent as any:—12 grains of tartar emetic; 6 do. of opium; 4 do. Peruvian bark; 2 do. nitre; 2 do. camphor. To be mixed up into nine balls, and two to be given every other day to a full-grown dog; one to a puppy.

**Tonic on beginning to Recover.**—2½ grains of quinine; ½ ounce of gentian powder; 1½ do. of bark in powder; 1½ do. of lemon-juice, or 8 drops of sulphuric acid. To be made into eight balls, and one to be given every other day.

Valuable as these opinions and recipes may be, however, we must make room for some apt remarks by another, in reference to the “infallible remedies” which have been supposed to have been discovered for this disease, as well as for a portion of the *rationale* of his own treatment of it.

“The treatment of distemper,” says this experienced veterinarian, “must necessarily vary considerably, according to the nature of
the attack, as well as the age, constitution, and locality of the object of it. It is somewhat singular, that while the very best practitioners so often fail in their treatment of the complaint, we seldom have met with a sportsman, or breeder of dogs, who, according to his own account, could not readily cure it, ‘being in possession of what he flattered himself was an infallible remedy.’ We once thought a remedy of our own discovery almost so; but though it remains a valuable one, it is far from infallible; and we suspect most of these are much further from deserving such a character than that we allude to. It happens, however, with these fancied infallible remedies for distemper among gentlemen, that under the exhibition of some supposed curative, they have met with two or three successful cases, which would, perhaps, have done well without anything; such medicament has been afterwards considered as the grand specific. But continued experience leads us to a conclusion that, although many different remedies are useful, according as one or other form of the disease prevails, yet that there is not, and we believe cannot be, a universal specific for this Protean disorder. As most cases of distemper commence by cough, or slight running from the nose and eyes, with loss of flesh, appetite, and spirits, an emetic is the first remedy, as it clears the stomach and bowels, and sympathetically lessens the inflammatory action going on. Should the pulse, the state of breathing, or a harassing cough, indicate any great determination to the lungs, take from three to five or six ounces of blood away, according to the size, age, &c.; particularly if the dog be fat and moderately strong. If bleeding is omitted, substitute a mild purge, if the bowels are not already relaxed. Emetics are useful as preparatory medicines in distemper; indeed very useful. Strong dogs may take from two to four grains of tartar emetic; or otherwise from four to six or seven grains of calomel. Sometimes one, and sometimes the other of these remedies is to be preferred. When there is any disposition to purging, already observed, give the tartar emetic only, from one grain to four, as a maximum; or the vomit may be made of equal parts of calomel and tartarised antimony, from one grain to three grains of each; or even four grains of each may not be too much for a full-grown dog of the largest breeds; and further, this latter vomit has the advantage of proving a laxative also. The purging and emetic articles used on these occasions by sportsmen, as Turpith mineral and crude antimony, are, from their drastic qualities, objectionable; and they can only be admissible for very strong dogs, not yet at all debilitated by the complaint; indeed, it is only in such cases that these violent remedies may be risked. Of this kind are large doses of salt, which occasionally do good when no looseness of bowels has already come on. The early insertion of a seeton should depend on circumstances: if an impatience of light present itself, and the pupils look red within, the cough being hard, dry, and frequent, insert one; but if, on the contrary, the discharge from the eyes and nose is become purulent and profuse, and particularly if the dog be losing flesh daily, by no means do so. While the dog is fat, should his inflammatory symptoms run high, two or three moderate purges are proper; but when distemper is at its height, always avoid them. Costiveness, however, must be combated; but do it by laxatives only in these cases: as already observed in other cases, a brisk purgative is admissible and highly proper; for unloading the bowels, like unloading the stomach, will tend greatly to lessen irritation, and reduce the inflammatory action of the heart and arteries; but, at the same time that, under these views, they are valuable agents, we must not lose sight of the diarrhea, which is so fatal a symptom of the disease, and which too free a use of them might tend to bring on. These primary depleting means having been carried into effect, proceed with the following fabrifuge:—Antimonial powder, two, three, or four grains; nitrate of potash (nitre), five, ten, or fifteen grains; powdered ippecacuanha, two, three, or four grains; powdered myrrh, four, six, or eight grains. Make into a ball with a minor, medium, or major quantities, according to the size and age of the dog, and give two or three times a day, as the symptoms are more or less urgent, diminishing the quantities if they occasion sickness. When the cough is very distressing, by which pneumatic symptoms may be apprehended, add to each dose of these from half a grain to a grain of digitalis.
Distemper. The Dog, and Its Varieties;  

(fox-glove). Should nothing new in the symptoms occur, and your patient remain strong, every third or fourth day repeat the emetic, and keep the bowels open; but now, more than ever, avoid active purgation."

The natural medicine of the dog is an emetic, he being easily excited to vomit. Whenever anything ails him, he himself runs to the dog-grass, eats it, vomits, unloads his stomach, and is at once well. In distemper, therefore, a vomit is the first thing to be given, no matter what form the disease may have assumed. If nothing else is at hand, Mr. Youatt concurs with Mr. Blaine in recommending common salt; but the best form of an emetic consists of a combination of equal parts of tartar emetic and calomel. From half a grain to a grain and a-half of each will constitute the dose. When calomel is given in too strong doses, it acts with great severity on the dog. The following is a case reported in the second volume of the Veterinarian, when that medicine has been too freely administered:—

"August 30th, 1828.—A spaniel, six months old, has been ailing a fortnight, and three doses of calomel have been given by the owner. He has violent purging, with tenesmus and blood. Half an ounce of castor-oil administered."

"August 31st.—Astringents morning, noon, and night."

"September 6th.—The astringents have little effect, or if the purging is restrained one day, it returns with increased violence on the following day. Getting rapidly thin. Begins to husk. Astringents continued."

"September 10th.—The purging is, at length, overcome; but the huskiness has rapidly increased, accompanied by laborious and hurried respirations. Bleed to the extent of three ounces."

"September 11th.—The breathing relieved; but he obstinately refuses to eat, and is forced several times in the day with arrow-root or strong soup."

"September 18th.—He had become much thinner and weaker, and died in the evening. No appearance of inflammation on the thoracic viscera, nor in any part of the alimentary canal. The intestines contracted through their whole extent."

For this scourge of dogs there is unhappily no specific that can act remedially in all cases. It assumes such a variety of forms, that it baffles the skill of the most eminent veterinary practitioners. "A disease attacking so many organs," says Mr. Youatt, "and presenting so many and such different symptoms, must require a mode of treatment varying with the organ attacked, and the symptom prevailing. The faith in these boasted specifics is principally founded on two circumstances—atmospheric influence, and peculiarity of breed. There are some seasons when we can scarcely serve a dog; there are others when we must almost wilfully destroy him to put him out of sight. There are some breeds in which, generation after generation, five out of six die of distemper; while there are others in which not one out of a dozen dies. When the season is favourable, and the animal, by hereditary influence, is not supposed to assume the virulent type of the disease, these two important agents are overlooked, and the immunity from any fatal result is attributed to medicine. The circumstances most conducive to success, will be the recollection that it is a disease of the mucous surfaces, and that we must not carry the depressing and lowering system too far. Keeping this in view, we must accommodate ourselves to the symptoms as they arise."

Palsy, more or less complete, is occasionally the termination of the distemper in dogs; and when accompanied by chorea, the case is generally beyond the reach of curative means.

In the Transactions of the Medico-Chirurgical Society, we are informed that this disease is not communicable to man. Neither the efluvia arising from the diseased dog, nor his bite, have proved in any instance infectious; but as the disease has often been confounded with canine madness, it is to be wished that it was more generally understood; for those who are bitten by a distempered dog, are sometimes thrown into a state of such terror, that actual symptoms of hydrophobia have arisen from the mere workings of the imagination. An instance of this occurred in a gentleman who received a severe bite from a dog, and who afterwards fancied the animal was mad. He felt a horror at the sight of liquids, and, on attempting to swallow them, was
days, during which time he must be kept dry and warm, and fed sparingly; let it be washed off on the fourth day with soft-soap and warm water, in which some common washing soda has been dissolved; give clean straw, plenty of exercise, and cooling diet, and the dog will speedily get well.

"When a dog is very bad, the skin or soles of the feet, and sometimes the claws, will come off, in which cases I would recommend steeping them in a decoction of strong oak bark and alum. It can be best done by tying the feet up in thick cloths, kept wet with the above mixture.

"Puppies are very liable to display a mangy-looking coat, at the age of from two to four months. The hair falls off in spots, and the skin becomes itchy, dry, and scaly. This is not genuine mange; but, if neglected, is apt to run into it. At this early stage it is easily cured by washing with soft-soap and water, and change of bedding; giving also a little sulphur in the food daily, and in very minute quantities. This appears to me to be only an effort of nature to throw off the old or puppy coat of hair, and assume the new one.

"Change of feeding is serviceable in the treatment of mange; but it is a mistake to suppose that the change must be to a reduced regimen. In many cases, mange is only the offspring of filth and hunger; and in these cases the change must be to clean bedding and generous diet. The change of food, however, should not be sudden; otherwise, not only may the existing disorder be aggravated, but other and less manageable afflictions may be superinduced."

When all things else fail, Mr. Youatt recommends a slight infusion of tobacco, cautiously used. If mercury is applied externally, care must be taken to prevent the dog from licking it, as diarrhoea, produced by mercury, often proves fatal. Much patience is necessary in curing this disease. Mr. Blaine had a favourite settler which was affected with a violent mange for five years. What misery must this poor animal have suffered during a period probably extending to nearly half of his life. He was ordered to be dressed every day, or every second day, before the disease was completely conquered. By this treatment, however, he finally recovered.
For the treatment of mange, Mr. Blaine recommends the following formulae.

No. I.

Powdered Sulphur, yellow or black . . 4 ounces.
Muriate of Ammonia, powdered . . . 3
Aloes powdered . . . . 1 drachm.
Venice Turpentine . . . . 2 ounces.
Lard, or other fatty matter . . . . 6
Mix.

No. II.

Sulphate of Zinc (white vitriol) . . 1 drachm.
Tobacco in powder . . . . 3 ounce.
Sulphur in powder . . . . 4
Aloes in powder . . . . 2 drachms.
Soft soap . . . . 6 ounces.

No. III.

Lime-water . . . . 4 ounces.
Decoction of Stavesacre . . . . 2
Decoction of White Hellebore . . . . 2
Oxymuriate of Quicksilver (corrosive sublimate) . . . . 5 grains.

Dissolve the corrosive sublimate in the decoctions, which should be of a moderate strength; when dissolved, add two drachms of powdered aloes, to render the mixture nauseous, and prevent its being licked off by the dog—a circumstance which ought to be very carefully guarded against.

COSTIVENESS.

Change the diet; give gruel and slops; and let the dog have full liberty; boiled liver will be found useful. If these measures fail, give small doses of castor-oil. No dog should be allowed to be costive longer than two days, as it may arrive at indigestion, generate worms, impart a fetid smell to the breath, and blacken the teeth. The best means of preventing this disease is giving a sufficiency of exercise. This, perhaps, cannot be done with watch-dogs, which have to be kept almost continually on the chain in yards and public works; but, where it can be done, it should never be neglected. In cases where it is requisite to administer medicine, an aloeetic ball may be given, or Epsom salts. Should these fail in producing the desired effect upon the animal, the castor-oil mixture, with spirit of buckthorn, and white poppies, should be administered; and recourse may be had to the clyster-pipe. Exercise, however, is the grand preventative.

DIARRHEA

This disease is frequently met with in dogs that are habitually petted; and it is very often the consequence of improper food, or overfeeding. When it shows itself, wait for a day or two, till you see if the discharge will cease, and a cure take place, without the necessity of giving medicine. Should this not happen, give castor-oil, with a few drops of laudanum.

There are many other diseases to which the dog is subject; but as these have been already treated in scientific veterinary works especially devoted to them, we refrain from introducing them here, but refer the reader to Mr. Blaine’s Canine Pathology, and the treatise of Mr. Youatt, on The Dog. In these works, every disease, so far as great experience has been able to determine its character, has been treated with judgment and skill; whilst ability, coupled with a desire to state nothing but what will bear the test of a trial, appears in every page.

MEDICINES USED IN THE TREATMENT OF DISEASE IN DOGS.

Dogs affected by disease should be handled with great gentleness; kept perfectly clean, and furnished with a warm bed. The medicines used in their cases are very numerous, and, as a general rule, should only be administered under the direction of a surgeon. They are given in the form of a pill, or bolus, or in a liquid state, most easily, by two persons—one sitting, and holding the dog between his knees, while the other forces the mouth open by pressure on the lips of the upper jaw, and administers the medicine.

ALCOHOL.—Used in tinctures, but never administered in a pure state.

ALUM.—A powerful astringent: ten to fifteen grains may be given in obstinate cases of diarrhoea. It is sometimes used in the form of a powder.

ANTIMONY in the form of James’s powders, used to produce gentle perspiration.

ALTERATIVES are intended to produce a slow change in the system without interfering with other arrangements. Five parts sublimate of sulphur, one of nitre, one of linseed meal, and two of palm oil is a useful alternative.

BARBADOES ALOE.—An excellent aperient, consists of eight parts of powdered aloes, one part antimonial
powder, one part ginger, four parts palm oil—well beat up together, and made into balls of about half a dram. Mr. Blaine says the smallest dog may take from fifteen to twenty grains, administered in half-drachm balls every four or five hours.

**Blisters.**—An infusion of two ounces of cantharides in a pint of oil of turpentine, kept on for several days, is a gentle blister, maintaining sufficient irritation and inflammation, without blistering the skin, to remove certain causes of lameness.

**Calomel.**—A dangerous medicine, but useful in small doses in cases of liver complaint, and, combined with aloe, in doses never exceeding three grains, in cases of virulent mange.

**Castor Oil** (acetum vicini) possesses the best properties of the fixed vegetable oils. Three parts of the oil, two of syrup of buckthorn, and one of syrup of poppies, form a useful medicine where a narcotic stimulant is requisite.

**Catechu.**—Extract of the acacia tree (acacia catechu), and possesses a powerful astringent property. Mixed with opium, chalk, and powdered gum, it stops diarrhoea. As a tincture, it assists the healing principle in hounds.

**Chalk** (creta preparata) is useful in combination with ginger. Catechu and opium in all cases of purging, particularly in the purging of distemper.

**Chloride of Lime** should be sprinkled, from time to time, in the kennel or dog-house, for purposes of cleanliness. It is useful for washing ill-conditioned wounds.

**Clysters.**—Applied when the nature and progress of disease renders necessary a quick evacuation of the contents of the bowels. It usually consists of warm water, rendered more stimulating, when necessary, by adding salts, oil, or aloes; for killing worms in the rectum, or larger intestines, using oils; for diarrhoea, using astringents; for nourishment, using gruel.

**Digitalis.**—Dried leaves of the fox-glove, which yield their virtues both to water and to alcohol. It is a powerful sedative narcotic, and is useful in all inflammatory and febrile complaints.

**Epsom Salts.**—A mild and effective aperient for most

DIVISION III.

SHOOTING, BY FIELD, WOOD, AND WATER.

CHAPTER I.

PRELIMINARY REMARKS; THE GUN.

To be "a good shot" is an enviable distinction in the eyes of many; and, perhaps, at no period of England's history was the art of handling the gun so much practised, so popularly esteemed as a kind of essentiality to the accomplishments of a country gentleman, as at the present time. Even the busy merchant in the city occasionally forgets the cares of his ledger, to have a day's shooting; whilst our tens of thousands of riflemen are daily practising an art which, whilst it has for its grand object the defence of our shores from foreign invasion, is, at the same time, inculcating a desire for field sports, far beyond what might be imagined by those who see nothing more in a riflemen but a civilian dressed in strangely coloured regimentals, and trained only to shoot at a target.

As one of the most captivating of British field sports, shooting has long held a prominent place; and we, ourselves, almost as far back as we can remember, have a lively reminiscence of a bachelor uncle of ours, who had long been in the West Indies, and who had passed the threescore-and-ten as the allotted period of man's life—taking us to the fields with him to practise partridge shooting, when he was with the greatest difficulty that he, himself, could see a covey twelve yards before him. We know of no sport that has so much to recommend it. Every one, however, has his hobby. Some delight in the quiet and solitary pleasures of the angle; some in hawking, which, by the way, is a noble kind of exercise; and some in the more violent sport of horse-racing. There is none of these, however, equal to the sport of the "dog and gun." Each, no doubt, has its individual charms to those who are so constituted as to make it an enjoyment; but the universality of "shooting"—of its practice in every country and clime—from the estimation in which it is held, and which, no doubt, in a great measure, arises from the open-air exercise which it causes, amid scenes exempted from the restrictions incident to artificial life, and redolent of all the charms of nature, whether belonging to the field or the forest, the moor or the mountain, has rendered this sport more general than any other. It is not all, however, that are allowed to enjoy even this sport as regards game. The law has stepped in to prevent this; and Byron has sarcastically noticed the fact in some of his lines.

"The corn is cut, the manor full of game,
The pointer ranges, and the sportsman beats,
In russet jacket—lynx-like is his aim,
Full-grown his bag, and wonderful his feats.
Ah! nut-brown partridges! ah! brilliant pheasants!
And ah! ye poachers!—'tis no sport for peasants!"

The lines alluded to certainly indicate the cause which has produced a direful chapter in the annals of British crime. But if game were not in some way protected, nobody but the farmer and the peasant would have anything living to shoot at. Some of these are constantly located where game is; consequently they would have all the sport to themselves; and the gentleman returning to his own estates in the country, after a residence in the city, or tour on the continent, would have nothing left for his own sport. The tables of his labourers and tenantry would be covered with game, whilst he would have none, except what he was forced to purchase with the hard cash from his own treasury.

THE GUN AND THE FOWLING-PIECE.

The origin of the word "gun" has not been determined with accuracy. In the Encyclopaedia Britannica, we find it observed that some derive it from the French word mandon,
which was a warlike instrument used before the invention of the gun now made use of, and employed in discharging arrows, and other missiles, before the manufacture of gunpowder. Others derive it from gun, an engine employed for similar purposes. Selden says, the word gun was in use in England, for an engine to cast a thing from a man, long before there was any gunpowder found out.

The hand-gun, or gunne, as formerly spelt, seems to have been the rudimental shape of our present bowing and military pieces. It is said to have been invented by one Billius, a nobleman of Milan, and was nothing more than an iron tube affixed to a club, or stick, with a hollow, without a cover near the breech, or base, to receive the priming powder. In the reign of Henry VI., a small priming pan was invented and attached; but still the weapon was of the rudest description, and scarcely worth the name of being an instrument well suited for either attack or defence. The stocked-gun was the next step in its improvement. The barrel was placed in a wooden stock, or frame, which was at first straight, but which was subsequently altered to a curve, for the purpose of enabling the marksmen to take better aim, and to obviate, to some extent, the severity of the recoil, which was an inherent defect in the straight stock. The match-lock and wheel-lock guns followed in the order of change. The first was used with a lighted match, brought into contact with the priming by means of a spring-trigger. The second was made in the days of Elizabeth; but, though introduced into the arena of war, it was still a very defective weapon, and was not at all well adapted for heightening the pleasures of the sports of the field. This gun was fired by means of friction, through the means of a wheel, which passed rapidly over the edge of a piece of flint. It was but a heavy, clumsy, and unhandy affair. It was succeeded by the flint-lock, which was long retained in use, and underwent various modifications down to modern times. The more recent improvement is the percussion-lock, which is now in high favour.

There are few practical arts which have advanced so rapidly as the one which is marked by the making, or the manufacturing of guns. "Judging of the perfecting of the art by the expense of the article," says the Encyclopedia of Rural Sports, "we might be led to conclude that gun-making had reached the acme of perfection. It has been no uncommon thing to pay fifty, sixty, or seventy guineas for a best London-made gun. The continent has even gone beyond us in this respect; for we are told, that when Napoleon I. was in the plenitude of his grandeur, he established a gun manufacture at Versailles; and, we are informed, that pistols were there made at 10,000 livres, or £100 sterling, each; and guns at 50,000 livres, or £2,000 sterling. Of these, the first consul often made presents to foreign princes, to general officers, and other favourites. The Marquis of Rockingham is also said to have given to Colonel Thomson a howling-piece which cost £400; and that Messrs. Roberts and John Wheeler, gun-makers, of Birmingham, presented George IV. with a gun of the most exquisite workmanship, which cost three hundred guineas.

The barrel of a gun is of the first consideration, both as regards its construction and the manner in which it is kept in order. Iron is the principal component part in its manufacture, and the kind of iron is of the last moment. The best description of this metal is that which possesses the highest degree of tenacity and ductility. Swedish iron is allowed to possess these qualifications or properties in an eminent degree, and is, therefore, almost universally employed in the manufacture of gun-barrels of any considerable value. It must be observed, however, that this article, like many others, is often made for sale, and not for safety; and that spurious and cheap pieces are made from kinds of iron that render them dangerous and worthless. When iron is mixed with certain mineral substances, it becomes unfit for safe gun-barrel making; but as every sportsman is not possessed of the scientific attainments of an expert chemist, nor has the pretensions to understand the art of gun-making, people are necessarily left, in a great measure, to chance, for the sort of instrument so necessary for their sport, as well as for their personal safety. The most prudent plan to adopt is, to deal with gunsmiths of acknowledged skill and reputation, and who make a point of issuing from their shops only such instruments as will prove both safe and effective.
Without aiming, however, at a scientific knowledge of iron or of gun-making, a sportsman should, nevertheless, be acquainted with a few plain principles respecting the quality of the materials of which his instrument is made, as well as of its adaptability to the purposes for which it is designed. Spanish gun-barrels have long been highly prized, and generally very justly. They are made of a species of iron remarkably well hammered, and which has received the technical name of scrope, being chiefly composed of the old nails taken from the shoes of horses, mules, and asses, used as beasts of burden in Spain. The Damascus barrels were once more highly esteemed than they are now. They were made of highly-tempered iron and steel, hammered with extraordinary labour, and polished to the highest perfection. There are several kinds of iron which are now generally used for fowling-pieces; such as wire-twist iron, Wiswold’s iron, charcoal iron, stub-twist iron, tuppenny, and threepenny shelp iron, and sham-dam shelp. Among all these varieties, the stub-twist is considered the best; but it is high-priced, and, like most other things of value, liable to considerable adulteration. When it can be obtained pure, most gun-makers are inclined to give it a decided preference, both for shooting purposes and safety.

A military treatise, written upwards of 210 years ago, gives us what may be considered, even in these advanced times, good advice as to the choice of a gun. We will modernise the spelling for the benefit of all our readers.

"He that loveth the safety of his own person, and delighteth in the goodness and beauty of a piece, let him always make choice of one that is double-breeched; and, if it be possible, a Milan piece, for they be of tough and perfect temper, light, square, and big of breech, and very strong where the powder doth lie, and where the violent force of the fire doth consist, and, notwithstanding, thin at the end. Our English pieces approach very nigh unto them in goodness and beauty (their heaviness only excepted), so that they be made on purpose, and not one of those common sale pieces with round barrels, whereunto a beaten soldier will have great respect, and rather choose to pay double money for a good piece, than to spare his purse and endanger himself."

The following is the test of Mr. Greener for discovering different gun-metal from the real stub-twist iron:—"Require the gun-maker to stain the barrel under examination with the smoke-brown (a staining composition, of which he gives an account in his book), and he will not be able to accomplish it if the barrel be not genuine; whereas nothing is easier, if it be really made of stubs twisted. The matter may be thus explained: hydrogen gas acts only on iron; steel resists its action; so that, when a barrel is properly finished, the steel remains quite bright, while the iron has become a beautiful jet-black, which will be easily recognised by attention to the appearance."

Testing gun-barrels is such an important matter to all who have to use them, either for amusement or war, that the legislature has been obliged to step in, for the purpose of endeavouring to save individuals from serious injuries, and often from death itself. It is not always from a defect of the metal of which a fowling-piece is made, that danger arises, but often from some defect in the workmanship, whence danger, and often serious consequences result. For a long time this country suffered severely from the want of proper attention to this subject; but the gun-makers themselves took the matter up, and established a proof-house, by which barrels could be tested. In 1813, this trade was incorporated by act of parliament; and by the powers granted to it, it was made penal to sell any gun without its being first proved at one of the proof-houses, established by the company in London and Birmingham. These enactments, however, were evaded; and such numbers of spurious instruments were thrown into the market, that the legislature had again to come to the rescue, and pass, in 1815, another more stringent enactment. "It was enacted that no barrel should be received by any person to rib, stock, or finish, that had not been duly proved, under a penalty of £20." It was also enacted that all barrels should be immediately dispatched, by the maker, to the proof-house before the same shall be sold, or transmitted for sale to any person whatever. A penalty of £20 is attached to the breach of this clause; and it further visits, with the like penalty, any one receiving such barrel to make up. The act also imposed the same penalty upon the forger.
of the proof-mark of the London company, or that of the Birmingham company.

The mode of making gun-barrels is thus described in the article on "shooting," in the Encyclopaedia Brittanica; and although it may appear somewhat foreign to our subject, still, we think there are many who would wish to know something of this operation. "Having fixed, in the first place, on the size of the gun, and ascertainment, as near as may be, the width of the bore, and the length and thickness of the barrel, the next thing the forger does is to take a portion of the metal of which he is to make the barrel, and to form it into the shape of a thin, flexible bar, something like a cooper's hoop; this bar or hoop must not be all of the same thickness; but that part of it which is to be towards, and is to form the muzzle of the piece, must be thinner than that which is intended to form the breech. An instrument, called a mandril, is then chosen, according to the size of the intended bore of the gun. The flexible bar or hoop is then heated, so as to make it ply easily, and is turned round the mandril, much in the same way as a riband of leather is turned round the handle of a whip. The edges of the hoop of iron, however, are made to overlap one another a little, so that, when welded, all their jointings may be compact and solid, and no slackness appear where the lips of the bar or hoop touch one another. When the metal has acquired its proper heat and the weldings are properly executed, the places where the bars overlapped each other are quite imperceptible; and the barrel appears as though it had been made out of one piece, and finished at one heat." The mode of making the twisted barrel does not materially differ from this description.

The use of the double-barrelled gun, in sporting, has greatly increased within the present century; and the instrument itself has undergone numerous important alterations and improvements. When first brought out, one barrel lay over the other, each having a separate pan, hammer, and hammer-spring. The barrels were consequently made to turn round at the part where their breeches were fixed to the stock; and it was so contrived that, when one barrel was fired off, the other was brought into its place by the simple pressure of a spring by the right hand, while, with the left, the barrels were turned on their common centre. This kind of gun was always esteemed an extremely clumsy and heavy instrument; and the locks were commonly so exceedingly complex, that it soon suggested further improvements in the make of this sort of gun. Accordingly, the next step in advance was an instrument that did not allow the barrels to turn round upon an axis; but, on the contrary, they were fixed one over the other, and each had a separate lock and trigger, which, for the under barrel, was, consequently, placed lower than the other. Still, although pieces of this construction possessed a great advantage over those made on the revolving principle, in the quickness of their firing, yet they were subject to one inconvenience, from which the others were exempt, and which arose from the situation of the under barrel; for that being fired under the same line of aim with the upper one, did necessarily shoot low.

The more modern plan, of placing the barrels in juxtaposition, or side by side with each other, is a great improvement; but there are still many things connected with guns of this description, which require consideration, with a view to readiness of use, and facility of movement. It has often been a matter of serious complaint, that each barrel is liable to be fired away too much at the breech, and likewise at the muzzle, in order to bring these two parts of the barrels as near together as possible. This renders the instrument unsafe. There are, also, important questions connected with the use of the double-barrelled gun, as to the way in which a true aim is to be obtained by it. These questions have, at various times, given rise to long discussions, both in sporting journals and sporting books, and very contrary opinions and suggestions have been arrived at. Still, there has been much light thrown on the general question, and decided improvements made within the last few years. In a past volume of the Sporting Magazine, it is asked—"What is the best method of making double-barrelled guns, so that a correct aim may be taken from the centre of the barrels?" To which the following reply is given:—"If the barrels were placed parallel to each other, it would be but a small objection.
having the sight between them; but as guns are commonly made, the thickness between the bores of each, at the breech, is three-sixteenth of an inch, and at the muzzle one-sixteenth. Therefore, if the length of a pair of barrels was two feet six inches, which is the ordinary length, and the sight taken from the centre, and a ball was projected from one of them, it would make one-eighth of an inch declination from its true course in every two feet six inches it had to travel, which would make, in forty yards, a declination of six inches. From this cause, the right-hand barrel always shoots to the left, and vice versa. Now, to remedy this, suppose the thickness between the two barrels to be at the breech three-sixteenths of an inch, then let the space at the muzzle be the same; and where the barrels are thus laid together, and the sight placed between them, the ball would only make a declination of half an inch (the bore being five-eighths of an inch), being the distance between the centre of the barrel-bore and the exterior of the barrel's surface.” The method by which this error is attempted to be rectified, by filing away so much of the breech-surface as shall bring the calibers of the barrels into a more rectilinear direction, is considered nothing more than remedying one defect by creating another. The great object should be to effect the junction of the gun-barrels, in such a manner as to bring the centres of the calibres of the muzzles, and the centres of the calibres of the breeches, if not exactly equidistant, at least much more so than is commonly effected; the approximation being in general in the direct ratio to the length of the barrels.

The late Colonel Hawker treats this subject with some degree of indifference; and Mr. Blaine dissents from the line of argument pursued by Mr. Greener regarding it. “Much as we admire Mr. Greener’s usual line of argument,” says Mr. Blaine, “we regret that on this subject we disagree with him, also, when he says—’To make them (the barrels) uniform (i.e., lessen the convergence we complain of), it requires that they be reduced, or flattened, to allow the thick or heavy end to join closer.’ If this be not incurring a risk, we do not know what is; and we do hope that no respectable gun-maker will rectify his convergency in the barrels towards each other by any other means than firmly setting the centres of the muzzles rectilinearly with those of the breeches, by the agency of an intervening substance, as hard soldering in the centre, mettle-ribbing it above and below; and then, and then only, the silver sight will not be a guide to error.”

ELEVATION AND ELEVATED RIB.

What should be the elevation and the elevated rib of a gun, involve nice and abstruse questions as to the precise movements of bodies thrown out of projectiles generally. The line which a charge of shot takes when fired from a double gun, is called, in gunnery, the line of impulse. Whether it be rectilinear or curvilinear is still a point of dispute. But one thing is certain, that the shot is under the influence of the ordinary and the universal law of gravitation, which acts upon it so as to bring it within the universal law of having a tendency to fall to the ground. The distance to which its flight may be prolonged, depends on the excellence and make of the gun, the materials with which it may be loaded, and the various minute matters which constitute the fact, aim, &c., of the person using the instrument. A curvilinear direction of the shot is assumed, as a fact, by gun-makers; and their grand object is, to bring the shot to the mark aimed at by the use of mechanical means—such as straight stock, or an artificial elevation of the muzzle of the piece, in proportion to the length of the barrel. All these points certainly appertain more to the express business of the gunsmith; yet the sportsman should know something of them, as they bear directly upon practical results necessary to his own safety.

On the Elevated Rib, Colonel Hawker and Mr. Greener have written at some length. Their opinions are entitled to great weight, and they maintain that different lengths of barrel require a corresponding height of the rib; and that a greater height is required by a person accustomed to use a crooked stock, and vice versa. Both writers, likewise, maintain that the elevation of the rib commonly met with is not sufficient. The usual elevations do not deliver the shot, even at forty yards, with a usual charge of powder; and where the shot is of more than average size, there must be a great defalcation in the result. Mr. Greener says, that the experiment he has
made, shows that, in heavy charges of shot, the
drop is fully twelve inches in forty yards; but
that with less charges of shot, the line of flight
will be more direct.

The great advantage of the double-barrelled
gun over the single one is now generally ad-
mitted by all sportsmen; but there are still
some shooters to be found who prefer the latter.
This preference, however, depends, in almost all
cases, upon some accidental circumstance,
or individual fancy. The quantity of game to
be obtained, especially in the earlier parts of
the shooting season, is much more with a
double than with a single gun. The weight is
generally greater in the former than in the
latter; but habit and custom soon bring the
matter to an equality on this point.

On the calibre, or bore, the length and
weight of barrels, their killing range, their
recoil, the regularity of their effect, their force,
their liability to burst, much might be written;
for on all these several subjects there have
been, and still are, considerable differences of
opinion. It is unnecessary for us here to
enter into full details regarding them. They
are of more interest to the scientific maker
than to the sportsman, whose experience soon
teaches him as to what sort of weapon he finds
to be the best to enhance his pleasure or
amusement.

CALIBRE, OR BORE.

It is recommended by a high authority that
flint-guns should not be bored cylindrically
through, but that a little contraction, just
where the shot first moves, should be pre-
served. This suggestion has, for many years,
been pretty generally attended to by gun-
smiths. It is of importance that every pur-
chaser of a fowling-piece should ascertain, by
the gauge, the exact diameter of each portion
of the bore of the piece, that he may adapt
his wadding accordingly. The proper wadding
for such kind of relieved barrels is that which
has some considerable degree of firmness, with
a certain portion of elasticity. Beckworth's
wadding is of this kind. There are, however,
many barrels now made which are bored
cylindrically throughout; and it is affirmed, by
competent authorities, that such pieces shoot
remarkably well.

PERCussion Barrels.

These are commonly made heavier and
stronger than the barrels of the flint-gun. It
is now the practice to bore such barrels with a
little relief forward, which, Colonel Hawker
maintains, "has the effect of making the gun
shoot as close as it can do, compatible with
the quickness and strength required." The
increased weight of the percussion-barrel has,
however, been objected to by others, whose
opinion upon this subject is entitled to much
weight.

LENGTH AND WEIGHT OF BARRELS.

There has been a great innovation upon the
length of gun-barrels. It was long considered
to be an indisputable maxim, that the longer
the barrel, and the smaller the bore, the farther
a gun would kill. Now, however, the barrel is
considerably shortened, and with good results.
Here again, however, some sportsmen think an
error has been made in running into the oppo-
site extreme, and making them too short. Mr.
Robins, who seems to have paid great attention
to this matter, says, "that the sportsmen may
please themselves whether the length of their
barrels be from twenty-eight to forty inches;
but that if they either go above or below these
dimensions, they will find that the range of the
shot will begin to fail them." We would
say, that at present, the general opinion is in
favour of moderate length of barrel. Such
fowling-pieces are decidedly better adapted for
general purposes, more portable, and are freer
from many inconveniences attendant upon very
long guns. The Oakleigh Shooting Code gives
the following judgment on the matter:—"The
fowling-piece to be recommended for general
use is a double-barrelled detonator, weighing
about eight pounds; the barrels thirty or
thirty-two inches in length, sixteen gauge, and
made of twisted stubs. It is not sportsmanlike
to use double barrels of a greater calibre; nor
are longer barrels convenient, on account of
their weight, although additional length, not
carried to an extreme, or a larger calibre, may
probably render them more effective, in so far
as they will sustain a heavier charge. Single
barrels, for general use, may be thirty-four
inches long and fourteen gauge." The same
authority says, that "the barrels of the
grousing gun should be thirty-two inches long, and sixteen gauge; a single barrel for grouse-shooting should be thirty-six inches long, and fourteen or fifteen gauge. If selected for partridge-shooting only, the barrels should be thirty inches long, and sixteen gauge; or a single barrel thirty-four inches, and fourteen or fifteen gauge. If selected for cover-shooting only, the barrels should be only twenty-eight inches, by sixteen gauge; or single barrels thirty-two inches, and fifteen gauge."

**EXTENT OF RANGE.**

On this subject there is much variety of opinion; and that, too, amongst sportsmen of great experience, and thoroughly practical in the knowledge they possess. It is, therefore, impossible for us to decide a problem so much involved in difficulty. Two points should be obtained by all guns—to keep the shot from being scattered, and to give them the greatest amount of force or propulsion. These are the ends desired; but the means best calculated to obtain these, have given rise to numerous and conflicting theories and expedients. Some think that the muzzle of the gun should be a little widened; some advise the mixing of oil and water with the shot; and some place all their faith in well-regulated charges of powder. There are advantages attending all these methods, but not to the extent which their respective advocates maintain. The distance of range that most fowling-pieces will carry, on ordinary occasions, is forty yards. This is considered a fair average shot. Some, of course, will kill considerably further, and some not so far. Mr. Daniel, in his *Rural Sports*, observes, that "there are few things in which persons have more faith than in the excellence of their own gun; the distance at which it kills, and the closeness with which it throws the shot, are inconceivable. Striking a card, with ten or twenty grains of shot, at sixty yards, is nothing uncommon; and the merits of the shooter and his gun bid defiance to rivalry. It is no easy matter to change the opinions of such persons respecting their guns; but when a gun is said to be sure at threescore or fourscore yards, the measure may be safely asserted to be of the proprietor's own making. The circumstance of knocking down a partridge at eighty yards may happen; but very few barrels of those that are generally used for the shooting of birds on wing, will throw shot compact enough to be certain of killing at fifty yards; one or two grains of shot are not sufficient so to strike a bird as to bring it to the ground; for when stript of its feathers, a partridge is a much smaller object than it appears to be, and possesses many parts not vital. Those who expect light barrels, of three feet or three feet six inches, to throw shot close enough to insure a small object at fifty or sixty yards, will be exceedingly mistaken."

From general observation, it will be found that from twenty-five to thirty yards is about the average distance at which nine out of ten of all birds are killed. Many are wounded nay, even killed dead, at forty, fifty, and even sixty; but it is clear that these are but solitary cases, and are chiefly the effects of mere chance, or random shots.

**THE RECOIL OF A GUN.**

All guns have a greater or less recoil, proceeding from the mechanical principle, that all force begets force. Inequalities of their bore, contractions at their breeches, the too great quantities of powder or shot used, dampness and confined air, &c., &c., are the commonly prevailing causes of guns recoiling unpleasantly. Even the material and peculiar construction of the weapon lend their aid to produce the same effect.

**BURSTING OF GUN-BARRELS.**

We sometimes hear of the bursting of barrels which have been made by the first manufacturers in the kingdom. These accidents often depend upon causes hidden from observation, and, consequently, little known. They are, however, sometimes lamentable in their consequences, and demand the constant attention of the sportsman to be upon his guard against the occurrence. The selfsame causes which produce great recoils in a gun, may make it burst. The recoil and the bursting differ only in degree and intensity. Overloading a piece; immersing its muzzle under water, and firing it off; leaving a ramrod in the barrel, and firing it off with it, and many other acts may produce this effect. There is no recipe to be given that will supersede attention and care.
to the various matters which are fully stated to the sportsman in most works specially devoted to the gun.

THE LOCK.

The manufacture of this part of the fowling-piece has been carried to great perfection in England, especially within the last thirty years; notwithstanding that the first spring-locks were made at Nuremberg, in Germany, about the middle of the sixteenth century. The inventor, and general manufacturer of them, is said to have realised an independent fortune from the success with which his invention was received. By degrees, he succeeded in making many alterations and improvements on his first model; and his son, who carried on the business for nearly half a century after his death, introduced still more decided improvements in its construction.

The Flint-lock must now be spoken of as an instrument of the past, as, except in the most primitive districts of countries, it is scarcely to be found. The invention of the Percussion-lock has completely supplanted its use. It is, perhaps, a somewhat curious fact in the history of a sporting and a military weapon, that this one was the invention of a reverend gentleman, of the name of Forsyth. His patent expired in 1821, since which it has been very much improved.

BREECH-LOADERS.

Until recently most guns were loaded from the muzzle, whereas now they are loaded at the breech. Of the different applications of scientific skill to the manufacture of this weapon, the following may be viewed as the principal.

1. Those in which a cartridge, with the powder and ball enclosed in some thin envelope, is pushed into the chamber of the barrel from behind, which is then closed, and the powder is exploded by a stream of gas from a cap perforating the walls of its case. 2. Those in which a thicker case of paper and metal, or metal alone, containing within it some substance explosive on percussion or friction, is filled with powder and ball, and pushed into the chamber from behind. This is then closed, and the explosion effected by a needle or pin being driven into the case, which is then withdrawn, leaving the chamber clear of all wads and other remnants of the discharge, except the fouling of the barrel caused by the residuum from the explosion of the powder. 3. Those in which the barrel is divided in front of the charge, which is placed in the hindmost portion of it, in the same order as if the loading was from the muzzle; after which the chamber is replaced. Here, if powder and ball are carefully inserted, good shooting can be effected; but then the loading is quite as slow as in the muzzle-loader; while, if a cartridge is used, some parts of the envelope are left behind, and miss-fires, accidental explosions in loading, and bad shooting, are the frequent result.

Perfect, however, as these instruments may be considered in a scientific point of view, recent events in the war between Austria on the one side, and Prussia and Italy on the other, have effectually proved that, on the continent at least, there is another, possessed of certain properties, which, when used with skill, may be said to have already overturned all previous theories respecting the arbitration of arms in the battle-field. We allude to the Prussian Needle-gun. The effect of this weapon, in deciding the late conflict between those powers, might, when judged by statistics, be considered as almost miraculous. In the summer of 1866, Prussia, long in a state of high military preparation, waged war with Austria, and, in a very brief period of time, succeeded in establishing her supremacy in Germany. In the conflict Austria is estimated to have lost 120,000 men in prisoners, wounded, and killed—90,000 against Prussia, and 30,000 against Italy. The Prussian loss, during the war of 1866, was officially reported at 19,875 men, exclusive of those who died of their wounds and from disease; the number killed in battle being under 4,000. The military and newspaper correspondents who visited the fatal field of Sadowa, were unanimous in declaring the vast excess of killed and wounded on the side of Austria. At the final exchange of prisoners, in August, there were released, by Prussia, 523 Austrian officers, and 35,036 rank and file, exclusive of about 13,000 Austrian prisoners in the hospitals, and not fit for removal. Austria gave up to Prussia seven Prussian officers, and 450 non-
commissioned officers and men; about 120 prisoners, from their wounds, unfit to be removed, remained in Austria. These returns, which are, no doubt, approximately correct, speak volumes as to the science and art of war. They have been everywhere understood; and the military monarchies throughout Europe are reorganising their armies, and arming them with the needle-gun, or some equally or more effective weapon. Prussia, as the leader of 40,000,000 of Germans, having a seaboard on the Baltic, is a very different power from the Prussia of even ten years back. What the probable effect may be in Europe it is not necessary now to consider. Still, there can be no doubt that it will be (if it is not now the time) very necessary for every European state to adopt the best means which may be in its power to place itself in an attitude of defence. The rapidity with which scientific skill, in the art of war, is daily developing itself, proves this advice not to be mistimed; we therefore offer it from a consideration of its usefulness, as well as from the hope that it may rather prevent than promote the destruction of our species.

THE GUN-STOCK.

This is an important part of the fowling-piece. In fixing upon the length, bend, and cutting of the stock, there has been much nicety laid down for the guidance of gun-makers. Colonel Hawker maintains, that the framing of a stock of a gun should vary with the precise make of the man who has to use it. It should be fitted to the shooter, who should have his measure for its several parts as formally entered into the gunsmith’s books as a man has in a tailor’s for a suit of clothes. Some manufacturers have a machine, or stock gauge, by which they measure the outlines of their customers as regards their length of arm, neck, &c., so as to furnish each man with a gun-stock that will agree with his peculiar bodily conformation. This has something like common sense to recommend it. It has been justly observed, that there is full as much skill required to fit a man with a gun-stock, in agreement with his make, as there is to fit a dandy with a complete suit of clothes.

Besides the parts which we have described, there are others belonging to a gun, of which it is necessary for the sportsman to have some knowledge. It is not essential, however, to describe them with the same degree of fulness which we have given to the preceding portions.

OTHER PARTS OF A GUN.

Bolts.—Irons which enter the loops or eyes of the barrel to fasten it to the stock.

Bridge.—A polished piece of steel which caps the tumbler, and is secured by two screws. It likewise receives the scear-screw.

Butt of Stock.—The shouldered extremity of the stock.

Cap.—It covers the ramrod screw-cap, and is also used for the tip of the stock.

Casting off.—The outward inclination given to the butt-end of the gun being intended to incline the line of aim inwards.

Chain or Siveed.—A small catch suspended from the neck of the tumbler, to receive the extremity of the mainspring.

Chamber.—The central cavity within the breech, to receive the powder. The ante-chamber is the small one which connects these with the touch-hole.

Cock.—In the flint-gun it holds in its jaws the flint; in the percussion-gun it is equally a cock, but there it is more frequently called the striker.

Cock-screw.—The screw that brings the jaws of the cock together.

Cup.—The cavity seen at the top of many of the improved breechings.

Escutcheons.—Ornamental pieces of silver to prevent the bolts from defacing the stock when the turnscrew and pinners are applied. Escutcheons are likewise used on other parts to receive initials, crests, shields, &c.

False Breech.—This receives the butt or nose of the breech when the barrel is fastened into the stock.

Elevated Breech or Rib.—This is a top piece much elevated, first used by Mr. Joseph Manton.

Fence.—The part between the cock and the pan which receives the solid stock.

Guard.—The bow which defends the trigger.

Hammer-spring.—That on which the hammer moves.

Hammer-bridge.—The part in which the tail of the hammer works.

Heel-plate.—The plate with which the heel of the stock is tipped.

Jaws.—The lips of the cock which holds the flint.

Lock-plate.—This supports the principal works of the lock.

Main-spring.—The spring by which the tumbler is worked with the cock.

Nipple or Pivot.—The small iron pillar that receives the copper cap of the detonator.

Pipes.—Tubes to receive the ramrod.

Rib.—A central piece of iron which unites the barrels and receives the ramrod.

Scroll-guard.—An extension of the guard which receives the right-hand in fixing the gun.
Sear.—That which catches the tumbler for half or whole-cock, and being pushed up by the trigger.

Sear-spring.—The spring which holds the sear in the notches of the tumbler at either half or whole-cock.

Side-nail.—A screw which fastens on the lock.

Sight.—A patch of metal, usually of silver, placed near the gun-barrel, to direct the aim.

Spring-crank.—A useful instrument, to assist both in taking to pieces and putting together the parts of the lock.

Till.—The neck, shoulder, or arch of the hammer.

Top-piece.—This opposes the rib which unites the lower arches of the barrel. When it is very prominent behind, it is called the elevated rib.

Trigger-plate.—The trigger works in it.

Trigger-springs.—Are small springs found in some highly-finished locks, and are intended to keep the triggers close to the screw.

Tumbler.—The movable centre-piece of a lock which falls with, and is subservient to, the cock.

Tumbler-screw.—This fastens on the cock.

Vent-hole.—Sometimes there are two or three tent-holes, which are intended to let out the gas in a detonator, and thus to lessen the recoil.

Worm.—The screw at the end of the ramrod.

Every sportsman should look to his own gun, as it is he who is to use it, and as it is to him that an accident is most likely to happen, should it not be in proper order for shooting.

There are few who have had an extensive acquaintance with guns, who are not aware of the carelessness and negligence of many servants in getting a gun into proper order, even for their master’s use.

All fowling-guns require to be taken completely to pieces at stated times, to be thoroughly examined, and every part of them put into such a state as to render them fit for use at any moment. Twice a year is considered not too often to look into their every crevice, taking most especial care to overlook nothing—not even the smallest screw or spring. To do this work well, the sportsman should supply himself with a bench, vice, turn-screws of various dimensions, from an eighth to half an inch; the latter size being required for the cork-screw, breech-screws, and for raising the bolts which bind the barrel to the stock. The spring-crank is a necessary article in this matter of overhauling the entire fabric of a fowling-piece. When a sportsman does not reside in the immediate vicinity of an experienced gunsmith, he ought to have by him duplicates of all the necessary parts of his instrument, that he may be able to supply himself, on all contingencies, with what may be requisite to keep it in working order.

Cleansing of guns.

The following instructions, altered from the Encyclopedia of Rural Sports, are well worth remembering:

In taking off the main-spring, let the lock be placed on full-cock; then cramp the main-spring; when this is effected, let down the cock, and the main-spring will fall off. When the lock has again to be fitted in, let the cock be left down; then look the end of the main-spring on the swivel or chain; move it up, and place it into a position on the lock-plate. When this is done, unscrew the cramp, and the lock is once more fit for use. When the hammer has to be taken off, first shut it down carefully; cramp the spring until, by shaking the lock, the hammer is heard to rattle. Stopping here, take out the screw behind, and the hammer will fall off. The replacing of it only requires the putting it in its former situation, turning the screw, and setting the spring at liberty. If it be requisite to take the hammer-spring out, the hammer must first be released, and the mainspring likewise, in order to get at the screw behind. The hammer-spring must then be cramped, till it is taken out and put on again to receive the hammer.

To take to pieces all the small springs of the lock, requires considerable care. The several screws must be kept distinct; and any little mistake in this matter may produce serious results.

When the main-spring is taken off, unscrew and take out the sear, by half cocking the lock. Clasp the fore part of the lock firmly; at the same time press the thumb against the back part of the cock, directing it forward; while the sear, and sear-spring, being now pressed together by the fore-finger and thumb, will readily enable the operator to take out the sear-screw. When this is done, undo the two screws, take off the bridge, and then unscrew and take out the sear-spring. The cock must next be unscrewed, which will readily separate from the tumbler, if it be gently shaken or tapped. Take out the tumbler, and the lock is separated into its component parts.

When it has to be reconstructed, put the tumbler in its place, and screw on the cock; do the same thing with the sear-spring, and set on the bridge with the two upper screws. Put in the sear; but in order to open a clear passage for the screw of the sear, see that you again, as before, press the fore-finger and thumb on the sear and sear-spring, and likewise that you again push the cock forward as when in the act of taking off the sear. Unless there be a pressure of this kind, it is not easy to place the hole of the sear opposite the hole of the bridge; and without this is effected the sear-screw will not enter. Great trouble often ensues from want of attention to this and other trifling points. After this, the cock must be let down to admit of putting on the main-spring; and then the process is finished.

In a detonating gun there is not near the same amount of trouble in dismembering the fowling-piece. The pivot, or nipple, should be now and then removed, and carefully examined, that the
first approaches of corrosion may be taken off before any injury is inflicted. When a gun is purchased, it ought to be provided with spare pivots, all mathematically adjusted to the barrel. It is likewise a good practice to put a little olive-oil, with a camel's-hair pencil, on the pivot mail, or centre of the tumbler, on which almost all the works of both flint and percussion-guns move. The same may be applied, with advantage, to the lock-plate under the works. In flint-guns, a little oil under the hammer is likewise useful, Mr. Lankester, in his printed directions given to gentlemen who buy percussion guns, offers the following directions:—

"Always clean those parts of the barrels and locks that the detonating powder acts upon, with a wet rag; then rub them dry, and leave them in oil to prevent rust. The pegs should not be taken out too often. Before you take out the barrels, bring the locks to half-cock. The locks do not require to be taken off every time the gun is used; once a fortnight is quite sufficient. Put a little fine oil to the parts where there is friction; but if the gun has been used on a wet day, the locks should be taken off to be cleaned, and oiled immediately." When, by accident or neglect, a lock becomes completely rusty, both within and without, it ought to be plunged into warm water, and well scrubbed with a hard brush, fine sand, emery powder, or levigated glass. The rust will, by this means, be effectually removed, and will not injure the gun, providing it is but a recent accumulation of rust; but if it is of long standing, it may have eaten into the core of the metal, and produced vital injury.

Most men have peculiar methods of their own for keeping their fowling-pieces clean; and though all employ the leading, or primary elements of cleanliness, yet they differ as to their precise application. On a point so apparently simple, it is astonishing to find so many opposite plans, and many of them enforced with a dogmatism and obstinacy far beyond what one would imagine the importance of the subject warrants. The following, among many methods, is chosen, because it has been found always to answer the desired end:—

Provide some boiling water and an empty pail; detach the barrel from the stock, and with a clear-ing-rod furnished with tow, begin to pour the hot water down each barrel. Scour it well with the clearing-rod, and discharge the barrel of the foul water. Pour hot water into it a second time, and wipe out the barrels with fresh tow, until they are completely dry, both without and within. Should there be any moisture lurking within the screw-joints of the breech and touch-hole, it is a good plan to let down an iron plug, of red-heat, which, being moved up and down the barrel or barrels for half a minute, will effectually absorb every particle of moisture or damp. All this should be done with the sportsman's own hand; and not, if it can be avoided, left to another person to do. There is an old maxim which applies to gun-preserving very forcibly;—"What a man wishes to have well done, he should do himself."

Mr. Lankester's directions run thus:—

Place the breech ends of the barrels in a bucket in which there is cold water, about three inches deep; then, after wetting the sponge, cloth, or tow, introduce the rod into the barrels, and work it well; next apply the wire-brush attached to the clearing-rod with some clean hot water, which will take out all the lead in the operation. This should be invariably attended to, as it is well known that washing only will not remove the lead. Wipe the rod and the outside of the barrels dry, and set the latter upright, muzzle downwards, for two minutes, to drain, after which rub them out perfectly dry. Wipe the barrels out clean, then pass an oiled rag down the inside, and rub over the outside; leave them a little oily, which will prevent rust. The use of cloth is preferred, as not subjecting gentlemen to the serious accidents that have happened from leaving tow in the chamber. But, brass being in its nature softer than iron, allows of the brush being used without the possibility of injury to the barrels.

How often a gun should be cleaned must depend upon many circumstances, as there is a wonderful difference of guns in accumulating dirt. This arises, perhaps, from their different degrees of internal finish. Then, again, some kinds are foul with powder more than others; and small shot fouls them more readily than large. Waddings, too, have an effect; some kinds keeping the gun comparatively clean much longer than other kinds. It is commonly maintained by practical shooters, that a barrel should be cleaned after the firing of twenty shots. But there can be no invariable rule laid down for this. A man who is careful, who understands what a gun is, and who knows the peculiarities of the one he is in the habit of daily using, cannot err very far from the right path in this matter. It is always safe to be over-anxious rather than otherwise on a point of such great importance.

To remove rust from the inside of the barrel, some sportsmen recommend an ashen rod, turned a few inches longer than the barrel, and so nearly of the size of the bore, as to allow of the following process:—Let the ends of the rod be cut lengthwise so as to make a slit of six inches long, into which slit enter as much of fine emery paper as will completely fill up the bore of the barrel, taking care, in folding the paper tightly round the wood, that the emery surface is outward. Force it into the barrel by screwing it downwards from the top to the bottom; and repeat the process until the barrel is as clean and as polished as when it left the maker's hands. No sand or coarse stuff of any kind should be used. It is of great moment that every sportsman, when he comes home, or goes into any house whatever, should keep a watchful eye on his fowling-piece. He ought always to displace the cap, and throw out the priming. But even this does not always secure an immunity from fatal accidents. A few stray grains of powder may still be productive of an explosion. It is therefore a wise plan, when a shooter arrives at a door, to remove the cap, if a percussion-gun; or if flirt, throw out the priming, let down the spring of the lock, draw the ramrod, and dropping down the barrel, put the gun away into a closet, or otherwise suspend it out of ordinary reach. Too much care cannot be exercised in a matter of this kind. How often have we heard
of families having been thrown into the utmost state of grief by a son or a daughter being unintentionally shot in a moment of playfulness, by some other minor member of the family. How often have we read of accidents of this kind, and sympathised with the living as they mourned over the sudden deprivation which had fallen upon them. When we reflect on these sad calamities, it makes us treat of every sportsman or shooter, never to carry a loaded gun into the house, but to fire it off in the air, even before he has arrived at the close neighbourhood of his own dwelling. Mr. Blaine objects to this, partly on the score of economy—an objection which appears to us alike mean and frivolous.

POWDER AND SHOT.

There is no discovery which effected a greater revolution in the art of war than that of gunpowder; for when taken in connection with the weapon by which it is used, it may be considered as the most effective decider of conflicts that possibly could be invented. Both on the battle plain, and in the sporting field, it has taken the place of the more simple construction of the bow and arrow, which, however annoying to an enemy in the hands of a practised archer, or however deadly in those of an Indian sportsman, bears no comparison, in the certainty of its effects, to the modern gun, loaded with powder and ball, or shot. The origin of this explosive substance has given rise to long discussions, and great diversity of opinion, among philosophers and antiquaries. Some have given it a very ancient date, while others carry its discovery down to comparatively recent times. Grose quotes a passage from Grey's Gunner, published in 1731; in which it is said that, "In the life of Apollonius Tyanaeus, written by Philostratus, about 1,500 years ago, there is the following passage concerning the people of India, called Oxydracae: 'These wise men dwelt between the rivers Hyphasis and Ganges. Their country Alexander the Great never entered; deterred, not by fear of the inhabitants, but, as I suppose, by religious considerations; for, had he passed the Hyphasis, he might doubtless have made himself master of the country all around them; but their cities he could never have taken, though he had led a thousand men as brave as Achilles, or three thousand such as Ajax, to the assault; for they came not into the field to fight those who attack them; but these holy men, beloved by the gods, overthrew their enemies with tempests and thunderbolts, hurled upon them from above.'" In Norton's Gunner (1664), it is said—"That the invention and use, as well of ordnance as gunpowder, was, in the eighty-fifth year of our Lord, made known and practised in the great and ingenious kingdom of China; and that in the maritimo provinces thereof there yet remain certain pieces of ordnance, both of iron and brass, with the memory of their years of founding engraved upon them, and the arms of King Witney, who, ho saith, was the inventor." In the works of Roger Bacon, written at Oxford, in 1270, the ingredients which constitute gunpowder are expressly named, with the characteristics which mark it when it is exploded.

On the other side of the question it is maintained, that the merit of the invention belongs to Barthold Schwartz, a German monk. It is affirmed, that he mixed together nitre, sulphur, and charcoal, for some medicinal purpose, and a spark falling accidentally upon the mixture, it exploded. The reader will find the subject discussed at considerable length in the works of Friar Bacon, Polydore Virgil, Baptista Porta, Spondanus, Bishop Watson, and others.

It is well known that gunpowder consists of a mixture of saltpetre, sulphur, and charcoal, in such proportions as to render it capable of explosion on the slightest application of fire. It has, however, a great tendency to absorb moisture; and should the nitre be adulterated with salt, as it sometimes is, this tendency is immensely increased. An experiment made before the Royal Society proved this. A quantity of gunpowder was taken out of a barrel, and dried with a heat equal to that in which water boils. A piece of ordnance was charged with a certain weight of this dried powder, and the distance to which it threw a ball was marked. The same piece was charged with an equal weight of the same kind of powder, taken out of the same barrel, but not dried, and it threw an equal ball only to one half the distance. This effect of moisture is so sensible, that some officers have affirmed, that they have seen masses of gunpowder, which were good in the morning, but which became (as supposed by attracting the
humidity of the atmosphere) good for nothing in the evening. This recalls to mind the remark of Cromwell, when about to engage with the cavaliers—"Praise the Lord, but keep your powder dry." He seems to have been aware of the absorption of moisture inherent in the material he was about to use with considerable effect against his enemies.

The chemical properties of gunpowder are thus described by the celebrated Dr. Ure:—

"This explosive substance consists of an intimate mixture, in determined proportions, of saltpetre, charcoal, and sulphur; and is better in proportion (everything else being equal) to the quality of these ingredients. The nitre, in particular, should be perfectly refined by successive crystallisations, and finally freed from adhered water, by proper drying, or by fusion in iron pots at a regulated heat. Nothing can surpass, in these respects, the nitre prepared in the government powder-mills at Waltham Abbey. It is tested by adding to its solution, in distilled water, nitrate of silver, with which it occasions no perceptible opalescence. The sulphur ought, also, to be of the finest quality, and purified by skimming, or even pulverised, if at all necessary. The charcoal should be newly made; it should burn without leaving any sensible residuum; be dry, sonorous, light, and easily pulverised. The charcoal for gunpowder is made either of alder, willow, or dogwood, the latter being preferred, which is cut into lengths, and ignited in iron cylinders, the wood before charring being carefully stripped of its bark. The three ingredients being thus prepared, are ready for manufacturing into gunpowder. They are first separately ground to a fine powder, which is passed through proper sieves or bolting machines; secondly, they are mixed together in certain proportions, but which do not seem to be definitely determined, for they differ in different establishments of great respectability, as is shown in the following table:

Thirdly, the composition is then sent to the gunpowder-mill, which consists of two edges of a calcareous nature, turning by means of a shaft on a bedstone of the same nature, which gives no sparks, as sandstones would be apt to do. On this bedstone the composition is spread, and moistened with as small a quantity of water as will, in conjunction with the weight of the revolving stones, bring it into a proper body of cake, but not of paste. When the cake has been thoroughly incorporated, it is sent to the corning-house, where a separate mill is employed to form the cake into grains of corn. Fourthly: here it is first pressed into a hard firm mass, then broken into small lumps; after which the grinding is executed by placing these lumps in sieves, on each of which is laid a disc of lignum vitae. The sieves are made of parchment skins perforated with numerous round holes. Several such sieves are fixed in a frame, which, by proper machinery, has such a motion given to it as to make the lignum vitae runner in each sieve move round with considerable velocity, so as to break the lumps of the cake, and force the substance through the sieves, forming grains of several sizes. The granular particles are afterwards separated from the finer dust by proper sieves and reels. Fifthly: the corned powder is next hardened, and the rougher edges taken off by being revolved in a close reel or cask, turning rapidly on its axis. This vessel somewhat resembles a barrel churn; it should be only half full at each operation, and has frequently square bars inside, parallel to its axis, to aid the polish by the attrition. Sixthly: the gunpowder is now dried, which is done generally by a steam heat, or by transmitting a body of air, slightly heated in another chamber over canvas shelves, covered with the damp gunpowder."

We have taken this extract from the Chemical Dictionary, where, in an article on gunpowder, the reader will find much interesting information on the rationale of the action of gunpowder, in regard to both its detonating and combustible powers.

As to the relative size of the grains of powder to be used in sporting amusements, there is a considerable diversity of opinion; some affirming one size to be the best, and some another. This question cannot be definitely settled without taking into account the nature of our guns, the purposes for which they are made,
the kind of game to be shot, and many other circumstances, all, more or less, calculated to modify the judgment, and to cause it to preponderate either to the one side or the other. Mr. Greenway maintains that, if we obtain powder of fine grain, and powder composed of the same ingredients, large-grained, the latter will be stronger than the former. He tells us he has made many experiments both by rifle and musket, and the coarser grain always pre-dominated over the smaller. These results have been denied by other respectable sporting authorities. Colonel Hawker says, the best powder for copper-cap guns is the fine cylinder of Curtis and Hervey, the large-grained powder being liable to miss fire. But the same authority qualifies his opinion by afterwards stating—"I have invariably observed that small-grained powder fails to answer in large guns; particularly on salt water, and in damp weather. It always shoots weak beyond fifty or sixty yards, and is very liable to hang fire. If a punt-gun is loaded with fine powder, and brought in at night, the chances are that it would hang fire in the morning. But with coarse cannon powder, I have known a gun that has been loaded for a fortnight go off as well as possible, by merely being probed, and fresh primed."

How far the glazing of powder is advantageous, is likewise a disputed question. Many sportsmen affirm, that they fail to detect any difference between the glazed and the unglazed kinds. Colonel Hawker prefers the unglazed; but he assigns no reason for this preference: the whole question probably resolves itself into a mere matter of fancy or taste.

On the ratio of force with which different kinds of powder act on resisting bodies, much curious and valuable information has been communicated to the world of late years. The substance of such information we shall attempt to condense into as brief a space as is compatible with clearness.

As Mr. Babbage, in his Economy of Machinery, favours us with remarks pertinent to this subject, we are glad to give the reader the benefit of them, as his work is not likely to be widely diffused amongst those who follow the gun as an amusement.

A gun loaded with ball, does not kick so severely as one loaded with shot; and among the different sorts of shot, that which is the smallest, causes the greatest recoil against the shoulder. A gun loaded with a quantity of sand, equal in weight to a charge of shot, is said to kick still more. If, in loading, a space be left between the wadding and the charge, the gun either recoils violently or bursts. If the muzzle of a gun has accidentally been stuck into the ground, so as to be stopped up with clay, or even with snow, or if it be fired with its muzzle plunged into water, it will, in all probability, burst. The cause of these apparently contradictory results is, that every force requires time to produce its effects; and if the time requisite for the elastic vapour within to force out the sides of the barrel, is less than that in which the condensation of the air, near the wadding, is conveyed in sufficient force to drive the impediment from the muzzle, then the barrel must burst. It occasionally happens that these two forces are so equally balanced, that the barrel only swells, the obstacle giving way before the piece actually bursts. This explanation will appear more obvious if we trace, step by step, the circumstances which arise on discharging a gun loaded with powder, confined by a cylindrical piece of wadding, and having its muzzle filled with clay, or some other substance, offering a moderate degree of resistance. In such a case, the first effect of the explosion is to produce an enormous pressure on everything confining it, and to advance the wadding through a very small space. Here let us consider it as at rest for a moment, and examine its condition. The portion of air in immediate contact with the wadding is condensed; and if the wadding were to remain at rest, the air, throughout the tube, would soon acquire a uniform density. But this would require a small interval of time, for the condensation next the wadding would travel with the velocity of sound to the other end, from whence, being reflected back, a series of waves would be generated, which, aided by the friction of the tube, would ultimately destroy the motion. But, until the first wave reaches the impediment at the muzzle, the air can exert no pressure against it. Now, if the velocity communicated to the wadding is very much greater than that of sound, the conden-
sation of the air, immediately in advance of it, may be very great before the resistance transmitted to the muzzle is at all considerable; in which case the mutual repulsion of the particles of the air so compressed will offer an absolute barrier to the advance of the wadding. If this explanation be correct, additional recoil, when a gun is loaded with small shot or sand, may arise, in some measure, from the condensation of the air contained between their particles, but chiefly from the velocity communicated by the explosion to those particles of the substance in immediate contact with the powder, being greater than that with which a wave can be transmitted through them. It otherwise affords a reason for the success usually attending the blasting of rocks. That the destruction of the gun-barrel does not arise from the property possessed by fluids, and in some measure also by sand and small shot, of pressing equally in all directions, and thus exciting a force against a large portion of the interior surface, seems to be proved by a circumstance mentioned by La Vaillant and other travellers—that for the purpose of taking birds without injuring their plumage, they filled the barrel of their fowling-pieces with water, instead of loading them with a charge of shot. The same reasoning explains a curious phenomenon which occurs in firing a still more powerfully explosive substance. If we put a small quantity of fulminating silver upon the face of an anvil, and strike it slightly with a hammer, it explodes; but, instead of breaking either the hammer or the anvil, it is found that that part of the face of each in contact with the fulminating silver is damaged. In this case, the velocity communicated by the elastic matter disengaged may be greater than the velocity of a wave traversing steel; so that the particles at the surface are driven, by the explosion, so near to those next adjacent, that when the compelled force is removed, the repulsion of the particles within the mass, drives back those nearer the surface with such force, that they pass beyond the limits of attraction, and are separated in the shape of powder. The success of the experiment of firing a tallow candle through a deal board would be explained in the same manner, by supposing the velocity of a wave propagated through deal, to be greater than that of a wave passing through tallow.

Experiments to try the strength of their powder have often been made by sportsmen; but the excellence of powder is generally determined by the quality of the nitre of which it is partly composed. This ingredient, as already observed, having a strong tendency to absorb moisture, requires that it should be kept in its purest state for the manufacture of powder. When mixed with salt its quality is greatly deteriorated; and, in all good powder, it is well known that its expansive force is in proportion to the velocity with which the communication flies through the whole mass. It is this principle which renders it so well adapted to sporting purposes. No bird or quadruped can fly or run with such rapidity as to get beyond the quickness of its action, provided either be within range. It is this quickness of ignition which gives, in the field, such an advantage to powder over every other substance.

The method of testing the quality of powder, instituted and pursued by the Board of Ordnance, is as follows:—The triers first take out of the several barrels of gunpowder a measure-full, of about the size of a thimble, which is spread upon a sheet of fine writing-paper, and then fired. If the inflammation be very rapid, the smoke rises perpendicularly; and if the paper be neither burned nor spotted, it is then judged to be good powder. Then two drachms of the same powder are exactly weighed and put into an epreuvette, which, if it raise a weight of twenty-four pounds to the height of three inches and a-half, is received into the government magazine as proved.

This powder-trier just mentioned, called an epreuvette, may be seen in many gunsmiths’ shops. It does not, however, test the power of the explosive substance with very great nicety, but it is, nevertheless, a useful instrument; and it furnishes the sportsman with a general idea on the subject, which enables him, in many cases, to detect a bad and impure commodity.

Percussion gunpowders have effected great changes in sporting art, and the science of projectiles generally. Detonating substances are but of modern date.

The discovery of fulminating mercury, which forms the percussion powder now in use, is attributed to Mr. Howard; the full particulars
of which are detailed in the Philosophical Transactions. It is thus manufactured, as given by Dr. Ure:—A hundred grains of mercury are to be dissolved by heat in an ounce and a-half, by measure, of nitric acid. This solution being poured cold into two ounces, by measure, of alcohol in a glass vessel, heat is to be applied till effervescence is excited. A white vapour undulates on the surface, and a powder is gradually precipitated, which is to be immediately collected on a filter, well washed, and cautiously dried with a very moderate heat. The powder detonates loudly by gentle heat, or slight friction. The fulminating mercury should be moistened with about thirty per cent. of water, then triturated on a marble slab with water, by means of a wooden muller, add six parts of gunpowder, and grind the two together.” Dr. Ure observes, that some of the best match-powders made in France do not, altogether, weigh more than two-thirds of a grain.

THE DIFFERENT KINDS AND SIZES OF SHOT.

In reference to this part of our subject, there is some degree of confusion, on account of the sizes and numbers not coinciding in all the manufactories where shot is made. This circumstance tends to mislead sportsmen, and very often to give rise to false theories upon the force and resistance of projectile instruments generally. An ounce of No. 7 shot taken from the manufactary of Messrs. Walker and Parker, contains 341 pellets; and the same weight from Mr. Beaumont’s, 308. Add to this, that in some places the usual numbers are reversed. The following is a list of the shot in Messrs. Walker’s firm, with letterings, number marks, and the number of pellets in an ounce:

<table>

As to what is the best kind of shot to be used for sporting purposes there are different opinions. Colonel Hawker maintains that, for ordinary purposes of game shooting, No. 7 is the best kind that can be used. It lies closer and more compact to the barrel, he says with reason, than any other. Other sportsmen, again, think the Nos. 3 and 4 are to be preferred to any other sizes for common every-day work in the prime of the shooting season. Captain Williamson pleads for No. 9, and General Hanger for No. 2. Another great authority informs us, that in the first month of partridge shooting, shot No. 5 should be used, because, at this time, the birds spring at hand, and we seldom fire at more than the distance of forty yards. If a shooter takes a fair aim, he can scarcely fail to do some mischief by such a circle or disc of shots. Hares likewise, at this period, sit closer, and being but thinly covered with fur, may easily be killed with this size at thirty or thirty-five paces. In snipe and quail shooting this shot is most to be preferred. When October advances, the birds are stronger on the wing, and then No. 3 will be found more suitable. This shot, it is maintained, possesses a proper medium between that which is too large and that which is too small, and will kill a partridge at fifty yards with certainty. It is adapted for all kinds of game. It is contended that distant objects may be killed with large shot; but this consideration cannot bear upon the question...
which involves the destruction of a number of birds within a comparatively short range, and where the shots are numerous. Having given these statements, we shall leave it to the reader's own experience to decide which is best. To go on alluding to the various and conflicting opinions on the subject, would only perplex instead of enlighten his judgment on the point of dispute.

Mixed Shot is used by some who have spoken highly of it. But here we have controversy again. Some sportsmen have even ridiculed the idea of such a thing in no measured language; but Mr. Daniel informs us that his uncle, "who was allowed to be one of the best marksmen of his time, after minute trials and mature experience, preferred it to every other kind." "Gamekeepers," he continues, "frequently use it; and many persons in this class are in the habit of trying and knowing what shot will do most execution; and are men who generally draw their reflections and remarks from actual and successful experiment. It is true they do not write a treatise upon the subject; yet, from killing game and animals at all times, are, at least, as likely to form a just decision as gentlemen who, for the most part, only use their guns three months at the commencement of the season. The numbers of shot proper to mix together, for general use, are 4, 5, 6, and 7." There is also a difference of opinion regarding the patent shot cartridges of Ely; and as it is impossible to reconcile opinions so at variance with each other, we will let the subject rest.

CAPS AND CAP-CHARGERS.

Copper Caps and Cap-Chargers are now almost in universal use. In the purchase of copper caps it is prudent to make a trial of one or two taken promiscuously from the mass, to prevent disappointment. All foreign caps should be purchased with care; some are excellent; others wretchedly bad, and even dangerous. All should be cupped to the exact gauge of the diameter of the nipple. If they are too small they will not explode; and, if too large, the cap of the second nipple will be apt to fly off when the other is fired.

Mr. Greener treats of iron percussion-caps, in the New Sporting Magazine (No. 65). He recommends them on the ground of the tendency of the copper to become injured, when exposed to damp, to such a degree as to be converted into a paste incapable of ignition. He maintains that when powder is flashed, or exploded around the nipple of a gun, the residue left, attracts moisture instantaneously. To remedy this, the use of iron caps is enforced. "They are much easier to explode; they detach no broken particles to wound the shooter, nor even expand so much as to stick in the head of the striker. They do not stain the hands, and they might be made cheaper."

Cap-chargers are of French invention. There are several varieties of them; some long, and some round; but, we believe, the latter stand highest in public estimation.

WADDING.

Gun-waddings have a considerable influence on the sports of the shooter. However good a gun may be, and however excellent all its principal appendages—powder, shot, &c.—still they may all be rendered nugatory if the proper wadding be not used. But we find in all questions relative to shooting, that in proportion to their real intrinsic importance, so likewise is there doubt and uncertainty in settling them. Some recommend card wadding, some hat wadding, and some pasteboard. But, whatever material is chosen for this purpose, it should be strictly regulated according to the bore of the barrel. Wadding punches are often made for distinct barrels, when more guns than one are used. The range and delivery of the shot are greatly influenced by the wadding. The common opinions on the matter are, that all waddings should be quite close to the barrel, but not rammed too hard. The material should be rather soft than otherwise, and yielding to a certain extent, but still of sufficient consistency to carry the shot in a body to a certain distance from the muzzle of the piece. For if the wadding is rammed too close, or is of a hard and rigid nature, such as stiff brown paper, the piece will recoil, and the shot will spread; if, on the contrary, the wadding is not sufficiently close, and is composed of a slight and too pliant material, such as wool or cotton, it will not have enough of consistency to carry shot, and the discharge will lose its proper force. Besides,
a certain portion of the shot, which is more immediately in contact with the wadding, will be melted by the explosion of the powder. Mr. Greener says, "that a substantial wadding, between the powder and the shot, is equal to a considerable artificial friction in improving the strength with which the powder expels the shot. It answers the purpose of completely preventing the explosive matter becoming mixed with the shot; and the powder is confined the same as it would be were there a ball in the barrel that fitted tight. Thus the whole force is properly exerted."

**Walker’s metallic gun-waddings** have a considerable reputation, partly from the fact of their metallic edges preventing the surface of the barrel from becoming leaded. Other waddings are likewise recommended, as Joyce’s, Wilkinson’s, and Beckwith’s. The principal object is to keep the whole charge in the gun as compact as possible, that it may act least offensively on the gun, and most effectively on the object aimed at.

**THE RIFLE.**

Up to this point we have said nothing about the Rifle-gun, which is used in deer-stalking, and rook-shooting. The barrels in all rifles are much stronger and heavier than those of the ordinary fowling-pieces. The bore has long been manufactured with indentations within, which form spiral grooves throughout the entire extent. The principle on which all rifles are made, and the object they aim at accomplishing, is to impart to the ball a rotary or spinning motion round its axis, as it passes out through the barrel. The old mode of manufacturing pieces of this kind failed to accomplish this purpose to any great extent; but modern art has effected a considerable change for the better. The barrel of a rifle is now cut with only two opposite grooves; and the ball being framed with a projected belt or zone round its equator, of the same form as the grooves, it enters so readily into these hollows, that little or no force is required to press it down upon the powder. The general result has been, that guns of this character carry either ball or large shot much further, and with a vastly increased impetus, than can be done by the common flint or percussion fowling-projectiles. The locks for rifles have, likewise, undergone a great change, and many important alterations and improvements have been effected in their structure and mechanism. By reversing the position of the main-spring, the general compactness and strength of the works have been increased, and rendered more powerful, durable, and easy of repair. The ignition of the powder is so certain, that a misfire is rare in good rifles. They are getting daily into more general use in sporting circles, not only in this country, but on the continent, and in the United States of America.

In bringing our observations and descriptions of the gun to a close, we may observe, that every reader of sporting works on this instrument, must have remarked the very conflicting opinions respecting its uses, and the nature and character of its prominent attributes. These opinions are so contradictory, and are frequently set forth with so much confidence and dogmatism, that the impression is forced upon us, that the true theory of projectiles is not yet perfectly understood. Much, however, is now being done to master the subject; and we have no doubt, that opinions more generally correct, and easier to be reconciled with each other, will, at no distant day, pervade the minds of all intelligent sportsmen throughout the country.

We find in almost all the more elaborate treatises on the gun, a loose and inconsequential mode of reasoning adopted. Facts are mingled with theories, and theories with facts; and there is no regularly concatenated chain of reasoning on the subject. The systematic writers on the fowling-piece seem, in many cases, to have set out in their inquiries with some preconceived theory, to support which they either mould facts already ascertained, or mould the theory to the party, and thus endeavour to establish much that is not tenable, or worthy to be established. The mere mercantile enterprises connected with sporting, have tended, in many cases, to prevent the free current of inquiry into the offices of the gun. A gun-maker invents something which he conceives of importance, and takes out a patent at a considerable expense. He is naturally desirous of having his invention made known, and he accordingly does all he can to have it puffed, or recommended throughout the country.
Sportsmen are generally greedy listeners to all novelties. The invention is found, when tested by a pretty general use, not to realise all the advantages anticipated from it. It is then taken out to nurse, and to be bolstered up with a mass of theoretical speculation, which appears on the surface very profound, but which is, in fact, nothing but a series of ill-digested notions, and gratuitous assumptions. Readers are bandied about from one theory to another, till they are lost in obscurity and chaos.

As every gun is an instrument per se, and has a character of its own, the person that may be accustomed to it feels quite strange when a new piece is placed in his hands. We have read somewhere of a sportsman being often amused with the conversation of gamekeepers, and others, about their respective fowling-pieces. They talk of them as if they had life and volition. They say, "I know that gun well; she'll do very well in one way, but she's obstinate in another. She's a curious-tempered piece. I have known her on a particular day take the sulks, and no good could be done with her; at other times she killed all before her." The fact is, that the gun is an embodiment of very important and hidden principles of mechanics and chemistry. We see the effect of it; but the causes are often, and, indeed, in nine cases out of ten, wrapped in impenetrable mystery. Daily experience is the only means of obtaining a perfect knowledge of the capabilities of this instrument, because its powers are so easily modified by causes which escape ordinary observation. This is the reason why practical men gain such a stock of useful information on the use of fowling-pieces, though they are seldom able to impart that knowledge to others.

CHAPTER II.

MOORS AND OTHER SHOOTINGS; NECESSARY COURTESIES; SELF-HUNTING DOGS; A SUMMARY; ENGLISH MANORS; HINTS TO YOUNG SPORTSMEN.

As many desire information on the subject of hiring moors and other shootings, and, at the same time, seek for a knowledge of the best method of getting up a head of game, and of preserving and protecting the same, this seems to be the most suitable place to supply these, from such sources as we have been able to bring within our reach. We believe it is admitted, by all practical sportsmen, that the months of March and April are the best for the purpose of ascertaining the stock of game on all grounds, and especially on the moors; and offering, at the same time, the most favourable opportunity for trapping and destroying vermin of all sorts, and of extending other necessary protection to game, without which the best prospects of sport may be neutralised. In the first place, we will confine our remarks to the Scottish moors, reserving the subject of manors, and the preservation of game in England, for after consideration.

Why, it may be asked, are the months just alluded to the most favourable for securing shootings in Scotland? The question is readily answered. It is because an accurate estimate may be obtained of the stock of grouse equally on the Highland and on the Lowland moors—the packs (or, more correctly speaking, the surviving portions of them) which had migrated during the severe weather of winter, from the high ground to the distant lowland moors, having returned to their native hills to breed; and the low grounds retaining only those birds which actually belong to them, and which alone can be relied on to remain and breed on such ground. This must always be borne in mind relatively to lowland moors; for, if an estimate were sometimes formed of them from the amount of grouse
found in the months of November, December, and January, great disappointment would be the result in the month of August. We are aware that there are lowland moors which are almost without grouse in the months of August and September, but are abundantly supplied from distant high ground as soon as the severe weather sets in in November, and sometimes as early as the end of October; but, should the winter be mild and free from storms, the migration is very limited. We mention this fact by way of caution to those who, in any subsequent years, may be about to rent a lowland moor, not to go over the same till the severe and wintery weather be passed, as grouse which have migrated from the high ground rarely return till the end of February. In some excepted seasons, when the severity of winter is protracted, they have been known to remain till March, simultaneously moving off on the first change of weather.

In March or April, no grouse will be found on either high or low ground, but such as belong to each respectively, and these may be relied on as the stock of the ground; and, as they will be in pairs, an additional reason for delay, till this season, is suggested in the facility which is afforded by this circumstance, of arriving at a tolerably fair estimate of the amount of birds on the ground, and of the prospects of sport for the ensuing season, through the medium of an intelligent keeper and a good brace of dogs.

The best moors are unquestionably those of Perthshire, Aberdeenshire, and Inverness-shire; and if the sportsman will take a lease of five or seven years, which he will find most conducive to his interests, he will adopt the surest means of having six years of first-rate sport; even admitting, for argument's sake, that the stock of grouse has been so reduced by previous hard shooting or other adverse circumstances, as to make the entire or partial sacrifice of the first year expedient as a foundation for future sport. This necessity may sometimes arise, and should not be disregarded, as a neglect of it might be attended with subsequent disappointment. The sportsman will, therefore, do well, if he will permit us to offer a suggestion, to be influenced by the report of a competent keeper as to the state of the ground, and be guided by his advice thereon.

In the counties just named, the moors are so good and so favourable to grouse, that one year's forbearance, with judicious management, admitting the stock to have been reduced by too hard shooting or disease, suffices to restore them to first-rate condition; for, in addition to the increase of the stock on the ground, many packs driven from adjoining moors, finding that they are not molested, will remain, and reinforce the native stock: in fact, the effect of one year's jubilee on a really good moor, surrounded by equally good ground, is wonderful; the effect, to be believed, must be witnessed. But these favourable results depend upon one important condition; which is, that the head-keeper is a first-rate man in his particular department, and is allowed a competent staff of subordinates, and all other requisite accessories. If there are a number of old cock grouse, these should be killed off, as they do infinite mischief in the breeding season; but an experienced keeper will be alive to this necessity, and will act accordingly.

As a proof of the excellency of some of the moors in the shires alluded to, we may instance the sport obtained by three gentlemen in one season, on the Carr-bridge shootings, which comprise thirty thousand acres. They are in Inverness-shire, and were visited a few years ago by Sir H. Wilmott, Mr. Bass, and Mr. S. W. Hurtell. They killed, during the season, 6,700 grouse, 211 black game, 400 hares, 136 partridges, 5 roe, 52 snipe, 26 teal, 12 woodcocks, and 12 plover; total, 7,551 head.

On another estate, in the valley of Findhorn, in the same shire, two guns, with a brace of dogs each, killed, from the 13th of August to the 10th of September, shooting on alternate days, or sixteen days in all, 1,035 grouse, 144 hares, 2 black game, 10 partridges, 1 wild duck, 1 woodcock, and 1 rabbit; total, 1,194. This estate comprises only 4,000 acres.

There may be moors as good in other counties as those which are found in Perthshire, Aberdeenshire, and Inverness-shire; but, as a rule, the sportsman will not incur any liability of disappointment if he hires a moor in any one of the three named counties, provided he
has a good lease; and this cannot be said of every other county in Scotland, as the complaints of sportsmen but too frequently testify.

NECESSARY COURTESIES.

Presuming that most sportsmen will make a partial sacrifice of their first year’s sport, should the necessity arise, the next consideration will be—what is the best policy to be pursued in commencing and carrying on the management of the moor? Are there any parties whose good offices will be of service, and whom it will be advisable to conciliate? Unquestionably. The tenants and shepherds, as they can be either the best of friends, or the worst of enemies (game generally being more or less in the power of the former, and all nests at the mercy of the latter), must be conciliated and made friends of; and a head-keeper, who understands his business, will immediately endeavour to cultivate an amicable alliance with both parties, but especially with the latter; and this he will easily accomplish with a little tact, and through the persuasive medium of a little tea and tobacco, judiciously moistened, at opportune intervals, with some whisky—tea for the wives, and tobacco for the husbands. The head-keeper, being generally a diplomatist in his way, will, of course, commence with the wives; tea, in this instance, being wonderfully effective. Its operation is similar to that of a well-set bracelet in the higher departments of life, opportunely introduced and judiciously applied, extending its influence, through the same medium, to the person whose services are required. A few pounds placed at the disposal of the keeper, will enable him to carry this policy completely into effect, and are well applied; and when the shooting party are on the ground, no favourable opportunity should be lost of cultivating the friendship of the shepherds and tenants by a kind word, *en passant,* accompanied by a glass of whisky. Those who neglect little opportunities of cultivating the good-will of farmers and tenants, neglect their own interest as sportsmen, and are but poor diplomatists in dealing with northern Highlanders, who are extremely sensible of any little act of kindness, and are not unmindful of what they consider as a slight, or discourtesy, and are true to their motto. Let those who visit the Highlands remember this. We would not, however, prescribe the use of whisky to the sportsmen themselves. They carry a dangerous weapon, and have to use it with steadiness and effect. We recommend it, however, as a powerful instrument for securing the good offices of others, as every man who calls on you, whether he be farmer, shepherd, or herdsmen, expects a “glass;” and if he does not get his “glass,” he is disappointed, and he mentions the circumstance. In fact, the payment of this little tribute is universally expected—it is the custom of the country. No marked event, or ceremony, ever takes place without the introduction of whisky; whether it be either a marriage, birth, a christening, or a funeral, it is the Alpha and the Omega, the beginning and the end. It is administered before and after a funeral; and so general is its use, that we have never seen any Scotchman refuse it, whatever his position in life may be. All Highlanders contend that it is wholesome and necessary, although some few exclaim against the abuse of it; but as it is the only stimulant, with the exception of tobacco, which is in use, it is not surprising that recourse should be had to it in a land of such frequent mist and rain.

SELF-HUNTING DOGS.

Moors, which have been somewhat neglected, are sometimes overrun with self-hunting dogs. These marauders, coming from a distance, equally in search of game and dead sheep, should be unceremoniously dispatched by trapping and with the gun, as they do infinite damage in the breeding season; but this business a Scotch head-keeper thoroughly understands. Farms and cottages are sometimes overstocked with dogs given to self-hunting. These should also be disposed of; but this requires tact, and must be done quietly and judiciously. The shepherds’ dogs must never be molested; moreover, there will rarely be any necessity to interfere with them when the shepherds are the allies of the keepers, as, in that case, they will always be kept in at heel, except when they are performing their necessary duties in keeping the sheep within particular limits, or driving them to fresh ground.
SUMMARY.

If shepherds are negatively of importance in abstaining from either poaching or destroying game, they can also be actively serviceable in giving information as to the incursion of any enemy, either in the shape of vermin or poacher. From being constantly on the ground, no moving objects can long escape their observation.

A SUMMARY.

A summary of the preceding suggestions, as to hiring and protecting moors, addressed to the sportsman, may be the means of fixing them more firmly in the minds of our readers:

1. If you are desirous of having grouse shooting in perfection, take your moor in Perthshire, Inverness-shire, Aberdeenshire, or Caithness.

2. Should your object be mixed sport, combining with variety of game, winter shooting and fishing, the parts of these counties which adjoin the sea-coast will answer your purpose best, as these districts, besides grouse, black game, and partridge, frequently afford good wild-fowl and cock shooting, together with trout and salmon fishing, and, very frequently, first-rate sea-locb fishing.

3. Although Perthshire, Aberdeenshire, and Inverness-shire, throughout the greater part of their extent, furnish as much variety of first-rate sport, of every kind, as any counties in Scotland, in addition to the very best grouse shooting; still there are some few of the very best inland moors on which there is no winter shooting—in fact, little game beyond grouse, there being no covers; and, on some few moors, little or no fishing. This fact is mentioned for the guidance of the sportsman who may require additional sport to grouse shooting.

4. Secure your shootings by a lease for five or seven years.

5. Before signing your lease, if you do not know the moor, and are not satisfied as to its immediate condition, send a competent person over it with a brace of good dogs; you will then ascertain what stock of grouse is on the ground, and make your terms accordingly relative to the first year; as, in the event of total forbearance being necessary, or the number to be killed being limited, in con-

sequence of the reduced stock on the ground, some allowance must be made in consideration of that circumstance.

6. Immediately on obtaining possession of your moor, locate a first-rate head-keeper thereon, with authority to provide himself with a competent staff, the strength of which will depend upon the extent of the ground.

7. Engage your moor, if possible, early in March, and not later than about the middle of April; because the trapping of vermin ought to be commenced, at latest, in March (as it cannot be delayed without damage to the stock of game on the ground); and, grouse being in pairs, a tolerably accurate estimate may be formed of the quantity likely to breed on the ground, and of your prospects of sport for the ensuing season.

8. If the moor you have in view be a Lowland one, do not examine or engage it before March, because a quantity of grouse might be found thereon prior to that period, not belonging to the ground, only waiting for a change of weather to return to the high ground from which they had migrated in the early part of the winter, and thus deceive your calculations, and disappoint your expectations of sport for August, should they be based on the number of grouse found in January or February.

9. The head-keeper should be a Scotchman, an Englishman being comparatively useless, Gallic being the language generally spoken in the Highlands; and, moreover, an English keeper has little influence with tenants, shepherds, and under-keepers. The head-keeper should thoroughly understand his business in all its branches; and, with intelligence, activity, and zeal, should combine honesty, sobriety, and courage. All these qualities are required for a thorough discharge of the duties incident to his position.

10. His duty, in the first instance, will be to go over every part of his ground, and make himself thoroughly acquainted with the marches—i.e., boundaries; and, if possible, obtain information respecting the adjoining moors and the tenants thereon, in order to regulate the beating of the ground when the season commences; as, of course, every precaution would be taken not to drive the birds off your own ground on to a moor where "hard shooting"
has been constantly pursued; being less particular as to a deer forest.

11. His next duty will be to ascertain, to the best of his ability, the number of grouse on his ground, the probable prospects of sport, and the number of brace which ought to be killed.

12. To cultivate a friendly alliance with the tenants and shepherds, and obtain from them all useful and local information.

13. To commence trapping and destroying all ground and flying vermin.

14. To counteract and prevent poaching.

15. To give thorough and complete instructions to the under-keepers, assigning to each of them his particular beat and separate duties, which he will personally ascertain that they attend to, by being up and on his ground frequently before daylight, so as to anticipate and watch their movements. If a head-keeper has not zeal and activity, as well as considerable intelligence, he is altogether unfit to take the charge of a large moor; but Scotch head-keepers are generally superior men, and thoroughly competent, in every respect, to fulfil the numerous duties which devolve upon them.

16. In the month of March, previous to the burning of the heather, the head-keeper will go over the ground with the different shepherds, and arrange with them as to the portions of heather which ought to be burned. If the shepherds are friendly, they will not exceed the limits agreed on; but, as it frequently happens, on a large moor there are small tenant-farmers, who look after their sheep and cattle themselves. These individuals must be attended to, as they are rather difficult to control, and will always burn to excess if not prevented. The keeper and his staff, on these particular occasions, must exert more than usual vigilance. No heather can be legally burned after the 10th of April, the penalty for each offence being £5.

THE MANORS.

Quitting Scotland, we now come to England, where it is much more expensive, and more difficult to preserve game. This arises from there being a far greater number of poachers; and from pheasants being generally the principal feature in a large preserve, in which feeding and watching are requisite at almost all seasons of the year. Hares and rabbits, also, occasion an expense, inasmuch as they do considerable damage; consequently compensation is frequently required by the farmer; and they also require protection from the poacher. We are not aware that partridges do any damage. The advantages of grouse are, that they require no food beyond that which the mountain produces; and, moreover, three or four men will, in Scotland, take care of thirty thousand acres of land; whereas in England, some half-dozen keepers will not, at all times, suffice to protect five thousand acres of land.

Partridges, pheasants, and hares, being the principal object of a sportsman's solicitude on a manor in England, let us inquire what means can be most effectually adopted for their protection. Partridges are easily protected, it being only necessary, immediately after the harvest, to have all the fields, in which they are likely to jug, staked with strong blackthorn, driven well and firmly into the ground, sufficiently close to prevent the use of a net; as it is by dragging a net over the surface of the land that whole coves of partridges are taken when they are jugging; so that a country is soon cleared if this wholesale description of poaching is not counteracted.

In Suffolk and Norfolk, some manors of four or five thousand acres will permit of two thousand brace of partridges being killed in a season; in fact, on some of the most favourable soils for them, the only difficulty is to shoot them sufficiently close to ensure a favourable breeding season, so numerous are they, and so difficult to be reduced by fair shooting. As a rule, where abundance of grain is grown there will be plenty of partridges. There are, however, exceptions; as there are large districts in which the finest crops of wheat are produced, where partridges are not numerous. The reason is obvious; the soil which produces wheat only not being so favourable to partridges as that which produces rye and barley. In fact, such a soil as that which pervades the greater parts of Suffolk, Norfolk, Cambridgeshire, and Huntingdonshire, is best for partridges; and, we believe, there are more of these birds, as well as of other game, in these
favourite districts than in any counties of England. On these soils the water never lodges; and in dry, hot weather, there are never any cracks or openings, which are frequently seen in stiff soils in hot weather, into which both young partridges and pheasants fall, without being able to extricate themselves, and are, consequently, victimised; and wet weather is equally prejudicial to young birds on the stiff clay soils. On a really good and favourable soil, any amount of partridges may be got up, which the land will bear, in one or two seasons, by a little forbearance, if the stock be reduced; but any deficiency is rarely the case in either Suffolk or Norfolk, if the land is fully cultivated. In the case of partial neglect in this respect, or in the event of a farm being accidentally left fallow one season, the same amount of birds cannot be expected, as partridges will always go where they can find most food; and, although they can live on grass, they will always leave pasture lands if arable land be contiguous.

It is conjectured by some, that partridges which are found in grouse districts eat heather. This, on the other hand, is supposed to be a mistake, as birds have frequently been killed, during the winter months, on the mountain-tops, and, on opening their crops, nothing found in them but grass, and that, on several occasions, of a very coarse description, having the appearance of water-grass. These birds, however, are of very fine flavour.

It is a good plan, and one which is frequently adopted in Suffolk and Norfolk with success, to introduce drills of buck-wheat here and there between the turnips, where the fields of these are large. This is advantageous to both partridges and pheasants, as these birds are particularly fond of this grain—it attracts and keeps them together.

In very open countries, where there are neither covers nor plantations, small patches of furze and broom should be sown, here and there, on all odd corners of land. These will be found wonderfully protective of partridges in the cold stormy weather of winter, and, moreover, will be secure breeding-places. Partridges generally breed by the hedge-side, or on grassy banks, and not unfrequently by the road-side. Where there are walls, if there is a little rough grass and brambles at the bottom of them, these are also very favourite spots, although close by a footpath. Where the country is very open, and there is a scarcity of shelter, they make their nests in grass and clover; and here they are in great danger, as both grasses and clover are generally cut before the hatching is over. Consequently many nests are destroyed, notwithstanding the utmost carefulness of the mowers, as partridges sit so closely immediately before hatching, that there have been instances of their heads having been cut off by the scythe. When the nest is discovered in time, a small quantity of clover left round it will suffice to prevent its desertion. These birds sit twenty-one or twenty-two days.

In the spring of the year, when partridges first begin to lay their eggs, the utmost vigilance is demanded on the part of the keepers, owing to the practice of stealing eggs, encouraged by poulterers, who carry on a large trade by the sale of them, partridges' and pheasants' eggs always being obtainable at the London markets, and from most London poulterers; and as long as gentlemen will continue to countenance this traffic, by buying eggs for the purpose of stocking their grounds, they must expect to be mutually pillaged. We could here introduce many letters upon this subject, but it would be unnecessarily filling our pages. Partridges will always make a second nest when the first is destroyed; but the number of eggs will be considerably reduced, and the coveys so late, that the young birds will not be ready for the sportsman by the 1st of September. Whenever a small covey of backward birds is found, it may be inferred, to a certainty, that the first nest was either robbed or destroyed; six or eight birds is generally the amount of a second covey. In an early covey, as many as twenty young birds have been found; but this is unusual; and, although as many as sixteen and eighteen eggs in the nest is a common circumstance, still fourteen young birds, on the 1st of September, may reasonably be considered a good covey. We cannot advise any sportsman to buy partridge-eggs for the purpose of stocking his ground, because we consider the practice wrong in principle, and one which is sure to meet with retributive punishment; and, moreover, on good soils, where partridges can be...
got up, the object is easily accomplished by a little forbearance combined with protection, without this extraneous aid. In the case of nests being found in dangerous positions, it is a very good plan to take the eggs and place them under a hen; and it might, perhaps, answer to take the eggs from some of the nests on the distant part of the ground, provided this be done at the early part of the season, as, in this case, there would be a second nest. It must be recollected, however, that these home-bred birds, even if success attended their rearing, are indifferent breeders for the first year. The experiment has been tried, and many of their nests found, but they seldom, if ever, contain more than fourteen eggs, twelve being the average. There is, however, one great advantage, that they will all breed near home; and, after the first season, the young birds will, in all probability, stock the more distant ground. When partridges are plentiful, it will always be advisable, at the end of the season, to have the extra old cock birds killed off, as there are always many more cocks than hens; and if the former supernumeraries be left, they will do infinite damage, by destroying many nests, and disturbing the hen birds whilst they are sitting. A good shot will easily pick the cock birds out on the rising of a covey, as the horse-shoe mark on the breast is very visible. This should be done in February and March.

In reference to the subject of stocking manors, some recommend the turning out of red-legged partridges, whilst others recommend their destruction; and, considering the many disadvantages attending the presence of these birds, it is a matter of surprise that they should have met with any encouragement from practical sportsmen, as we are not aware that they possess any one single redeeming feature to counterbalance their numerous bad qualities, with the exception of their appearance, which is decidedly in their favour, as they are, unquestionably, a handsome bird. They are constantly to be met with in both Suffolk and Norfolk, where, by many, they are considered as a great nuisance. But it may be as well to enumerate the objections which are made to them.

In the first place they are very pugnacious, and, from being a larger and more powerful bird than the grey partridge, they easily drive these off their beat; consequently, if they were encouraged to any extent, a considerable diminution in the stock of the ordinary partridge would be the result. In the next place, they invariably spoil sport, as they are ever on the move, either flying or running, consequently disturbing the other birds when disposed to lie and give sport; and, moreover, do not compensate by giving you a shot at themselves, as it is very rare that you can get a chance at them, except in the case of a surprise in the corner of a plantation, or cover, or thick piece of turnips, at the end of which a strong fence may prevent them from running further, as they never cease running when once in motion, except their course is obstructed by some impassable obstacle. We have frequently marked them down in turnips and furze, and been disappointed in getting a shot, finding, by the time we had reached the spot where we had seen them drop, they had already emerged, and were running as fast as their legs could carry them, at the distance of some hundred yards or more. In fact, it is an endless and hopeless affair to follow red-legged partridges in an open country, however well it may be supplied with turnips. We have frequently made the experiment, and can, therefore, speak with some degree of certainty on this point; and, moreover, in the pursuit of these birds, you not only fruitlessly exhaust your patience, but spoil your dogs, as they will sometimes run a mile before them, at least, if the dog's patience will last so long; but it sometimes ends in his having a run too. In fact, these birds will ruin the best dogs, and are only fit to be hunted by spaniels. The bird is certainly a fine bird on the wing, and affords a good shot when you can get it; but the last, and by no means the least, consideration is, that when you have shot him he is not worth eating—at least we think so; but far be it from us to dictate, or prescribe, in matters of taste. However, we have never met with any Englishman who differed with us on this point. Their flavour is flat and insipid—in fact, disagreeable. We are aware that this bird is highly esteemed in France; but as he is rarely eaten au naturel, but generally accommodated with a copious supply of truffles,
enhanced by some sauce piquante, his natural insipidity is disguised; and then, as Monsieur Chevet observes, of some of his favourite comestibles, il se laisse manger. We have seen him brought to table on many occasions dressed au naturel, and withdrawn without discussion. Ho may, perhaps, have been tasted, but no further honour was paid him.

Regarding the pheasant, we must remark that he is well worthy of all the care and protection which can possibly be extended to him. He is unlike the partridge in one respect, not being attached to any particular spot of ground, although he will remain in any suitable cover when he can find sufficient food, and is free from molestation; but if he cannot find food, and the soil does not produce it, and it is not supplied to him, he will take to his legs, and search for it for miles till he finds it, and remain in his new quarters so long as he is undisturbed. Where partridges have once bred they will breed for years, and very near the same spot; hence the policy of never killing any covey entirely down. This is not the case with pheasants, as the hens will remain to breed in any cover to which they may have been driven at the end of the season, provided it be a suitable one, and there be food; hence the necessity of always providing sufficient food as an inducement to them to remain. But even this will be ineffectual unless the covers be kept perfectly quiet, as pheasants will not remain where they are constantly disturbed. The slightest movement in a cover sets them in motion, running at their best pace, and not stopping until they reach some thick place, where they can conceal themselves. If the cover is large, it may be occasionally disturbed without much risk; but if it is small, and thin at bottom, they will run clean through it, and, perhaps, continue their course for miles. The best cover to keep pheasants in, is one of furze and broom, as they can conceal themselves in it; and, if it be spacious, even a dog has some difficulty in dislodging them. In an open country where there are no natural covers, this artificial cover of furze and broom will be found to be of the greatest advantage. It can easily be got up in a few years; and a few rabbits turned into it, will be useful in making runs through all the thick parts of it. It is also undeniable for hares; and, moreover, game of all sorts is easily protected in it, as a poacher can only operate in and about such a cover by daylight; and therefore must be seen approaching, if a good look-out be kept. A small cover of this description, of about six acres, adjoining a keeper's cottage, has been known to hold several hundred pheasants. It was surrounded by corn and turnip fields, and some few plantations running up to it, into which the pheasants strayed by day, returning always at feeding-time, or in the event of their being disturbed.

If there be water handy, it will be a great advantage, as pheasants cannot do well without it. It must, therefore, in the event of there being neither spring nor pond near, be supplied by artificial means—tanks, sunk in different places, which the keeper will take care to fill regularly, will answer the purpose. Pheasants require, more or less, feeding nearly all the year round; less in summer than in winter, and but very slightly after the harvest. A little food, however, occasionally at all seasons, keeps them together, and prevents them from prowling. Barley, oats, white peas, buckwheat, and boiled potatoes, comprise what they are most partial to. Of buckwheat they are especially fond, a few acres of which will attract them, and partridges also, from very long distances; consequently, this being known, its use in both Suffolk and Norfolk is almost universal, not only on the general principle of preserving, but on that also of self-defence.

The advantages of the furze and broom covers, consists in their affording protection to the pheasant by night as well as by day, as pheasants frequently jog in them, so that they are out of the poacher's reach. But as, in this case, they will be accessible to ground vermin, the keeper must be very particular and vigilant in this department of his business: the weasel, stoat, polecat, and common cat, would do infinite mischief in a preserve of this description. As the presence of these depredators, however, is easily ascertained, and as they are trapped without difficulty, the keeper must have neglected his duty if more than an occasional visitor is ever seen; but he must always be expected, as vermin are sure to be plentiful where game abounds. In all preserves it is a good plan to have a few rabbits, as they frequently save the lives of pheasants when any
SHOOTING.

This species of poaching, like the egg-stealing, would, in all probability, cease to exist, if sportsmen would refrain from purchasing live pheasants. Advertisers of live pheasants for sale, sometimes put forth, in their advertisements, that the pheasants which they offer have been reared by themselves, from eggs laid by birds in their own possession; but if there be one instance of this sort, it is an exception, even if the birds which laid the eggs were not originally poached; and, moreover, this may only be a blind to more extensive transactions of an illegitimate character; but, as we have before intimated, its discontinuance rests with the sportsman. A combined resolution amongst sportsmen, not only to discourage the traffic in pheasants' and partridges' eggs, and in live pheasants, but also a determination to prosecute all offenders in this respect, would be productive of immense advantage, not only to sportsmen but to the community at large, as the stock of game is seriously injured by this yearly illegitimate practice. That the trade to which we allude is carried on, and pretty extensively, may be ascertained by any one who will give himself the trouble to make inquiry. The vendors are, of course, aware of their liability, and may not, perhaps, give information to every one requiring it, as we believe some caution is exercised in these transactions.

Having thus discussed the manner of proceeding in reference to the Moors and the Manors, we will now give a few hints to young sportsmen.

There are numbers of shooting sportsmen who, from want of observation, or a "Mentor," to guide or direct them, plod on in their own invariable way, and suffer no end of inconveniences, when a few hints would entirely change the nature of things to their advantage. To such, and especially to the younger and less experienced, we crave permission to address ourselves. Our hints will be only to "little things;" but in little things lies the secret of enjoying greater. First, as to dress.

The Cap.—We will begin with the head, and end with the feet. The cap ought to be as small as possible, for reasons we shall shortly explain. The kind, of all others, to be preferred, is exactly the size and make of a heavy dragoon officer's forage cap, but with the peak a trifle longer, and not lying quite so flat on the forehead. Wide-awakes are all very well, but you must, in the least wind, be always either snatching at them with your hand, or be keeping your head bent down on your chest, with the muscles of the forehead so contracted as to induce headache with many people. The cap should be small for another reason, and that is the liberty, especially in a wild country, of having to exert your energies in creeping after wild birds, such as carrion crows, hawks, &c., which may be detected in situations where they may be got at, and when a small cap may be carried in one of the pockets.

The Coat and Trousers.—Grouse-shooting is the only game-shooting in the three kingdoms that really requires attention to the colour of your dress. We should recommend, therefore, a good "heath mixture" coat and waistcoat, and the cap of the same colour. The trousers should be of stout material, of much the same colour as the other parts of the dress, and, for real service and comfort, be made as follows:—Procure, at a respectable currier's, two seal skins, and have the trouser legs covered with them in the form of a Napoleon boot—viz., coming well up in front of the thigh, and being hollowed out down the thigh behind, till you get two inches above the calf of the leg. With these trousers you can go through any cover, such as gorse, &c., with impunity; and, in case of having to drop on a kene in damp ground, no water will penetrate. An old pair of trousers will do to be covered with the skins, so that they are stout and not decayed; and, when worn out, the skins (which will last six or seven years) can be sewn on to another old pair. The seal skins cost about
BY FIELD, WOOD, AND WATER.

Boots and Stockings.—The only sort of boots worth having are good strong country-made lace-up ones, with six holes laced, then six hooks, and after that two more holes. Have good nails in them, and let the toes be tipped with steel plates on the sole, and project at least three-quarters of an inch in a slanting direction downwards. This will defend the upper leathers at the toe from being cut by the strong shanks of the heath. In regard to snipe boots, the following plan has been found by far the best to be pursued:—Have the laced boots made sufficiently large to wear with a pair of Macintosh’s waterproof fishing stockings, over common woollen socks. Walk to the snipe ground, carrying the waterproof stockings (which fold up into about the size of your hand) in your pocket. Then take off the lace boots, and put the waterproofs on, and the boots over them. The stockings reach right up the leg. When tired of shooting, rinse both boots and stockings in the nearest water-hole, and dry out the boots with a handkerchief, which is done in a minute; and then turn the stockings inside out, and carry them home in your pocket, and thus save the trouble of wearing them. You will not perceive the damp of your boots through your woollen socks. You will find the inside of the fishing stockings get quite cold and damp after they have been off some time; but that is not a sign that they let water in, but merely that the perspiration generated by walking has condensed. Let the stockings be well dried a good way off the fire, and they will last a long while—about six years. The original price of them is 16s., and the cost of new footing, 8s.

The Cloak.—The next thing to recommend is a small waterproof cloak, and the solid comfort of this must be felt to be appreciated. Although naming a cloak, there is no need for considering us as composed of either sugar or salt. In every situation of life comfort is everything. We therefore recommend a cloak, one of the beautiful light ones, made of black waterproof, that you can buy for about twenty shillings, and which will go into a small case. This case, if made with a couple of buckles, is fastened into the gun-sling, and is quite out of the way. The gun-sling we mean is the sort previously sold by Dean and Adams, and may be truly called a real blessing to sportsmen. It is no cockney or foreign apparatus, but a first-rate invention; and, for riding or walking home a long way, is invaluable. The gun sticks close to you, and you hardly know you carry one, and it will not move a hair’s breadth if you run, stoop down, &c. We name a cloak, for a coat is detestable, and wets both yourself and your gun, instead of keeping you dry. With a cloak, you only need to turn it “rear rank in front” if the rain comes in your face, and you may laugh at a storm, for the trousers we before named will keep you dry above the knee.

The Shot-bag and Powder-Flask.—For the convenience of carrying the shot-bag and powder-flask, we offer the following suggestions:—Have a thin leather strap sewn tight round the shot-bag, where the charge screws in. Another strap should be sewn to the one named, and continued endways round the bag through the D at the end of it, till it joins the other side of the strap round the collar, where it must again be sewn to that strap, and be continued loose for two inches; and at the loose end there must be a D. When held by the last-named D, the shot-bag will hang charger uppermost. Then have a strap to go round the waist, with a short bit of leather, three inches long, sewn on at right angles. This bit of leather should come on the right hip-bone when the strap is buckled round the waist. We can only say, that any one who will try this plan of carrying a shot-bag, will never return to the old plan of carrying it round the shoulder. The short hanging strap must have a steel swivel to it, to hook into the D of the shot-bag.

The powder-flask should be carried in the
right-hand large pocket below the waist, and the wadding also; because you save one movement in loading, by taking a wadding out when you put your hand into that pocket to return the powder-flasks. Speaking of powder-flasks, we have seen a very simple contrivance for a drinking-cup, by having it made of German silver, or plated, and fitting on to the lower part of the flask. This is the invention, we believe, of a well-known and very excellent sportsman, living in Derbyshire.

Telescopes.—There is another article forming the outfit of a shooter; and though the last, it is not the least important part of a field equipment. This is a pocket telescope. Two are sometimes carried, of the following descriptions:—One about fifteen inches long when drawn out, and three-and-a-half when closed; and with it you may, on a tolerably clear day, tell the hour by any church clock at three miles' distance; and it will, consequently, enable you to identify the person of any one you may see poaching at a distance; and it is, of course, equally available on the thousand-and-one occasions when its use may be required in an open country. The price of these glasses, in leather case complete, is about 1l. 16s. The other glass is about three inches when drawn out, and two inches closed. It has only one slide. The power of this small telescope is extraordinary, and would not be conceived by most persons till tried. The handiest way to have it is to draw it out, in the first instance, to the right focus, ranging to about a mile, and then cut a piece of card that fits round the moving slide, keeping it from pushing in, and have the card stitched with thread so as not to come off. You can carry it thus in a clean pocket on the right-hand side of your shooting-waistcoat, and you are ready to mark birds when they get up, without the loss of a second of time. The relative uses of the two glasses will be obvious to any man who has shot much in an open country. The price of the small one is 12s. 6d.

Having thus equipped the young sportsman, and treated of the Moors and the Manors, we will, in our next chapter, treat of Shooting, in connection with the modes of handling the Gun and the Dog.

CHAPTER III.

SHOOTING.—THE ONE-EYED AND THE TWO-EYED SYSTEMS; USING THE GUN; LOADING; PRECAUTIONS.

The theory of shooting involves a complete knowledge of the most advantageous manner of directing the gun when placed to the shoulder, relatively to the game intended to be killed; and as birds present themselves in various ways—flying away from us in a straight undeviating line at one time; at another time descending; sometimes crossing before us either to the right or to the left, or coming directly over our heads—there must be fixed rules for the management of the gun, the accurate knowledge of which may be considered as part of the theory of shooting. These rules must be adhered to or deviated from according to circumstances, as the judgment of the sportsman, matured by experience, may suggest at the moment. For instance, firing at a bird proceeding in a direct straight line, neither rising nor descending, provided the distance do not exceed thirty-five or forty yards, it will suffice to cover it; that is to say, to have the elevated rib of the barrel in a straight line with the bird, so that no daylight be visible to the eye between the sight of the gun and the lower part of the bird, in which case the bird will be hit by the centre of the charge. If the bird, however, be ascending, the gun should be directed slightly above it, and, if descending, below it; and in all cross-shots, and those coming over the head, the gun ought to be directed one or two feet, and sometimes even more, before the bird—the degrees of distance being regulated by the supposed pace of the flight of the bird at the time. But why shoot so far before a bird with a quick-
Because it is found by experience that, notwithstanding the force and quickness with which the shot is propelled by the best of guns, if the gun be directed at right angles at a crossing bird which is at the distance of thirty-five yards, the charge will arrive too late. The bird has, during the transit of the charge, advanced about two feet through the atmosphere, although, doubtless, a minute portion of time is lost between the pulling of the trigger and the discharge, as well as between the determination to pull and the actual pulling. At all events, from these combined causes of delay, the bird obtains an advance of from one to three feet, the judicious anticipation of which by the sportsman is requisite to success.

A further consideration presents itself as involved in the theory of shooting; and this is in the gravitation of the charge towards the earth. As this tendency, however, is remedied in all good guns by the proper setting of the barrels, the sportsman is under no necessity of making any calculations in regard to it, at least within the distance of forty yards, as all guns, turned out by first-rate makers, are so well put together, that what is termed a point-blank aim may be taken at that distance. This point-blank aim means, that the centre of the charge will hit the object to which the gun is directed, if a correct aim be taken, the rib being elevated in proportion to the length of the barrels and the strength of their shooting, so that the direction of the latter, in point of fact, at a distance of forty yards, is from eight to twelve inches above the line of sight, whereby the gravitation of the charge is remedied.

As the rib is not parallel with the calibre, and as the breech end of the barrels must be sunk into the stock, more or less, according to the thickness or elevation of the rib, it is evident that the elevation of the barrels will be increased in proportion to the elevation of the rib; but it is hardly necessary to enlarge upon so clear and obvious a mathematical truth—as the French say, “cela saute aux yeux.” We will, therefore, only make the following short remark, which will obviate all misapprehension: if one straight line be drawn from the rib, and another from the centre of the calibre, to the distance of forty yards, they will be found to be from about eight to twelve inches apart, provided the elevation of the rib and the setting of the barrels be correct.

If all guns were of similar strength in their shooting, the precise degree of elevation might be ascertained to a mathematical nicety, and the gun-maker would have a fixed rule for his guide, irrespective of trials; but this not being the case, proofs must be resorted to, and the rib elevated accordingly. Not that this is always the case, as guns badly set are not unfrequently to be met with, and to which the elevation is insufficient, consequently occasioning much disappointment at all long distances, by wounding and breaking the legs of birds, instead of killing them; and although the sportsman is oftener in fault than the gun, yet, we believe that there are some instances in which the fault is in the gun. In addition to the proper setting of the barrels, and the correct elevation of the rib, the balance of the gun and the peculiar make of the stock, from the locks to the point or tip, merit the attention of the sportsman, especially in a heavy gun. Heavy guns, with the point of the stock bent too much downwards, are apt to deceive the best of shots in quick shooting, and, with moderate shots, create frequent disappointment, especially at the end of a long day’s shooting, after much hard faggion. We think the gun ought to balance evenly, when placed on the palm of the hand, immediately past the end of the locks.

Much has been said on the superior advantages of the use of two eyes over one: in fact, some of the advocates of the two-eyed system have spoken very disparagingly, and, as we cannot help thinking, with unbecoming severity, of those who support the one-eyed plan—the latter being represented as slow-coaches, their practice behind the times, obsolete, &c. But is this the fact?—is it true? We think not; and, if we may be permitted to judge from observation and experience, we should say the one-eyed men, ceteris paribus, are quite as competent to “fill the bag” as their opponents, simply because we believe each system to have its relative advantages and disadvantages, presuming each party to have guns of similar make and construction, of like setting as to the barrels, and of equal elevation of the rib. But, if guns are badly set, and with insufficient elevation, then it must be
readily admitted that the two-eyed man will have a most decided advantage in helping himself to that which the gun-maker has denied him. But, with guns constructed and put together on modern improved principles—with proper setting, sufficient elevation, and peculiar fitness for the use of one eye—it strikes us that the two-eyed man has not all that superiority over his opponent of which he boasts; for, if the one-eyed man occasionally shoots under a rising bird, the two-eyed man must sometimes shoot clean over a bird which is rapidly descending, if he shoots in a wild, hilly, and mountainous country. In a flat level country, we are sensible that this latter case would rarely occur; consequently, there the two-eyed man would have the advantage.

Having shot many years over an uneven and mountainous country, where there were as many shots one way as the other, and being in the habit of using sometimes one-eye and sometimes both, we must admit having occasionally shot over birds quickly descending when using both eyes, and sometimes having shot under rising birds when only availing ourselves of one eye. Here we allude to snap-shots presenting themselves unexpectedly, in the taking of which the most experienced may occasionally be surprised, and reverse the principles on which they generally act. If, therefore, we may be allowed to judge equally from experience and from observation, we should conclude that neither system is perfect, each being liable to occasional failure; and, if both parties will dismiss amour propre, and be candid, we think they will arrive at the same conclusion. The use of both eyes, unquestionably, gives extra elevation—in fact, almost indefinitely so, according to the judgment of the sportsman. But is this necessary, and is it always an advantage? We think not; for, if a gun be properly put together, we cannot see that this extra elevation is required, except for a small proportion of rising shots at long distances; and we believe that the difficulty presented even by these, will be readily overcome by the one-eyed man of experience, who possesses nerve and presence of mind. If the two-eyed system be as superior to the one-eyed one as its advocates insist that it is, why require any assistance from the gun-maker in the setting of the barrels—why have any elevated rib?—as it is evident all this is superfluous and unnecessary for the carrying out of the two-eyed principle. For, if we judge rightly of it from the statements of its most strenuous advocates, they despise the steady old plan of looking along, or in the direction of the elevated rib, in line with the sight, holding their heads above the barrels, and taking their own elevation and line of sight—exercising their own judgment on the spur of the occasion; so that in this speculative system, much practice and experience are requisite, in order to acquire the habit of accuracy and precision. From this, we think, it may be fairly inferred, without illiberality towards the two-eyed men, that their system is not infallible; that they sometimes err, and, consequently, that their practice has not that decided superiority over the one-eyed system which it is presumed to have; as the latter, as far as it goes, is not liable to mistake, and is easily carried out—the precise extent of elevation being already determined and arranged by the gun-maker on unerring principles. The hand will, to a very great extent, follow and obey the eye.

We are therefore convinced, that in snap-shots, even at such large birds as blackcocks, when they slip off the high top of a mountain, instantly gliding down below, the two-eyed man would, if he were inexperienced in that sort of shooting, shoot over many more birds than he would ever hit. This result, we think, must strike every one, even if experience were not referred to for its confirmation: but let any one, who doubts it, test the point by experiment—bring up his gun quickly to the shoulder, with both eyes directed to a particular object, and he will find, on immediately closing one eye, that the point of the gun is above the object aimed at; and if that object be a blackcock slipping from a high mountain-top, and rapidly descending, he will not only miss his mark, but the charge will be at least three feet over the bird. The one-eyed man would, in this particular shot, have the advantage; because, if a similar experiment be tried with one eye—to that which we have just suggested as a partial test to the two-eyed system—and the gun be brought up quickly to the shoulder, it will be found that the point of the gun will be under the object aimed at, and never over it, which, in snap-shots at rapidly descending birds, will
be an advantage which the one-eyed man will unquestionably have over his opponent. This occasion will frequently arise in shooting in the Highlands, at all sorts of game, but particularly at black game, whose flight is peculiar. These birds rarely ascend, even when found on the open heather, or in corn-fields; and not one in twenty rises vertically, but emerges from the heather, corn, or bushes obliquely, and immediately takes a horizontal direction, except when it leaves a high mountain-top—in which case, in the first instance, it descends, subsequently preserving its horizontal course; and when disturbed in cover, always escaping through the first openings which present themselves, emerging horizontally, and never rising vertically, except its horizontal flight be obstructed. Having shot hundreds of these birds, and seen thousands of them on wing at different times, we can speak with some degree of certainty on this point; and if we allude to the peculiarity of their flight, it is merely as illustrative of the position which we have assumed, that all the advantages are not on the side of the two-eyed men. Black game are remarkably easy birds to shoot, when a fair chance can be got at them; but they constantly rise near, without affording the opportunity of a good shot, especially in cover; and this is very intelligible, when their peculiar mode of flight, we have just explained, is considered.

THE GUN AND THE TARGET.

The examination or trial of a fowling-piece is one of those duties so essential, even to the safety of the sportsman, that he must by no means neglect it. Nor must he neglect to make a thorough trial of the instrument which he intends to use, under every change of weather, before he ventures upon the moor or the manor to seek for his sport. In the manufacture of guns there is as much deception as there is in the manufacture of any other articles of commerce; therefore, it behoves the gun-purchaser to bring all his skill and judgment to bear upon the general make of the instrument he desires to purchase, before he has taken it into the field with him. "It is not altogether true," says the Oakleigh Shooting Code, "that the best guns are made by the most celebrated makers; but the reason why a gun made by one of these makers is to be preferred by a person not thoroughly conversant with the arcana of the trade, is the probable certainty of his obtaining a good one; for a first-rate maker will not hazard his reputation by turning out an indifferent one. The unwillingness, however, to give a first-rater's price, induces the shooter to look out for a second-hand piece; and the eagerness with which second-hand pieces are sought for, has led to a species of deception to entrap the unwarly. The following remarks on second-hand fowling-pieces, are by a gun-maker—'Eight out of ten of the guns sold as second-hand are new guns, made up purposely to suit the public taste, or predilection for second-hand guns by a good maker.' And really one might suppose that none but mere novices could be imposed on by them, for they generally bear the names of makers, many of whom were dead before the invention of the copper cap; such as Henry North, W. Mortimer, Fenton, Hewson, &c.; but all these are warranted genuine.

"In making trial of the gun, care should be taken that it is what we will venture to call a thoroughly agreeable piece; that it is easy and pleasant to handle; that it fits the shoulder well; and that it is altogether an instrument that pleases the eye. There is more in this last observation than many would think; for, if the eye is not pleased with the appearance of the piece, good shooting is apt to be marred by it. After the examination, let the breeching be taken out; and remember that the screw, both male and female, be examined carefully; that the male ribs and the female indentations fit so closely together as to harbour no wet; but that, when screwed up, they make a solid mass. This is often little attended to; but, if the amateur will take out the breeches of some of the cheap guns, he will be convinced, by the ill-fitting of these important parts together, of the liability of such guns to corrode, and eventually to burst. We therefore say, buy no gun that shows any marks of disunion between the breech-screw and the barrel; also, look down it against the glare of a large candle, and if any flaw appears, let it be carefully examined with callipers. The breech or breeches being replaced, proceed to an equally close examination of every other part of the barrel. Next examine the stock and its mount-

3 x 521
For the target, milled-board will form an excellent substitute, where iron cannot be had; and each sheet should be suspended by tenter-hooks against a wall; or, what is still better, to a square or boarding raised on a pole. "The dimensions of the square (or it may be a circle if the trier pleases) will rest with the sportsman; we should recommend one about a foot and a-half, marked off in squares, and the same crosswise, if a circle be employed. The paper, when it is used, should also, like a draft-board, be squared around by chalked lines, drawn an inch and a-half or two inches apart. At proper distances, on the outer circumferences of the target or wall to be shot against, tenter-hooks should be placed to secure the brown paper. Measure off the ground to certain distances, commencing at fifteen yards, and increase each trial by five, until it arrives to fifty yards, with as many more as the trier pleases. As soon as a shot has been made, note the range, the charge used, the number of shot which have entered each square, and the depth to which they have penetrated. Chalk over each indentation, and repeat the experiment at another distance."

The *Encyclopædia of Rural Sports* recommends the squares or circles within the circles of the target to be marked in such a manner as to represent the dimensions of the various kinds of game usually shot at. Thus, the first square may be two inches, which will take in the snipe; as that of two-and-a-half may be considered appropriate to the dimensions of the quail; of three-and-a-half to the woodcock and young partridges. Older birds would spread their limits to four inches; the grouse to four-and-a-half; and the pheasant, if a hen, to five; and a full-grown cock would hardly escape any shot that struck within the limits of the square of five-and-a-half. Of course, the tips of the wings of the birds here mentioned might meet with a shot that extended beyond the limits appropriated to it. We only give some clue to a knowledge of what may be expected from the garnish of a gun as displayed on the trial. We have not yet observed, that when much accuracy is required in the trials, particularly if made by an unsteady hand, a "rest" will be a great assistance in gaining a just indication of the shooting of the piece. It is not unlikely that *some*
may call this wire-drawing; we are, however, certain they will not belong to the body of reflecting or experienced sportsmen; they will know better how to appreciate rule, method, and illustration.

**LOADING.**—Success in shooting greatly depends upon the art of loading properly. The first thing to be done is to squib up the gun several times in order to dry it, and give a little warmth to the barrel, before putting in the load with which you are to begin your day’s sport. Your gun is here supposed to be of the percussion make. Having squibbed sufficiently, drawn up the cock, and removed the broken cap, hold the gun in an upright position, and pour in the charge, striking the butt-end of the piece against the ground, to carry down such grains of powder as may be lodged against the sides of the barrel, and also to settle it completely in its place. Now pass down the powder-wadding until it reaches the powder, on which it ought to be very lightly pressed, not rammed. Next pour in the shot, and give a shake or two to settle them evenly and solidly in their bed. Place over them a wadding of sufficient substance and elasticity to preserve the shot in their position; for which purpose give a pressure to the wad, taking care, however, not to ram it hard. It is usual, however, to give the first charge a little more pressure than the charges that are to succeed it. When the powder is wadded, it will be well to observe whether it makes its way into the nipple by the pressure of the confined air, made in passing down the wad. It does not always follow, that if the powder is not seen in the pivot, it will not explode; it is, nevertheless, more satisfactory to see it there; and when this is not the case, we should give the breech a slight tap or two, to introduce it further up the touch-hole. The circumstance of the powder not being seen at the touch-hole, is more likely to happen with the perforated, or serrated wadings, made to let out the confined air, than with those that are entire. The last act of gun-loading is that of putting on a fresh cap, and letting the cock down very gently to fasten it on the nipple.

In charging the flint-gun, it is also prudent to squib it first, and then to introduce the powder and shot into the barrel. Sufficient priming should be put into the pan, but not in such quantity as to allow the pan-cover to crush it. If a double gun be employed, it will be optional with the sportsman to load both barrels alike, or to give, as many do, a somewhat heavier charge to the second barrel, be it right or left, that he usually fires on the longest shots. If the quantities of powder used are the same in both barrels, the size of the shot may, for the second barrel, be a little larger. Many shooters increase the quantity of shot for the charge of the second barrel; but this can only be expedient when the weight of the powder is somewhat increased also; and even then, by many, its propriety has frequently been questioned. It is always more or less dangerous to alter those exact proportions between the powder and shot which experience has pointed out as being precisely suitable to the piece. When a gun has been discharged, the barrel should be loaded while it is still warm; for, when allowed to cool, the moisture begins to settle on its inner surface, and this catches some of the finer particles of the powder-charge, and either decomposes them there, or prevents their falling to the bottom. In either case the detention diminishes the projectile force which is to act on the shot.

What are found to be the just proportions of powder and shot most suitable to his piece, the sportsman should make it his anxious study to discover. A considerable amount of practice will be necessary for this; but it must be done, if he wish to attain to the character of being "a good shot." In experimenting for this, he must make use of different kinds of powder and shot—in short, adopt every method and material that may suggest themselves to accomplish the end he has in view.

To achieve all this, requires not only nice observation, but a just mode of reasoning, and the establishment of general rules, and the marking of their occasional exceptions; all of which mental habits are by no means very common among the ordinary run of sportsmen. Hence it is that we find the actual practice of shooting so loose and unscientific; and when a man does succeed in practically acquiring the art in the highest degree, he seldom has the power of correctly communicating his knowledge to others, or of marking, with sufficient clearness, the various steps by which ho
has attained a mastery amongst his craft. Between just theories, and accurate practice, there is always a wide gap; and it happens, now and then, that the one is made to throw light on the other.

Many trials must be made with every fowling-piece before it can be fully ascertained what are the proportions of powder and shot that will suit it best, and produce the most pleasant and most effective method of using it. When, however, something like a general idea on the point is obtained, a series of what may be called small experiments should be made, in the way of variations in the quantity of loading, that the truth of the general opinions formed may be tested. A detonating piece requires a little less powder than a flint-gun; but the exact difference of proportion between them is not a matter that can be subjected to any general rule; from a fourth to a fifth less is often adopted. Colonel Hawker says—"To load a single gun of six, or double gun of seven, eight, or nine pounds' weight, take a steel charger, which holds precisely an ounce and a-half of shot; fill it brimful of powder, from which first prime, and then put the remainder into the barrel; to this add the same measure bumberful of shot, and then regulate the tops of your flasks and belts accordingly." This, however, is the prescription for a flint-gun, of which the colonel is the aegis. The same authority says, that for a gun of twelve pounds these proportions may be doubled; for one of eighteen, trebled; and for one of twenty-four, quadrupled. Although these proportions for powder be correct, yet the experience of shooters shows that a certain diminution of the quantity of shot should be made for each kind of gun now mentioned. The commonly received regulations are the following:—The sixth part of an ounce of powder for a single percussion-gun, and the seventh for a double. The weight of shot for an ordinary piece of this kind may be one ounce and three-quarters; a much heavier gun will bear one ounce and seven-eighths. For a double gun an ounce and three-eighths may be used for the left barrel, and for the other an ounce and five-eighths. Many sportsmen load the left barrel with less shot than the right, which has to be fired at a greater distance than the first. A young sportsman, commencing to make experiments on the gun he is about to use in the field, should begin with small quantities of powder and shot, notice the effects produced by an increase, and endeavour to ascertain, with the most scrupulous care and nicety, the exact proportions which are best calculated for the make and calibre of his piece. All written rules only serve as general landmarks or finger-posts to direct the way to set out on the journey, but cannot supply the place of well-regulated experiments and accurate observations. It may be remarked, as a leading maxim in game-shooting, that heavy loading does not facilitate the sportsman's success. If too much shot be put into a gun, the expansive force by which the charge is thrown out will be disregarded, and, in consequence, both its range and propulsive power will be diminished; if, on the other hand, too much powder be used, it may be ejected, or at least disturbed, before it acts on the mass of shot. Such are the results of experience.

In loading a double-barrelled gun, the ramrod should not be put down one barrel whilst the other is being loaded; because, if a stray grain of shot gets down, it may be so fixed by the ramrod in the barrel, as not to be got out without difficulty; and it may even injure the internal coating of the barrel. After the fired barrel has been re-charged, the piece should be slightly shaken, so that it may be ascertained whether the shot in the right-hand barrel has been removed. If there is heard any vibration of the shot against the sides of the barrel, then the charge must be more firmly rammed down. The slightest vibration will detect the loosened shot.

Mr. Greucuer, a gentleman of great experience of the gun, says, in reference to the proper charge—"Suppose you begin with two drachms, and vary the charge one-eighth of a drachm each shot up to three-and-a-half drachms, or, as may be required, according to the length and bore of the gun, and, for precision, taking three shots for each charge, at a sufficient number of sheets of paper; whichever you find strongest, with the least quantity of powder, that is the best charge, as very likely the two additions of powder will shoot equally strong, and yet not stronger, because more of it remains unburnt. Therefore the least quantity that shoots equally strong is the
proper charge, which having once ascertained, never change for any other person’s plan. In respect to the proportion of shot, all guns, according to their bore and length, will shoot a certain weight and a certain size of shot best. A great deal of shot in a small bore, lies too far up the barrel, and creates an unnecessary friction; and the shot, by the compression at the moment of expulsion, becomes all shapes—a circumstance which considerably affects and modifies its flight. If too great a weight, the powder has not power to drive it with the speed and force required to be efficacious, because the weight is too great in proportion. Those who reason from mathematical calculation will object to this doctrine. They say, the greater the weight the greater the effect. No doubt it is so, if thrown with a proportionate force; but that cannot be obtained with a small gun. We must adapt the weight of projectile force to the power we are in possession of; and from experiments, accurately made and recorded, we find that a fourteen-gauge, two-feet-eight barrel, should never be loaded with above an ounce and a half of shot (No. 6 will suit best), and the utmost powder she will burn. A fifteen-gauge will not require more than one ounce and a quarter; and no doubt No. 7 would be thrown by her quite as strong as No. 6 by the fourteen-gauge gun, and do as much execution at forty yards with less recoil; and, setting aside all other reasons, we should prefer a fifteen-gauge gun, if both be of a length, as we should find as much execution at the same distance as with the other.”

As we have already observed, however, experience is the best teacher. That, and that alone, is the only true and safe director in the use of the gun.

To shoot a bird when on the wing is a feat requiring great practice, and one which it is sometimes very difficult to accomplish. Sometimes men are, themselves, not always in proper trim for shooting. We remember being out on one occasion, on the borders of Perthshire, for a whole day, with a good shot, and, although birds were not plenty, they were not scarce; yet we only killed a couple of brace. On other occasions the same shot was often most deadly. But there are all manner of grades of excellence in shooting; some will feel a degree of self-complacency if they hit one bird in ten; while others will only miss one out of an equal number. A good deal of the proficiency in shooting birds on the wing may be referred to bodily temperaments; some persons are so nervously constituted, and so hurried in their movements, that they never attain to the degree of coolness and self-possession requisite for a good and steady marksman. A nervous anxiety shakes their system too violently, and they fire without obtaining any decided aim whatever. The real foundation of the art of shooting flying will be found to be in the sympathy which exists between the eye and the hand, the sight and the touch, and the power of so combining, as it were, the sections of the two senses, that, in their united action, they seem to be the effect of one. The art of measuring distances, and directing objects to a definite mark, are learned by degrees; and so readily is this effected, that very often the best shots are totally unconscious of the internal process which is continually going on in their understandings, when in pursuit of their game. Some sportsmen shoot with one eye shut, others with both open. There is no rule on this matter; it is entirely resolvable into early training and habit in shooting flying. The great desideratum in all failures is a want of coolness; still, many writers say that coolness may exist in excess, and that many birds are lost from the fingers being too slow in their movements after the game is on the wing.

It is good to go through the entire manual training of shooting. To obtain a mastery in this fine art, it is best to begin at the beginning. When we commence to be taught the art of writing, we begin with strokes, and go on progressing, until we have, with practice, completely mastered the art of the calligraphist. So, with learning to shoot, we should commence in such a manner as will gradually lead us to the attainment of the end in the highest possible degree. With this point in view, the following plan has been recommended:—Let the handling and the shouldering of the gun be expertly acquired, in its unloaded state, taking care to look at the height, length of arm, and the inclination of the shoulder of the pupil. This handling of the fowling-piece should be practised for an hour or two for some days, until complete familiarity with all the
required movements is obtained. Expertness in rising or depressing the gun to every kind of level, and taking aim at various objects, should be acquired. Holding the gun firm to the shoulder is a great essential; for anything like looseness and unsteadiness in this particular is entirely incompatible with the art of shooting flying. The left hand should also be placed close, or nearly close, to the trigger—an act which, in a great measure, secures any injury from the bursting of the piece. This precautionary rule is, however, neglected by a vast number of able and expert shooters, who have perfect confidence in their guns; and who maintain, that by placing the hand a little forward, it prevents the piece from being point-heavy, which is apt to cause an unpleasant feeling.

After this initiation has been fairly passed through, the fields should be entered for the purpose of practising at living objects. Firing at martens and swallows has been recommended; but others do not think this to be the best means of acquiring the power of good flying shooting. The movements of these birds are altogether different from those which distinguish game of all kinds. Sparrows having been entrapped, and pieces of paper put round their neck, and then let off, make very good marks. Learn the art of keeping both eyes open. This is, with some, an extremely difficult matter to attain, as young lads are often from infancy accustomed to take aim only with one eye—the right one. These early habits are sometimes so powerful, that it is almost hopeless to expect their relinquishment in after life. "If the young shooter begins to shoot with both eyes open," says Colonel Hawker, "he will save himself the trouble of learning to shoot so afterwards. An aim thus from the right shoulder, comes to the same point as one taken with the left eye shut, and it is the most ready method of shooting quick." Celerity of motion should be learned; but the happy medium between snap-shot and dead-shot should be considered the principal point, and sedulously studied.

A steady and decisive mode of walking and standing is another point requiring great attention in the shooter. An indecisive gait, and everything indicating the slightest degree of hurry or trepidation, are inimical to successful sport. It is said that a firm placing of the limbs greatly assists the arms in readily and gracefully elevating and presenting the fowling-piece. In the regular ranks of the soldiers, we never witness anything like trepidation. There, every movement is performed with the utmost coolness and precision; and the same should be observed by the sportsman in the field. The gun should be carried with the barrel upwards, and sloped towards the left arm, the lock being clasped by the hand of that side, the fingers embracing the stock, which allows the arm, though supporting the gun, to do it with readiness and ease, and to be placed with facility within the grasp of the hand previous to the designed elevation. The points are, "to carry the gun with the cock inwards, and down, and the side of the stock imbedded against the inside of your left arm, taking an easy position, considerably below the chest."

"In the acts of cocking," says the clever author of the

"Kynopaedia," "let your fore-finger quit the front of the trigger, and, extending itself sloping forward through the guard, only feel the side of it with a gentle pressure. Your body, by this action of throwing out the butt, combined with the step-out of the left leg in taking form, will be brought with its weight principally upon that limb; a position assumed as more immediately called for, when the flight is nearly in a line from you, or to the left, which will comprise four out of five of all your shots." Again, when the word

Present! is used audibly or mentally, let the barrel, at the moment, inclined over the left shoulder, be swept in a circle forwards with a smart motion, the fore-finger of the right hand (sloping, as we have before placed it through the guard, and clear of the front of the trigger) being, as it were, the centre of motion upon which the gun turns during the sweep; by which action the butt should be raised nearly to its full height, and then brought back with something of a thump into its place within the shoulder, whilst, at the same time, an increasing grasp with the left hand, which till now has kept its hold rather loosely, combines with that of the right hand upon the grip of the stock, to keep it firmly there. The direction of the barrel to the mark, or what may be termed the line of level, to be taken, in the first
instance, a little below that which, as already
drawn by the eye to the object, we may distin-
guish by the name of the line of sight.
The latter should be firm and immovable; to
which a precise adjustment of the line of level
must finally be made by an easy flexure of the
upper part of the body altogether, but without
any loosening or twisting of the butt from its
firm hold within the shoulder; and on the in-
stant that you get these two lines in contact,
or, in other words, at the moment that you
bring the muzzle of your gun from your first
level below, bear direct upon the object.
In all these directions, examples, or illustra-
tions of them, should be given by the expe-
rienced shooter, when the eye of the pupil
would far more readily embrace their scope,
and the understanding comprehend their appli-
cation much easier than by any other mode of
tuition. Hence, if the tyro can be taken to the
field in company with a fried hand, or, in other
words, a practical sportsman, he will much
sooner attain a mastery over his gun, than he
will be able to do if he pursues his sport
tirely alone, and depending for success only
on the necessarily tardy progress of his own
experience. However acute may be his un-
assisted perceptions, his progress will still be
comparatively slow; therefore, he should en-
devour to court the experience of another,
who is an adept in his art, and who, generally
speaking, will afford him all the assistance
that lies in his power. There is this charac-
teristic of sportsmen—that they are rarely
niggardly in giving instruction in the use of
the arm in which they take such delight them-
selves. Their opinions, too, no matter how
widely they may differ, are always more or
less valuable. They are so much added to the
general stock of experience, and afford to the
tyro the greater variety to choose from. His
own practice must confirm him in the use of
the one or the other; and, no doubt, he will
act upon the one which, in his judgment,
appears the best. In giving his directions to
the tyro, Colonel Hawker thus writes, in
reference to the movements of the bird:

"Before an object crossing—full high for a
cird rising up, or flying away very low, and
between the ears of hares and rabbits running
straight away; all this, of course, in propor-
tion to the distance; and if we consider the

velocity with which a bird flies, we shall rarely
err by firing at the crossing bird, when
at forty yards, at least five or six inches
before it. As the barrels of double guns
usually shoot a little inwards at long dis-
tances, there is, so far, a preference in favour
of the right barrel for an object crossing to the
left, and vice versa; so that, if we were beating
along the sides of a hedge, it would be best to
keep the barrel next to it in a state of pre-
paration. Till the pupil is fully master of all
this, he will find great assistance from the
sight, which he should have precisely on the
intended point when he fires; he will thus, by
degrees, attain the art of killing game in good
style, which is done by fixing his eyes on the
object, and firing the moment he has brought up
the gun. He may then, ultimately, acquire the
knack of killing snap-shots, and bring down a
November bird the moment he tops the
stumble, or a rabbit popping in a furze-brake,
with more certainty than he once used to shoot
a young grouse in August, or a partridge in
September."

To young sportsmen, the Rev. B. Sym-
onds says—"When a bird gets up he is
certain he cannot kill it (we must premise
that his gun is uncharged), therefore he can
wait until he gets the bird at the end of
his gun. He must never draw unless posi-
tive of seeing the bird in that very point of
situation. Let it go; every fresh spring of
the bird will make the sportsman more com-
posed; and, as the tremor wears off, he will
grow more uniform in his manner of getting
to it, till, at last, he will cover it almost to a
certainty, or very near the same distance.
Let him accustom himself not to take his gun
from his arm till the bird is on the wing, and
ever to vary his eye from the very one he
first fixed upon. Three words should be men-
tally used, with a pause between, before he
puts his piece to his shoulder; this will keep
him, as it were, in awe of himself; and as
there is no charm in any particular combina-
tion of letters at this time, Hold! Halt!
Now! may serve as well as any. A day thus
spent, he may put some powder in the pan,
and flash away in that manner; the next, pur-
suing the former direction, till he can stare
with steadiness, and pull with a wink. The
day following, load with powder only; and he
should continue this lesson two or three days, more or less, till he is as calm as if the leather was still in the chaps. Now the grand and last trial—complete loading. If he feels any flutter or anxiety on his advance to the point, let him draw his shot at once; nay, powder also, before he goes up to his dog, and repeat this, *totties quoties*, till he has whipped himself into good temper, and disappointed himself into the accomplishment of his wishes. In cross-shooting, if a bird goes to the left, step forward with the right foot; and the contrary, if to the right hand. This removes at once the complaint often made, of not killing one way so well as the other. Shoot at the head in every direction, if possible; and there cannot be any necessity for greater allowance. In elevation, let the front of the guard be a stop for the grip of the left hand; in which situation, if the barrel should burst, it will not be so liable to be injured; and the thumb being erect, an avenue is artificially made by means of its corresponding with the cock nail, that gives great direction to the eye. The moment that the eye, in conjunction with the muzzle of the gun, bears upon the object aimed at, fire; for when the eye bears too long on the object, the sight becomes weakened, whilst the object itself is extending the distance between itself and the shooter."

One of the standing topics of discussion among sportsmen, *is the average distance of a fair shot*. Much has been said and written upon this question; and, like all questions upon which much is both said and written, it has become as hazy in some minds as a Scotch atmosphere in the month of November. Forty yards is, however, pretty generally allowed to be a fair average shot; but there are many who kill at almost double that distance. The subject, however, is not susceptible of any determined solution. Most sportsmen know, with tolerable accuracy, what can, and what cannot be done by their fowling-pieces.

A code of laws for the government of parties shooting in company, has been framed, in order to determine what is right and what is wrong practice in the field. In this code, all birds that cross, are to be considered as belonging to the gunner to whose side their heads are pointed, unless a previous understanding was come to, that either party may take an after-shot at a tailing bird. When single birds rise and go away fair for either party, it may be proper to have it previously understood that such should be taken alternately by each shooter.

*Precautionary observations* are commonly appended to all formal treatises on the gun. These are frequently of great value; yet they are often disregarded; and to the volume of accidents which have already taken place, through carelessness, an additional sheet is every season appended. Even this, however, is far from being a complete record of all that happens, whilst some of them are of the most painful description. The habit should be formed to attend to certain minute matters; when this is acquired, it becomes second nature, and affords a firm confidence in the mind of the sportsman himself, as well as in that of his friend.

In reference to the mode of carrying a gun, Mr. Daniel is especially particular. He says, "Always hold the gun with the left hand, close to the guard, and not forward upon the barrel, but strongly grasp it near the entrance of the ramrod, which has been very frequently strenuously recommended. All the requisite steadiness in taking aim, and even of motion, in traversing the flight of a bird, can be obtained by thus holding the heaviest pieces; and, in case of a barrel's bursting, the certainty of having a hand or arm shattered, by grasping the barrel, is reduced to a certainty of escaping some of the effects of such an accident, by placing the hand close to the guard beneath it. With double guns a danger arises, from the shooter, after firing but one barrel, often setting the butt of the gun upon the ground. A sense of self-preservation will soon render it habitual not to do this; and a man who is so absent, or eager, as to disregard this precaution, had better confine himself to carrying a cane, instead of a gun."

The following remarks are worthy of the sportsman's attention:—

1st. If you or your dog should at any time get a severe blow, instantly foment the wounded part for at least half-an-hour with warm water, as hot as can be borne, and you will thereby greatly reduce your sufferings, and also the time you will be kept from your sport.

2nd. If you burn yourself in shooting, wrap the part affected immediately in cotton, the application
of which, like magic, in ameliorating the effects of a burn.

3rd. If you should take cold, and the inflammatory process becomes rapid, bathe your feet in warm water, as hot as you can bear it; if a little salt or bran, or both, be added, so much the better. Get into a warm bed, and take some whey, or whatever can be got to promote perspiration.

4th. Never fast too long, and avoid anything approaching to excessive fatigue.

5th. Never go out with a stomach quite empty, to wait for game of any kind, particularly in the morning. Should you wish to rise early, before any of the household are up, you can have a little crust of bread or a biscuit, with a glass of milk, left for you the night before. This may be taken with a little sugar, nutmeg, ginger, and the yolk of an egg. These items are superior to what is called the "Doctor" (rum and milk), because you then dispense with taking spirit in the morning—a habit that should always be avoided, except you are sporting in a country where ague is prevalent. In this case a little spirit is advantageous.

6th. Never sit down with wet feet, nor with wet clothes on any part of your body. If a change cannot be procured, keep walking about; or, what is better, go to bed, till some dry clothes can be procured; or, if you want to start again after taking refreshment, first wet your feet with spirit or essence of mustard, and then be as quick as possible in taking your refreshments. Many take the spirit internally, instead of applying it to the feet; but this is invariably bad. Nothing produces chilly and damp kind of feelings readier than spirit taken internally under such circumstances. To keep the frame warm, dry, and comfortable, is the surest plan of increasing your sporting pleasures, and of rendering them really conducive to health.

If all sportsmen were aware of the care which some artists take of not introducing a false hue or shade into their drawings and paintings; or if they saw the care with which good authors criticise their writings, and substitute one word for another, they would surely be much more careful in a matter of infinitely more consequence to themselves. In other words, they would be extremely anxious in looking after all that relates to the use of the gun. When a keeper of the Earl of Chesterfield was preparing for the field, in January, 1759, and stooking to buckle on his spur, as he sat with his gun resting on his knee, and the muzzle close to his check, it seemed improbable that a part of the lock should break at that particular point of time; but his instantaneous death was the terrible effect of his not having guarded against what was possible. The muzzle of the gun pointing obliquely upwards, and between the left elbow and left check, if the piece fires ever so often by accident, can never do harm; and, from this position, it may be presented with more ease, expedition, and correctness, than from any other. Beware of the muzzle of the gun being kept hanging downwards: when so carried, the shot is apt to force its way from the powder, especially in clean barrels. If it happens that a space of sixteen or eighteen inches is thus obtained, and the gun fired with its point at all inclined downwards, it is ten to one but the barrel bursts. There are other perilous consequences besides the disruption of the barrel; for men, horses, and dogs, are in perpetual danger of being shot when a gun is carried in the before-mentioned pendent manner. In shooting with a stranger, who, perhaps, keeps his gun cocked, and the muzzle usually pointed to the left, plead for the right-hand station, and urge that you cannot hit a bird flying to the left. With a game-keeper, take the right hand without ceremony. In getting over a fence, endeavour to go last, notwithstanding the usual assurance of, "My dear sir, I am always remarkably careful," and, if a person beats bushes with a cocked gun, get out of his company as a shooter, with all possible expedition. Recollect, both in the house and in the field, always to consider a gun as loaded, and never suffer it to be pointed, for a moment, towards any human being.

Before entering upon the amusement of shooting, we will explain some of the terms used by sportsmen, and with which fowlers only are supposed to be acquainted. The following are the principal phrases:—A seige of herons and bitterns; a herd of swans, of cranes, and of curlews; a depping of sheldrakes; a covert of coots; a spring of teals; a goggle of geese; a solt, or sute, of mallards; a badelynge of ducks; a bevy of quails; a musteer of pheasants; a nye, or nide of pheasants; a corey of partridges; a walk of snipes; a congregation of plovers; a building of rooks; a full of woodcocks; a brood of hens; a murmuration of starlings; a flight of swallows; a host of sparrows; a charme of goldfinches; and a watch of nightingales.

Having now initiated the young sportsman into all that is necessary for the successful pursuit of his art, we will, in our next chapter, enter into the mysteries of Grouse Shooting.
CHAPTER IV.

GROUSE SHOOTING.—WHAT GROUSE ARE; WOOD GROUSE, OR CAPERCALLIE; BLACK GROUSE; RED GROUSE; PTARMIGAN; LOCALITIES OF GROUSE.

Having now treated of all that we deem the most essential matters to be attended to as the preliminaries to the actual sport of shooting, and having given such instructions as cannot fail to be serviceable to those who are desirous of entering the field as sportsmen, and of becoming what are usually called "good shots," we will now enter upon the actual practice of shooting itself; introducing the reader to the different sorts of game which have the magnetic power of attracting the lover of the gun from the mansion to the moor, where, under the influence of fair or foul weather, he is still an enthusiast in the pursuit of his sport. In the sense in which we have just used the word game, of course the reader will understand that we mean it to be applied only to such animals as are usually considered so in this country; or, in other words, to such birds and beasts as come under the protection of the game-laws. Such animals as lions, tigers, and elephants, may be accounted game in the eyes of the Indian sportsmen; but as these monsters of the woods and wilds of the tropics have neither home nor habitation in the moors and manors of Scotland and England, we shall have no occasion to make any observations on the best manner of shooting them. Our province lies within the boundaries of our own island; and it is to its feathered and furred wild inhabitants that our remarks will be confined.

WHAT GROUSE ARE.

Sir William Jardine informs us, in his Naturalist's Library, vol. iv., that, "by the word Grouse, we, in general language, are apt to associate our ideas with the common moorfowl. But, in the technical terms of ornithology, the generic name, Grouse and Tetrao, is restricted to those bearing the form of the European wood grouse, dusky grouse of America, &c. They are the largest birds of the family; of a very round and powerful form, and frequent healthy forests in preference to the wild and open moor; perch and often roost upon trees, where young shoots and tender bark supply them with food; and although the legs are plumed with short feathers, the toes are naked. The tail is composed of broad feathers, and is proportionally long and rounded. They are mostly polygamous, and the females and young differ considerably from the males; the plumage of the former being shades of brown and tawny, with black bars and markings; the colours of the latter distributed in broad masses of black, glossy green, or steel-blue, and deep brown. They inhabit North America and Europe; those of the latter country extending into Northern Asia."

THE WOOD GROUSE, OR CAPERCALLIE.

The wood grouse (Capercaillie, cock-of-the-wood, or giant grouse) is polygamous, and, when incubation begins, the male selects a situation remarkable for its conspicuousness; and here he commences his call which attracts the females, and which he accompanies by throwing himself into various attitudes. This call is described as resembling the word peller, peller, peller, which is answered by the females croaking somewhat like ravens, and rapidly assembling from all parts of the surrounding woods. When this gathering has become sufficiently numerous, the male descends from his eminence, introduces himself, and joins the company. His gallantry, however, soon ceases, and his love do not seem to partake of that romantic or inextinguishable nature which we have known to be exhibited in the history of higher races. When his females commence incubation, he abandons them, and skulks among the brushwood, where he renews his plumage, and leaves his wives to hatch, and rear their progeny as they best can. He stands at the head of feathered game in these islands, but he is very seldom to be
met with. From authentic accounts, it appears he once abounded in the forests of both Scotland and Ireland. Bewick describes him thus:—"He is as large as a turkey, and is about two feet nine inches in length, and weighs from twelve to fifteen pounds. The bill is very strong, convex, and of a horn colour; over each eye there is a naked skin of a bright red colour; the eyes are hazel, the nostrils are small, and almost hid under a covering of short feathers, which extend under the throat, and are there much longer than the rest, and of a black colour; the head and neck are elegantly marked with small transverse lines of black and grey, as are also the back and wings, but more irregularly; the breast is black, richly glossed with green on the upper part, and mixed with a few white feathers on the belly and thighs; the sides are marked like the neck; the tail consists of eighteen feathers, which are black; those on the sides are marked with a few white spots; the legs are very stout, and covered with brown feathers; the toes are furnished on each side with a strong pectinated membrane. The female is considerably less than the male, and differs greatly in her colours: the throat is red; the transverse bars on the head, neck, and back, are red and black; the breast is of a pale orange colour; belly barred with orange and black; the top of each feather is white; the back and wings are mottled with reddish brown and black; the scapulars tipped with white; the tail is of a deep rust colour, barred with black, and tipped with white."

The pairing season of these birds commences about the spring, the sexes having assembled together in packs, during the winter, of fifty or a hundred in number. When the pairing has been effected, the female makes a rude kind of nest; she lays from eight to sixteen eggs. The young, like farm-yard fowls, are active, and can run along as soon as they leave the shell; and it is even said that they have frequently been seen looking after their living, with part of that appendage hanging to them. These birds are now rare in this country; but, in some parts of the continent, particularly in Sweden, they form an important item in the game-list. They are commonly, in this country, flushed from the ground in autumn, when they are feeding on a species of berry, of which they are passionately fond. Their flights are but very short; and if there are any trees in the way they usually alight upon the branches. In the forest, capercailles do not always present an easy mark; for, dipping down from the pines nearly to the ground, as frequently is the case, they are often almost out of distance before an aim can be properly taken. No. 1 or 2 shot may answer very well, at short range, to kill the hens; but, for the cocks, the sportsman should be provided with much larger. Towards the commencement, and during the continuance of the winter, the capercailles are generally in packs; these, which are usually composed wholly of cocks (the hens keeping apart), do not separate until the approach of spring. These packs, which are said to comprise fifty or a hundred birds, usually keep to the sides of the numerous lakes and morasses, with which the northern forests abound; and to stade the same in the winter-time with a good ride, is no ignoble amusement.

There have been various attempts made to re-introduce these birds into Great Britain. The late Mr. Powell Buxton, and the Earl of Breadalbane, spared neither money nor care to have them reared in this country. But the success attendant on their anxiety has not been great.

THE BLACK GROUSE.

The Black Grouse (Tetrax Tetrix, Linn.) is a noble-looking bird, and is commonly designated the Blackcock, and the female the Greyhen. According to Mr. Daniel, the male bird is from one foot ten inches to two feet in length; but some specimens have exceeded this by three inches. The breadth is about two feet nine inches. The ordinary weight is nearly four pounds; but some stray birds in the moors of Cumberland, have gone beyond this by half a pound and more. The bill is of a dusky black; the eyes dark blue, below each of which there is a spot of a dingy white colour, and, above the larger, one of a bright scarlet. The plumage of the whole bird is very imposing. It is of a shining bluish black, and very glossy over the neck and rump. The covert of the wings are of a sort of dull brown; the greater are white, which runs along to the ridge of the wings, forming a spot of
that colour upon the shoulder when the wing is closed. The quills are brown; the lower parts and tips of the secondary ones are white, and make a bar of white across the wing. There is likewise a spot of white upon the bastard wing. The legs and thighs are tolerably thickly covered with dark brown feathers, mottled with white. The toes are toothed on the edges, like those of the capercalle. The tail is much forked, and consists of sixteen black feathers; the end of the outer feather, which curves outwardly, seems as if separated or cut off. The feathers under the tail, and the inner covers of the wings, are of a pure white. The female bird is considerably less than the male; having a length only of one foot six inches, and a breadth of two feet six inches. Its weight averages about two pounds. Like the male bird it has a dusky mark beneath the eye. The head and neck are marked alternately with bars or stripes of dull red and black; and the breast has a dusky white and black appearance. The coverts of the wings, the back, and the tail, are of the same colour as the neck, with the exception of the red being of a deeper hue. The inner webs of the quill feathers are spotted with black and white. The inner coverts of the wings are white, and there is a white spot on the shoulder of both the male and female birds. In the latter, the tail is slightly forked, and it consists of eighteen feathers richly variegated with red and black. Under the tail the feathers are white, marked with a few bars of black and orange. The nest on the ground is of the most simple and artless kind. The female lays from six to eight eggs, which are of a dull yellowish-white colour, marked with a number of very small ferruginous specks, and, towards the smaller end, with some blotches of the same hue. They are hatched late in the summer. The young males quit their mother in the beginning of the winter, and keep in flocks of seven or eight until spring. During that period they frequent the woods. In their first feather they resemble their mother, and do not acquire their full plumage till near the end of autumn, when it gradually changes, and assumes that bluish-black colour which it afterwards retains.

The black grouse, like other members of the family, are polygamous; and in January, February, and March, the plumage of the male bird assumes a rich glossy steel blue, which, with his majestic form, imparts to him a very imposing appearance. At the beginning of spring, when the severity of winter has passed, the males, after feeding, may be seen congregated together on some turf-furze, sheep-fold, or rude paling, pluming their wings, and practising various devices to attract the notice of the female. "Here," says Sir William Jardine, "after, perhaps, many battles have been fought, and rivals vanquished, the noble, full-dressed blackcock takes his stand, commencing at first dawn; and where the game is abundant, the hills, on every side, repeat the murmuring call, almost before the utterers can be distinguished. The cocks strut around the spot selected, trailing their wings, inflating the throat and neck, raising and expanding their tails, and puffing up the plumage of those parts, and the now brilliant wattle above the eyes, displaying the beautifully contrasting white under-cover, and imitating, as it were, the attitudes of the little turkey-cock. He is soon heard by the females, who crowd round their lord and master." After incubation is fairly commenced, this fighting among the males is at an end. When the young are hatched, the mother guides them to some high situation where there is plenty of shelter from long grass and luxuriant herbage, and where an abundance of food can readily be obtained. This consists, in summer, of the seeds of the cranberry, crowberry, and blackberry, &c.; and in the winter, of fir shoots, and the catkins of hazel and birch, which impart to their flesh a peculiar flavour, well known to epicures.

The black grouse are to be found in many districts of England—on Leith Hill, Ashdown in St. Leonard's, and in the New and the Bere forests. They likewise abound on the estates of the Marquis of Anglesa, at Beauchef Castle, Staffordshire, Barnstable, Devonshire; and in many of the moor districts of Northumberland, Durham, Cumberland, Westmorland, and Yorkshire.

The shooting of the black grouse does not commence till the 1st of September; and they are esteemed as royal game. They are generally considered as shy birds; but those who are acquainted with their haunts, find no great difficulty in reaching them. They are partial
to long ling and roughish copse-wood. Under the bank of a deep ravine, particularly in mid-day, and if there be a cold wind blowing, they will be readily found. The young are comparatively tame till they have mates; and the sportsman has often almost to kick them out from among low thick brushwood. After they have done their first coat of feathers, they seem to increase in wisdom and cunning; and frequently bid defiance to the art of the shooter.

Black grouse require full-sized shot; and a single is often preferred to a double-barrelled gun. According to the strict laws of sporting, it is not held good to kill the hen bird.

In Russia these birds are numerous, and they are captured by the use of decoys. Huts, full of loopholes, like little forts, are built purposely in the woods. Decoy birds are placed at a short distance from these spots. These are mere artificial imitations, made of black cloth. As the grouse assemble, the shooters fire through the openings; and if they succeed in keeping themselves out of sight, the birds are not frightened by the mere report of the gun. In this way large numbers are killed. During the winter season, in Siberia, the inhabitants capture them in the following manner:—A certain number of poles are laid horizontally on forked sticks, in the open forests of birch; small branches of corn are fixed to them by way of a lure; and, at a short distance, certain tall baskets, of a conical shape, are placed with the broadest part uppermost: just within the mouth of the basket a small wheel is put, through which passes an axis so nicely fixed as to admit it to play very readily, and, on the least touch, either on one side or the other, to drop down and again recover its position. The birds are soon attracted by the corn on the horizontal poles; and, after alighting upon them, and feeding, they fly to the baskets, and attempt to settle on their tops, when the wheel drops sideways, and they fall headlong into the snare.

THE RED GROUSE.

The Red Grouse (Tetrao Scoticus, Linn.) has the same noble bearing characteristic of his other congener, and is, in the northern parts of Great Britain, the bird that gives the most shooting of the Grouse family. Its length is about fifteen inches, and it weighs about nineteen ounces. The bill is black, the eyes hazel, and the nostrils shaded with small red and black feathers. At the base of the lower bill there is a white spot on each side. The throat is red, and each eye is arched with a large naked spot. The body is beautifully mottled with red and black feathers, and has a tortoise-shell appearance. The breast and belly are of a purple hue, and crossed with small dusky lines. The tail consists of sixteen feathers, of equal lengths; and the four middlemost are barred with red, and the others are black. The quills are of a dusky colour, and the legs are clothed with soft white feathers down to the very claws, which are of a strong texture, and of a light-brown colour. The female is a little less than the male. The naked skin above each eye is not so conspicuous, and the colours of its plumage, in general, are much lighter than those of the male.

This species of grouse pair in the spring, and lay from five to ten eggs, and occasionally, but not often, twelve. Sometimes these are found on the bare ground, and sometimes on a rude kind of nest, composed of a little heather and moss. This is generally placed in a somewhat sheltered and secluded situation. Both male and female birds attend to the young, and guard them with all the vigilance of which they are possessed, against their numerous enemies, in the shape of vermin, and birds of prey. The young, or poultis, follow the mother the entire summer, in the same manner as partridges do; nor is the male bird neglectful in watching over the welfare of the brood, although he generally keeps alone, and remains some distance from them. The practice of burning the ling is often very destructive to eggs of the grouse; and thousands are annually destroyed in this way.

The habits of red grouse are not of so wild a nature as are those of others of the same family. Birds of this kind have occasionally been entirely tamed. A gentleman in Ireland had, for several seasons, two brace of birds, so domesticated, that he used to take them into his parlour, where they played with his setter dogs. They are often found descending from the moors, and locating in the vicinity of cornfields, and sheltering themselves among the stubble, both of barley and oats. In severe winters, when pressed for food, they will leave
SHOOTING.

the hills and visit the cultivated grounds, and will even, sometimes, be found perched on the tops of the labourers' dwellings.

A bird of this kind ought to be a favourite with mankind—a favourite, we mean, apart from any gastronomical pleasures its flesh may afford. "In hunting him, " the light air of the early morning," says Sir William Jardine, "and the free, open, almost unbounded prospect, exhilarate the spirits; while the boldness of the game upon discovery, utterly uttering his cry of warning to his brood—his vigorous, lengthened flight, so as to create doubts of his being again seen—carry with them a continuance of excitement long after it is satiated with following the skulking black game, or the more rural one of waking-up partridges. But, independent of this claim upon the sportsman, it has another. The red grouse is exclusively confined to the British Islands, and has never been found in any part of the continent; and it would be much regretted, if unlimited persecution, or want of preservation, should, in after years, exterminate the bird so exclusively natural."

The shooting of red grouse has been largely handled by different writers; and many minute particulars, as well as contrary opinions, have been laid before the public on the subject.

Mr. Daniel informs us, that in shooting red grouse, the old English spaniel or setter is better adapted to follow the gun than the smooth pointer. The former has a better nose, and his feet are defended by long hair from the chafing effects of the ling, which, in dry weather, cuts like wire. Setters, also, have the advantage of being generally of higher metal than pointers, and exhibit more zeal, and more untiring courage. They require, however, a plentiful supply of water; and this is sometimes a great drawback to their use during the very hot months of August and September. Some gentlemen well skilled in grouse-shooting, take the pointer in preference to any other kind of dog; so that, perhaps, upon the whole, there may be a fair balance of advantages accorded to each kind.

Red grouse differ in numbers and in size, according to the season. Wet, cold, ungenial weather, not only retards the pairing of the birds, but is likewise extremely prejudicial to the hatching of the broods, which, in fine sunny days, take great delight in revelling in the luxury of a pure atmosphere. When they emerge from the shell, they assume, among sportsmen, the name of creepers; and when they advance to a more stately size, they are called pouls. They are to be found on their feeding-grounds, both morning and evening; but when disturbed, seek out some favourite spot of shelter, chiefly in those sections of the moors which abound with long ling and roughish brushwood.

The time of the year has considerable influence on the habits and movements of the grouse. Frosty weather is favourable for their capture, as they then seem very torpid and lifeless. Wet and windy weather is not favourable to the shooter. At such times the birds leave the high grounds, and seek out sheltered spots in some comparatively dry and secluded localities. Red grouse generally become very wild in the months of November and December; although, when the season is favourable, some good days' sport may still be obtained. The lower and sheltered grounds are then the best places to find them; for the advancing season daily cuts off their resources in food, and they are driven to seek provender in lower and more cultivated grounds.

In rising, grouse almost take a perpendicular direction, and then fly in a straight line, at an elevation of ten or twelve yards. The exact moment to fire, is when they are just about to change from the perpendicular to the rectilinear direction. There is a sort of pause in their flight, which is favourable to the sportsman, when he can avail himself of this movement. But this requires a quick eye, and a good deal of practice. When red grouse begin to associate in large numbers, as they invariably do about the end of October, or the first or second week in November, they are approached with considerable difficulty; for they post sentinel birds to keep a look out, and it is a mere chance if you can get within a hundred and fifty yards of them. When the weather, however, becomes, and continues long cold, this wildness is considerably abated, and they often show themselves as tame as barn-door fowls.

Colonel Hawker directs that, "for shooting grouse, select a fine sunny day, from about eight till five in August and September, and
from eleven to three at the later periods of the season, as they are then extremely wild, and will only lie tolerably during the few hours which are favoured by a warm sun. Unless the weather is very fine, you will see them running, and getting up five hundred yards before you. In this case, let one person take an immense circle, so as to head them; while the other remains behind to press them forward when he is ready; and, above all things, you should, for killing them at this time, use either No. 1, 2, or 3 shot, in the largest single gun you can possibly manage; or, what is better, a good stout double gun, with Elly’s cartridges. Grouse take a harder blow than partridges, and do not fly quite so regular and steady.”

Should a sportsman be solitarily engaged in shooting red grouse, he ought not to travel far, but hunt the ground well. This not only saves much fatigue, but often leads to success. Birds do not generally take very extended flights; and if the ground should be irregular or undulatory, they will commonly be found on the sides of some hill, or knoll, or where the ling is long and strong. They are always variable, even when there is no apparent cause to the sportsman’s comprehension for their being so. Their movements depend upon circumstances which are hidden from our serenity, and which we have not generally the power to discover. There is always a chance of meeting with birds where the berries of the ling are plentiful, particularly if these localities be visited at a proper time of the day. Noontide is not a very favourable period; but when the mists hang long on the mountain’s brow, it is the only time a shooter has to practise his art. Then he should be up and doing. He should range the country in the spirit of one who is not only bent on making his sport a pleasure, but a source of health, heightened by the enjoyment of the beautiful and the grand in Nature, wherever she unfolds those attributes before him. It should always be remembered that the mere amusement of shooting is by no means all that is to be obtained from a judicious handling of the dog and gun. The field and the forest, the mountain and the glen, have each its appropriate points of attraction. One has its beautiful line to gaze on; another its melodious birds to delight the ear; another its majestic form towering up to the sky; whilst another affords a channel to a stream of “sweet waters,” that is rolling itself to some distant loch. These are some of the objects to be enjoyed whilst engaged in shooting, with which they should be connected in the mind of every sportsman.

THE PTARMIGAN.

The Ptarmigan, or White Grouse (Tetrao Lagopus, Linn.), is found in almost every part of Europe, the northern portions of Asia and America, and, some writers say, even in Africa. According to Sir William Jardine, it is spread over most of the Alpine districts of Europe; and is sought for with great perseverance, as, to the inhabitants of these inhospitable regions, it is an actual necessary of life. This bird is nearly of the same size as the red grouse. Its bill is black, and its summer plumage is a pale brown, or ash colour, and the upper parts of the body are mottled with a number of small dusky spots and bars. On the head and neck these bars are broader, and more intermingled with white; as are, likewise, the wings, with the exception of the shafts of the quills, which are black. In the winter season this plumage is changed into pure white, except that, in the male, there is a black line between the bill and the eye. The tail consists of sixteen feathers, the two middle ones being ash-coloured in summer, and white in winter; the two next, slightly marked with white near the ends, and the rest are wholly black. The upper tail coverts are tolerably long, and almost cover the tail entire. Its habitat is found to be on high and lofty grounds, and it can bear the most intense cold. It even lives and thrives amid the snows of Greenland. In Britain it is chiefly found in the Highlands of Scotland, in the Hebrides and Orkney islands, and, occasionally, in the more elevated localities of Cumberland and Wales. Bellon tells us, that it sedulously avoids heat, and loves the biting frosts on the tops of the highest mountains; and when the snow melts on the sides of the hills, it constantly ascends to loftier regions, till it gains the summits on which it forms holes, and burrows in the snow. These birds pair at the same period as the ordinary grouse. The female lays eight or ten eggs, which are white,
PTARMIGAN.

SHOOTING.

[378]

ptarmigan.

There is no form of nest prepared; they are laid on the bare ground. In winter the birds congregate in flocks; and they are so little accustomed to the devices of the fowler, that they suffer themselves to be easily taken either with the snare or the gun. They feed on the wild and rough produce of the hills, which imparts a bitter taste to their flesh, though it is not by any means unpalatable. It is of a dark colour, and, in taste, resembles that of the hare.

This kind of grouse has attracted the attention of sporting writers, on account of the singularity of its character and habits; and many valuable reflections on the general harmonies of nature have been made on the subject. It is contended that its plumage is admirably and singularly adapted to the general appearance of the grounds it frequents. The brown patches of health, on the rocky declivities of the mountains, are so assimilated to the broken and blended tints of the summer plumage of the bird, that it is very favourable for the purpose of concealment. When the whole country is covered with snow, and presents one extended mass of dazzling white, the dress of the bird is again suited to this change of nature, and greatly assists in its preservation. The plumage is now not only white, but very thick and downy; and even the legs are thickly clothed with feathers resembling hairs, which secure the limbs to the very toes.

As we have already intimated, the ptarmigan family are to be met with in all the elevated and Alpine regions of Europe, and in North America.

"The palaces of Nature, whose vast walls
Have pinnacled in clouds their snowy scalps,
And throned Eternity in icy halls
Of cold sublimity, where forms and falls
The avalanche—the thunderbolt of snow!
All that expands the spirit, yet appalls,
Gather round those summits, as to show
How earth may pierce to heaven, yet leave vain man
below."

In Greenland they are taken by nooses, hung to a long line drawn by two men, who drop them over their necks. They eat them with train oil, or lard; and their skins are converted into shirts to wear next the skin. The Laplanders take them by forming a hedge with the boughs of birch trees, leaving small openings at certain intervals, and hanging on each a snare. The birds being tempted to come and feed on the buds of catkins of the birch tree, pass through the openings and are caught. In North America, in the territories of the Hudson's Bay Company, and in the neighbouring countries, there are immense numbers of ptarmigan taken every season. And here it is curious and instructive to notice, that as the frost becomes intense, the feathers of the bird, with the exception of those of the wings and tail, become double—a downy one shoots out from the base of each, which provision seems admirably fitted to protect the bird from the piercing effects of the long-continued cold. In the months of October and November, flocks of two and three hundred assemble, and take up their residence among the willows, the tops of which they greedily devour. Hence they are often called the willow partridge. We are told by travellers, that their flesh is much esteemed at Hudson's Bay, and in many provinces of North America. Nets, twenty feet square, and supported on poles, are used for their capture; and they are so numerous, that ten thousand have been taken from November to April. In the locality of Hudson's Bay, they must, at one period, have been extremely abundant. Sir Thomas Button relates, that in the winter of 1612, he took eighteen hundred dozen of these and other fowl. This capture may surprise us; but the success and appetite of M. Jerome, and his companions, surprise us still more, when it is known that there were taken and eaten, in one winter, between himself and seventy-nine others, 90,000 grouse, and 25,000 rabbits, being about 1,125 grouse, and 312 rabbits per man.

GROUSE LOCALITIES.

Even from the general conversation of sportsmen in London, it may be known that grouse-shooting, of which they are so passionately fond, has its locality principally in the north. Being off to the moors, is synonymous to being off to Scotland; for it is there, among the hills, that the grouse is to be found; and, after the 12th of August, the gun may be heard reporting its presence with a rapidity that proves the fatal work in which it is engaged. In former days, there used to be found con-
considerable quantities of black grouse in the New Forest of Hampshire, in some parts of Devonshire, Staffordshire, and Derbyshire; but it is now questionable if there be any, either of this species of the grouse family, or of the red grouse, in these parts of England. The moors of Yorkshire are, to the London sportsman, the nearest spots where any portion of grouse can readily be obtained; and even there, for several years, there has been a diminution of their numbers progressively going on. The increase of manufacturing and mining operations in this section of the kingdom, has been the principal cause of this; and, as those are further extended, the birds will retreat still further northward, until they finally locate themselves amid the solitary wildernesses of Scotland.

The cheap and rapid mode of travelling by railway has, however, thrown open to the English shooter, considerable tracts of moorland that were scarcely accessible before; he can traverse the country from London to the distant Highlands of Scotland in a day, and can find moors and game to his heart's content. There are, however, wide ranges of grousing country nearer home. The moors of Westmoreland, Cumberland, and Northumberland, are very extensive; and there are great numbers of grouse upon them, of all kinds. There are, in Westmoreland, shooting districts of immense extent; but the country is so wild, bleak, and mountainous, that a guide is necessary for strangers, and a pocket compass is indispensable. The Cumberland moors are likewise extensive, and pretty well supplied with grouse; but here, too, the country is exceedingly wild and rugged. In the neighbourhood of Hexham, in Northumberland, and in the moors belonging to the Duke of Northumberland, at Keildar Castle, grouse were wont to be plentiful, and the range of country is a very interesting one in point of scenery. England, Ireland, and Wales, however, must yield to Scotland as grousing countries.

This comparatively Alpine land can now, by railway and steamboat, be threaded in all its localities, at a very small cost of time and money. The sportsman can transport himself, in a few hours, from one spot to another, a couple of hundred miles apart; and this gives him a great command of the whole country.

If one spot does not come up to his expectations, he can remove himself and establishment to another, an advantage which the grouse-shooters of former times did not possess. Then, a removal to any great distance engrossed nearly half of the shooting season, and was attended with great expense.

To expatiate upon the noble scenery which a Highland shooting excursion presents, is superfluous, as the localities most remarkable for this have often been described by tourists, anglers, &c.; but still, to an intelligent and imaginative grouse-shooter, these mountain peaks and passes must be ever new and full of interest. In many places, the sportsman will find guides indispensable, especially if he wander among the more northern heights, such as those of Ben-na-buird, Cairngorm, and Ben-na-macdui, which lift their snowy summits to an elevation of nearly four thousand feet above the level of the ocean. An expedition with the gun to any of these places is quite an adventure, and must be performed on foot; and as there are few cottages to be found amongst them, the sportsman must not forget to supply himself amply with provisions, as the sharpness of the air whets the appetite, and hunger is a bad companion upon the solitary sides of a measureless mountain. Everything here is upon a scale of singularly wild and rugged magnificence. The mountain torrents—some of which are almost one continued waterfall—foam and dash over ledges of rock, and peculiarly affect the mind of the spectator by their grandeur and turbulence. The higher glens are likewise surrounded and hemmed in by rocks and precipices, clothed with the birch and heather, and so far removed from human ken, and human sympathy, that they are seldom visited, save by the red deer and the eagle. Here shooting is both a fatiguing and dangerous amusement; for if the sportsman be a complete novice to such scenes, the chances are that he will tumble over some pointed and half-hidden elevation, and, perhaps, break both his head and his fowling-piece. When less elevated localities are frequented, the shooter will find a small Highland pony of some service. Though attended with care and trouble, it will transport him more easily over a larger tract of country; but where a man is in robust health, and has youth
on his side, there is nothing like footing it; as it keeps him independent in his movements and rambles, improves his health, and exalts his spirits, and enables him to enjoy his sport with an intensity unknown to the pampered body of the luxurious loungers.

We have already observed, that England, Ireland, and Wales must yield the palm to Scotland as a grousing country; but there are in Wales considerable ranges of grousing grounds; and the Black mountains, which divide the counties of Hereford and Brecknock, have some good sporting localities. The country is like the Highlands, wild and rugged, and the sportsman will find some of the higher elevations laborious to reach. The only method, in many cases, is to follow the rough paths of the mountain torrents, which, being dry, afford a kind of winding way to the highest grounds. The picturesque beauty of the country is beyond all description and praise, and must be seen to be duly appreciated.

In Ireland there are some tolerable hills, but they are far behind Scotland, and even some parts of Wales. In the counties of Cork, Limerick, and Tipperary, in the vicinity of the Galty mountains, there are both black and red grouse, with a fair sprinkling of other kinds of game. There is likewise a fair portion of grouse in the Kerry, Wicklow, Cloughheen, and Negagh mountains. The moor bird shooting is not quite so fatiguing in the Emerald Isle as it is in Scotland; but the general accommodation is superior in the latter country to that of the former. Ireland is, by some, highly extolled for grouse shooting; while others speak very indifferently of its supplies of this kind of game: but the truth will be found to be, that in some well-preserved localities there is an abundance; while in others, which are equally prolific, there is a remarkable scarcity, arising chiefly from poaching, and indirect means taken to destroy them. In travelling through this country, it has been remarked that, wherever there is anumerous and poor panasenary, game of all kinds is scarce. It can easily be imagined how precious to a half-starved Irishman will a well-stocked preserve of grouse be; and how difficult it must prove for him to keep his hands off them, as a nice relish to his meal of potatoes.

The following remarks of Mr. Lascelles, on the subject of breaking dogs to the moors, and other points, are really so practically valuable, that, notwithstanding their length, we cannot resist the temptation to quote them:—

"An English atmosphere," he observes, "is generally much more favourable to this diversion than a Highland one, as, from the innumerable lochs, and the immediate vicinity of the ocean, the mountains are so concealed in the vapours arising from them, as, at all times, to render a day's sport extremely precarious. A very little will soon cause a grouse to become wild and unassailable; and the chance of pursuing him to any advantage is very uncertain, until, perhaps, in the middle of the day, when the sun may establish a temporary influence. His habits are exceedingly regular, always taking his food and water at particular times; the latter at noon: he will then retire to the sunny side of some bank, and, beneath the cover of high heath, bask in all the delight of imagined security. If a good shot suddenly come upon a brood in this situation, he may, very frequently, annihilate the whole; for they will immediately separate in different directions, and each bird will get up singly, so that he has nothing to do but restrain the ardour of his dogs, and in some measure, also, that of himself. The impetuosity with which many sportsmen, and young ones in particular, travel over their ground, is one great reason why they meet with so little game. They no sooner find a brood, and gain one shot, than they give up any idea of further pursuit, without even marking the progress of their flight, or that of an individual, which may, perhaps, be induced to shorten or vary his, from the infliction of a wound. From the circumstance of heath presenting so continued and smooth a surface, and the little variation in every object upon it, it is more difficult to mark down a grouse with certainty than a partridge; but, by following the course of him carefully with your eye, and afterwards trying in that direction, you will seldom fail of gaining his retreat. It should be a maxim with all sportsmen, never to leave a yard of ground untired which is likely to harbour a bird; by this means you will sooner learn the nature of game of all descriptions, teach your dogs a better system of duty, and give yourself a very
decided advantage indeed, over every other person who pursues a different method. According also to the number of dogs you hunt, at the same time will be your chance of sport; where you possess such a latitude of range, a greater scope is open to your exertions; and, as the fatigue of moor-shooting is much more severe than that of any other amusement, you should endeavour, by every means, to reduce its effects. Two brace of good steady dogs are, in my opinion, the number best calculated for this purpose; and they will work as long as any gentleman ought to continue out. The plan which many sportsmen adopt, is to shoot with one brace of pointers till the time of dinner, and then take a brace of fresh ones for a couple of hours in the afternoon, working the four alternately, morning and evening. The method suits very well with such a system; but there are few men who feel inclined to renew their endeavours after a cool and comfortable repast; and a good fire then becomes a luxury, which we are seldom willing to make so immediate and voluntary a resignation of. Provided every dog be tolerably steady, you can scarcely, in reason, trust too many together; but, where there is a want of discipline, or where it is totally disregarded, it would be absolute folly to use more than one. The opinion which is held by many, of the advantage attending a dog's running up to his game, appears to me a strange subversion of every principle of profit or satisfaction; it totally ruins that cool and even conduct which should characterise a good shot, and excites a contention generally terminating in mutual discontent. The danger, also, is, in many respects, not the least objectionable feature; for, in the anxiety of the moment, you may forget to mark the second barrel; and, should you stumble, which is by no means an improbability, its contents may be lodged in the first object that unfortunately intervenes. I have known an instance, also, where, in the struggle for possession, the thumb of the sportsman had nearly been sacrificed to the consequence of disappointment in his dog.

"There is yet another objection to this mode of breaking, which is, perhaps, still more serious; and that is, the alarm that is given not only to a single bird, but frequently to a whole brood or covey, which instantly take wing, and de-
next tried a very sharp spiked collar with cord attached to it; and to have him at all times within reach, I loaded him with shot, by hanging about two pounds round his neck, so that he might be said to be in a constant state of exertion. Finding, however, that all this was mere trifling, and that after reducing the length of the cord to about two yards, and fastening the end to the middle of a good strong hazel—which had the effect, at any extraordinary or improper exertion, of pulling him completely over—I had not the most distant prospects of remuneration, I was at the point of yielding to necessity, when a circumstance happened, which gave me an opportunity, once more, of trying how far this subordinate spirit might be reduced. The old bitch began to show symptoms of approaching desire; and, during the period of their amour, I allowed him a perpetual and unlimited intercourse with her, keeping him, at the same time, low in flesh, and taking them both out together as usual. In the course of a couple of days, I found so decided a change for the better, that I persevered more diligently in the plan of restriction; which, at the end of a fortnight, so completely succeeded, as to leave me in possession of an animal which, of his kind, was the very best I ever saw. The produce, also, of that litter was invaluable, and required less breaking than any dogs I ever was master of."

As sportsmen often make presents of game, it is very necessary to know how they should be preserved and packed, so as to keep them agreeable and sweet until they arrive at their destination. Mr. Thornhill says—"If you wish to send your game to any distance, never draw it, particularly a grouse; that is, do not follow the usual directions of taking out the entrails. The best mode is, not to pack them until they are perfectly dry. First of all, procure bladders, and put a brace or more in one, if the bladder will contain them; tie the bladder tight round the neck, and seal it with sealing-wax, to prevent the air from getting in; and, in that state, if they are put into boxes, they will keep for three weeks, if required." The compiler tried this experiment last year, and found that it answered better than any mode he had ever before made use of. He sent a gentleman some game from Cumberland to London, packed as described; and the gentleman not being at home, it lay in the box till his return, which was fifteen days after its arrival; and this gentleman assured him that he was surprised to find, on eating it, that it was as good as if killed only the day before, and was perfectly sweet, although the distance it went was nearly three hundred miles. Colonel Hawker says—"To send grouse any distance, put pepper to the parts where they have been shot, as well as into their mouths; then pack them, carefully separated from each other, and kept as air-tight as possible in boxes of hops."
CHAPTER V.

THE PARTRIDGE.

The partridge of Britain (\textit{Tetrao Perdicæ, Linn.}) is of two kinds; the one is the grey, or common partridge; and the other is sometimes termed the French partridge. Bewick thus describes the common partridge:—"It is about thirteen inches in length. Bill light-brown, eyes hazel; the general colour of its plumage is brown and ash, beautifully mixed with black. Each feather is streaked down the middle with buff; and the sides of the head are tawny. Under each eye is a small saffron-coloured spot, which has a granulated appearance; and between the eye and the ear there is a naked portion of skin, of a bright scarlet, which is not very conspicuous except in old birds. There is a crescent on the breast, of a deep chestnut; and the tail is short and drooping; the legs are a greenish white, and furnished with a small knob behind. The female has no crescent on her breast, and her plumage, in general, is not so distinctive and bright as that of the male. The moult takes place once a year." It was long a received opinion among sportsmen as well as naturalists, that the female partridge has none of the bay feathers on the breast, like the male. This, however, on dissection, was proved to be a mistake; for Mr. Montague, happening to kill nine birds in one day, with a very slight variation as to the bay mark on the breast, was led to open them all, and found that five of them were females. On carefully examining the plumage, he found that the males could only be known by the superior brightness of colour about the head; which alone, after the first or second year, seems to be the mark of distinction. Partridges are chiefly found in temperate climates, the extremes of heat and cold being equally unfavourable to them. The female lays from fourteen to eighteen or twenty eggs, making her nest of dry leaves and grass, upon the ground. The young birds run as soon as hatched, frequently encumbered with a part of the shell attached to them. The affection of the partridge for her young is peculiarly strong and lively; she is also greatly assisted in the care of rearing them by her mate; they lead them in common; call them together; gather for them their suitable food, and assist in procuring it by scratching the ground. They frequently sit close to each other, covering their offspring like the common hen. In this situation they are not easily flushed: the sportsman who is attentive to the preservation of his game, will carefully avoid giving any disturbance to a scene so truly interesting; but should the pointer come too near, or run in upon them, there are few who are ignorant of the confusion that follows. The male first gives the signal of alarm by a peculiar cry of distress, throwing himself, at the same time, more immediately in the way of danger, in order to mislead the enemy: he flies, or rather runs along the ground, hanging his wings, and exhibiting every symptom of debility, in order to decoy the dog, in the too eager expectation of an easy prey, to a distance from the covey. The female flies off in a contrary direction, and to a greater distance; but returns soon after by secret paths; and she then commonly finds her scattered brood closely squatted among the grass, when she collects them with haste, and leads them from the danger, before the dog has had time to return from the pursuit.

The partridge subsists chiefly upon grain, along with small seeds from other plants. Her nest is made on the ground in grass fields, among standing corn, in clover, in furze, and sometimes even at the top of a ditch. The eggs are generally laid in the month of May; and, from this time to the latter end of June, the process of nidification takes place. In all the stages of this natural process, the male bird takes a certain share. When the brood is hatched, he manifests the greatest solicitude, and leads them abroad in search of ants' eggs, and larvae among insects. His call is in
SHOOTING, [PARTRIDGE SHOOTING.

a sharper key than that of the female. Naturalists have noticed that the two birds have various notes or cries, as if to distinguish their several states or conditions, as to safety, food, or danger. When they settle down in the evening, their jucking is well known. Mr. Lascelles tells us that he has often watched their movements, and listened to their cries for hours; and always observed the male bird even more solicitous, in appearance at least, than the female, for the provision and protection of the brood. This care, however, is left to the female as soon as the birds are able to fly. Even then her watchfulness continues, and, indeed, seems increased. She is never far from them, but searches for food for them, and takes them abroad to their scratching-ground; and when they seem tired, she gathers them all around her with great care. When they are about their full size, or within a third of her own bulk, they are left, in a great measure, to shift for themselves.

PARTRIDGE SHOOTING.

There is no sport in which the gun is employed as the instrument of amusement, so fully and so universally practised as the shooting of partridges. It is more homely and domestic than moor shooting; and can be enjoyed by those whose strength and age render them less capable of pursuing sports requiring greater physical exertion. The successful prosecution of it must, necessarily, vary with the numerous circumstances under which it is enjoyed. If a sportsman has a limited estate with which he is well acquainted; if he has himself taken great care of his coveys of birds; knows their haunts, their times of feeding, and resting; if his enclosures are small, and well fitted for the birds taking short flights; if these, and many more minute and favourable matters fall to his lot, his sport may, ceteris paribus, be reasonably expected to be much superior to what a mere stranger to the locality would find. There are scarcely any two shooting grounds, or any two sportsmen, that can fairly be put on a par with each other, in all their diversified characters; therefore it is that so many varied accounts are found of the sport, and so many different adventures encountered in its prosecution. Every shooter has a history or tale of his own to tell; he has joys and sorrows with which strangers do not interfere; and he lives and moves in a little world of his own creating.

Distinguished sportsmen inform us, that the footing of partridges, though a very requisite qualification in pointers, is one of the last things that should be expected from them, as they are not to be relied on until they fully comprehend from the sportsman that they are not to catch the bird; and that they are only required to point out where it is. It is well known that partridges will generally lie closer and better to dogs that wind them, than to such as track them. The reason assigned for this is, that when they are winded, the dogs do not go straightforward towards them, but follow the scent left by their devious course. When birds see dogs tracking their footsteps down the wind, they will fly off, for their scent cannot be caught by the dog till he is near them. Another matter is of some importance in commencing partridge shooting in September; and that is, that dogs brought immediately from the moors, and put upon the hunting of the partridge, are in many instances, for some days, unfit for their duty, till they are again broken-in to their new task. The hunting of grouse in the moors is altogether a different operation from the work to be done in the fields in September. A dog that is really well trained will soon find himself at home in both occupations; but when this is not the case, there will always be more or less of disappointment experienced from the sudden transition from two such opposite conditions of life.

It has been recommended, that to be early in the field is necessary for any one who desires to secure a good day's sport at partridge shooting; but here Colonel Hawker steps in and says, "that he never saw much execution done before breakfast." To this it has been replied—"True; but without putting ourselves to the expense of sending two or three sturdy fellows to warn off intruders, if the birds have escaped being killed by that time, they are certainly dispersed abroad; and the advantage of our knowing their feeding and basking grounds is nullified." However this may be, we believe it is a general opinion amongst the experienced that the colonel is correct. If it were possible to take anything like an accurate census of the success of sportsmen in partridge
shooting during the months of September and October, we think it would generally be found that the most productive hours range from eleven till three in the afternoon. Of course general rules of this kind cannot be laid down but with many reservations: we believe, however, the result of a test of this kind would establish the truth of the point without any doubt. There are other advantages, however, to be realised by the early-rising sportsman, unconnected with the capture of game. The habit induces good health, and tends very much to strengthen and preserve it. It has an excellent and sustaining effect on the animal spirits; and these are by no means of slight consideration. After the month of October, and from this to the end of the partridge season, we should not insist on being earlier in the field than about mid-day; as, after this period, the weather becomes lowering in the fore part of the day.

Both the weather and the season have a great influence over the birds, as well as the state they themselves have been in, relative to quietness, from previous fowling excursions. The flights they take vary with the nature of the country in which they are bred. Where the enclosures are small, and the general aspect of the country undulating, short flights are taken; but, where the fields are large, and the landscape open and level, the birds will often take a mile or two at one flight.

As a general rule, it might be asserted that a prudent sportsman will not injure his diversion by following the birds every day in the same track. Relative to the shooting of partridges in windy weather, too, there is great difference of opinion. The weight of argument, however, seems in favour of those who maintain that this kind of weather is not, upon the whole, favourable to sport. Indeed, when it is boisterous, it can only be favourable under one view, and that is on account of birds not so readily hearing the approach of the sportsman. It may likewise be observed, that in a high wind they seem bewildered, and will often lie so close as to afford good sport; but then it is again found by experience, that for one windy day, when they will lie like stones, they will, other ten days, be as wild as hawks, particularly if there be showers of rain with the wind. In the latter case they generally betake themselves to the woods and to furze; and cole-

seed is said then to entice them. In Ireland, partridges, in a high wind, uniformly make for the potato fields. In weather of this kind, the sportsman should always take the windward side of his beat, otherwise he will run a chance of driving them off his ground, and into the hands of other parties who may be abroad on the same mission as himself.

In the practice of mid-day shooting, it may be laid down as a common rule, that, in ordinarily fine weather, the birds leave their feeding localities about ten o'clock in the month of September, and eleven in October; but after this period, their movements become less regular, so that no calculation relative to their movement can be depended on. This has been attributed to the variable weather to which a Scotch climate is subject, and to which all things living in wood or wilderness must be subservient. When there is a rapid succession of rain, sleet, snow, wind, and sunshine, we have a variety of disturbing causes operating on both the sportsman and the birds; therefore any universal rules must, in such cases, prove almost entirely useless. The stubbles may be tried in mid-day, sometimes with advantage, for the birds do not always leave them for basking grounds. These stubbles are the principal feeding localities; and as the day advances, birds are almost sure to be found at one time or another. When birds of prey appear, coveys will often disperse, which is favourable to the sportsman. One bird will perhaps take shelter near a clod of earth; another will run behind a tuft of grass or a low piece of copse; and a furze-bush may shelter another. Sometimes, in the latter end of the season, the partridge will be in foul lands—such as are left in a rough state before the agricultural operations of spring commence.

Among partridges, there are always more cocks than hens; and this often tends to check the breed considerably. The hens are so tormented by the numbers of males, that they drop one egg in one place, and another in a different spot. It is said, the best mode to destroy the superabundance of males is, during the first three weeks of the season, to net the covey, and destroy all the old cocks, leaving as many young hens, and even one less; for it is certainly better that the old hen should look for the cock, than a number of cocks run
SHOOTING, [PARTRIDGE SHOOTING.

after one hen. It should be recollected, that where old birds are left, they will, at the pairing season, drive off the young ones, and prevent their breeding; for, let any sportsman declare if ever one find a brace of partridges in the shooting season that have not bred (and are termed by sportsmen a gelt pair), whether he has not found a covey near the same place—a circumstance which can only be accounted for by the old birds driving the young ones from the ground, and preventing their breeding there. It is, therefore, a wrong notion that some birds should not be killed every year; and those gentlemen who have manors, will find, that by not allowing some to be killed, in a short time their grounds will be entirely destitute of game. The late Earl of Kingston had a great quantity of grouse on his mountains in Ireland before they were preserved; but he thought that, by leaving them quiet for a couple of seasons, he should have had a much greater abundance; he therefore did not allow a shot to be fired on those mountains for two seasons; and, it is well known, they were carefully preserved during the whole time. On collecting, however, a large party the third season, and going out to grouse, many of the gentlemen who had been in the habit of shooting there prior to its being preserved, were surprised to find so great a scarcity. The reason of this was, that the older birds had driven the young ones off, and all the mountains adjoining his lordship’s preserves, were swarming with game, although they had not been preserved.

The principle of domesticity is not very strong in the partridge. Those birds which have been reared under a common hen, soon manifest their dislike to restraint; gradually become wild, and eventually fly off altogether to enjoy their native freedom. We have heard of one being reared by a clergyman, which became so tame that it would come to the parlour window to receive its breakfast, and would, also, occasionally enter the house. It was not, however, completely domesticated.

It is generally said, that broken coveys yield the best sport; and that, while the young birds have the old ones with them, they are "up to every move on the board," but when deprived of their natural leaders and protectors, they seem lost, and have no settled idea of safety.

This is the fortunate time for sportsmen to make play upon them, and press the dogs to their duty in tracing them from one spot to another.

As the season advances, the size of the shot to be used for partridge shooting should be enlarged. For the first fortnight, Nos. 5 and 6 are recommended; after this, Nos. 4 and 5. In October, No. 3 will be found the most eligible.

RED-LEGGED OR GUERNSEY PARTRIDGE.
This is the Tetrao Rufus of Linnaeus, and is often called the French partridge. It is larger than the grey, and the bill and irides are red. The forehead is grey brown; the hind head is rufous brown; the chin and throat white, encircled with black; and there is likewise a band of white over each eye to the hind head. The fore part of the neck and sides of it are cinereum, with two spots of black on each side, and the hind part of the neck is rufous brown. The back, wings, and rump are of a greyish brown; the breast, pale ash colour. The belly, sides, and thighs, are rufous; the sides marked with lunular streaks of white, black, and orange. The quills are grey brown, with the outer edges yellowish. The tail is composed of sixteen feathers; the four middle ones are rufous on both sides. The legs are red, and the male only, has the blunt knob or spur behind. Mr. Daniel says, that it is a common pastime in the Isle of Cyprus to use these birds as we do game-cocks, for the amusement of the people. This partridge is abundant in most parts of Europe, Asia, and Africa; in many parts of Italy and France; and also in the islands of Madeira, Jersey, and Guernsey.

Surprising stories are told of their numbers in some countries. In the Isle of Namsio, they are so common as to amount to a positive nuisance. The inhabitants make a rule to collect as many eggs as possible every year, in order to lessen the breed, which, in some seasons, have been so numerous as to have eaten up the entire produce of the harvest crops. These eggs, which are taken by thousands, are prepared with different sauces, and supply the people for a considerable time. Tournefort says that partridges are so tame in the Isle of Scio, that they are driven to seek

544
their food in the fields, like so many sheep, and that each family entrusts its partridges to the common keeper, who brings them back in the evening; and he calls them together with a whistle, even in the daytime. Another account states that, in the country around Trebizond, a man was seen leading above four thousand partridges; he marched on the ground, while the birds followed him in the air, until he reached a certain camp, three days' journey from Trebizond; when he slept, the birds alighted to repose around him, and he could take as many of their number as he pleased. We are told that, in Provence, in France, persons have acquired the art of assembling numerous flocks of partridges, which obey the voices of their conductors with wonderful docility. Willoughby mentions, that a man in Sussex had, by great skill and attention, made a covey of partridges so tame, that, for a wager, he drove them before him, from that county to London, although they were free, had their wings fully grown, and in right feather.

The red partridge takes up its habitat in mountainous regions, well covered with wood. Its flesh is tender and white, and, by many gastronomes, is considered of a richer flavour than the flesh of the grey partridge. The French make it into pies, which are highly esteemed. From the common partridge it differs in its habits, from being found in flocks; while the other species are only known in coveys; and the red bird perches likewise on trees, which the ordinary bird never does.

"So far back as the time of Charles IL," says Mr. Blaine, "several pairs of these red-legged partridges were turned out about Windsor, to obtain a stock; but they are supposed to have mostly perished, although some of them, or their descendants, were seen for a few years afterwards. The late Duke of Northumberland preserved many, in the hope of their increasing upon his manors; but the late Earl of Rochfort, and the Marquis of Hertford, were at the most expense and trouble to establish them in this country. Both of these noblemen had not only numbers of the birds sent over from France, but, also, at a proper age; by this means there are now plenty of the red birds upon the latter nobleman's estate, near Orford in Suffolk." These birds, however, are not so agreeable for the table as our own native partridge; nor do they afford sport equal to that afforded by the other.

"September comes to cheer the Fowler's heart,
And raise his anxious hopes; day after day
He marks the fruitful country change around,
With eager eye. First, from the fertile meads,
Divested of their widely waving head,
The pregnant hay-rich rises. Gentle swains,
If chance should lead you to the chosen spot,
Where the shy partridge forms her simple nest,
The embryo offspring spare; and when your sport
Leaves the grassy valleys, should your foot
Approach the helpless brood, step back with care,
Nor our fond hopes destroy."

We will close this chapter with an extraordinary account of the enemies of game, captured a few years ago on estates of the Marquis of Ailsa. It is taken from the columns of the Inverness Courier:

The Marquis of Ailsa has, for some years, encouraged his gamekeepers in the destruction of vermin, by paying so much per head for those brought in. Every keeper and assistant-keeper has a record of all the vermin killed by him; and receives payment every three months accordingly, besides the regular and liberal wages to which they are entitled for their services. All kinds of vermin were thus brought low—even to the jackdaw and common rat, which, we are informed, caused great destruction to the eggs of pheasants and partridges. The rat has become very common there, and is found to burrow in rabbits' holes to such an extent, that, in ferreting rabbits, it sometimes happens that a rat and a rabbit are shot right and left. Whole broods of young pheasants and partridges have been found dead, and partly eaten, near rats' holes, and sometimes even young hares and rabbits. The owl, generally supposed to be harmless, has been shot with young game in its talons; and hedgehogs have been found with large accumulations of egg-shells in their burrows, or in the long grass where they coil themselves up, and have always been taken in traps baited with rabbits, hares, or wood-pigeons. Adders are included among the vermin to be destroyed on the marquis's property, but we believe they do not injure game. In four years and a-half, the sum paid on the estate of Culzean and Craigieburn moors, in Ayrshire, for vermin destroyed by the keepers, amounted to £231 13s. 10d.
CHAPTER VI.

THE PHEASANT.

There are two sporting varieties of the pheasant—the phasianus colchicus, Linnaeus; and the phasianus torquatus, of Temminck. They interbreed, however; and from this circumstance it has been supposed, by naturalists, that the difference between them arises more from accidental causes than from any law determined by the will of nature.

Bewick describes the common pheasant as being two feet eleven inches in length. The bill is of a pale horn colour, and the nostrils are hidden under an arched covering. The eyes are yellow, and surrounded by a space, in appearance like scarlet cloth, finely spotted with black. Under each eye there is a small patch of short feathers, of a dark glossy purple; the upper sections of the head and neck are of a deep purple, inclining to glossy green and blue. The lower parts of the neck and breast are of a reddish chestnut, with black indented edges; and the sides and lower portion of the breast are of the same hue, with rather large tips of black on each feather, which, in various lights, vary to a glossy purple. The belly and vent are dusky; the back and scapulars beautifully variegated with black and white, or cream colour speckled with black, and mixed with deep orange on all the feathers, edged with black. On the lower parts of the back is a mixture of green; the quills are dusky, freckled with white. The wing-coverts are brown, glossed with green, and edged with white; the rump is a pale reddish brown, and the two middle feathers of the tail are about twenty inches long; the shortest on each side less than five, and are of a reddish brown, marked with transverse bars of black. The legs are dusky, with a short blunt spur on each; but in some old birds, the spurs are sharp as needles, and between the toes there is a strong membrane. The female is a good deal less, and is not gifted with that variety and brilliancy of plumage which characterises the male. Her general colours are light and dark brown, mixed with black; the breast and belly are beauti-
In Siberia, the pheasant is also abundant; and, though not originally belonging to the American continent, has been introduced to it. They are, however, not very well adapted for moving from place to place, on account of the shortness of their wings. From this cause, we are informed that they are kept in complete imprisonment in the Isolo Madre, in the Lago Maggiore, at Turin, as they are not able to make their flight over the lake. When they make the attempt they generally perish. It is stated by Sonnini, and other travellers, that the pheasants of some of the northern islands of the Archipelago, and which come thither from the woods of Thessalia, are larger and handsomer than those of other countries; and that it is a great source of amusement among the Turks, to let birds of prey, which they carry in their hands, fly at them. When the pheasant takes its flight, the bird of prey, which they let loose, hovers above it, and compels it to perch on some tree. The former then places itself on another branch, over the head of the pheasant, and keeps it in such terror, that it suffers itself to be approached, and taken alive. This fact, it is remarked by Sonnini, sufficiently develops the mystery of fascination.

As a bird for the table, the pheasant is extremely salutary. When ancient physicians made comparisons as to the wholesomeness of any viands, the pheasant was always chosen as the standard of excellence. The hens are the most juicy, and, in every way, preferable to the cocks; still the true sportsman will never kill a hen if he can help it. They are sweetest roasted; and the best mode of dressing a cock is to stuff him with the lean of the inside of a loin of beef cut into pieces, the size of dice, and well seasoned. The gravy issuing from the beef gradually diffuses itself over the flesh, and renders it less dry and hard than it is when destitute of this supply.

Exclusive of the common pheasant, there are six other varieties; namely, the gold, the silver, the ring-necks, the white, the pied, and the Bohemian. That the ring-necked pheasant and the common pheasant interbreed has been denied, or at least doubted, by several naturalists of note. The ring pheasant, it is said, is a native of China, where the common species are very abundant; but there is nothing to establish the fact that it interbreeds with the common pheasant. The eggs of the ringed bird are of a pale bluish colour, and marked with small spots of a deeper tint; while those of the common pheasant are of an olive white, and are destitute of any spots. In a wild state the ringed species are uniformly less in size than the common bird, both in length of body and in tail. The head of the former is of a whitish fawn colour, tinted with bluish green; and above each eye there are two white lines, which constitute a sort of eyebrow. The marking in the back of the ringed kind is different and smaller; and the rump feathers display the same peculiar tints which the mixture of fawn and greenish blue exhibits. But the most distinctive mark of difference is, that the white ring is broadest upon the sides of the neck—a circumstance which cannot be overlooked in considering this question of identity. The female of the ringed pheasant is likewise less than the female of the common kind, both in size and in length of tail. The entire question, however, of distinction, is not by any means satisfactorily settled. Sir William Jardine says—"The pheasant sometimes also crosses with the domestic fowl. M. Temminck mentions this as requiring great attention to accomplish; but, where poultry are kept upon the borders of a wood abounding with pheasants, it occasionally happens, and would do so more frequently if favourable opportunities occurred. A specimen in my own possession, exhibiting all the mixed characters, was procured in a wild state. M. Temminck also records a solitary instance of a male between the female pheasant and male golden bird, which exhibited a curious but splendid mixture; all his endeavours, however, to procure a second specimen were ineffectual. The common pheasant also breeds freely with the ringed bird, and the offspring is productive. This has been considered by many as a proof that these two birds were identical; but, in the whole of this order, and its corresponding one among quadrupeds, this law has a much more extended modification, and can scarcely be taken as a criterion, except in very opposite instances."

The rearing and preserving of pheasants forms an interesting branch of sporting science. The bird being naturally strongly averse to domestication, it is subjected to many usual-
ties which lessen its numbers, and which greatly prevent its numerical increase. Could they be housed, and headed, and secured at night like our common farm poultry, they would "multiply and replenish the earth;" but it has been found, over and over again, that the young birds which may have been hatched under a hen, although they apparently might assume many of the habits of tameness and domesticity which are characteristic of common poultry, yet, if any one approach them unawares, they fly off to the nearest cover in a state of complete wildness. Mr. Waterton, of Walton Hall, whose studies, in the various species of animal nature, have been extensive, says, "that, notwithstanding the proximity of the pheasant to the nature of the barn-door fowl, still it has that within it which baffles every attempt, on our part, to render its domestication complete. What I allude to is, a most singular innate timidity, which never fails to show itself on the sudden and abrupt appearance of an object. I spent some months in trying to overcome this timorous propensity in the pheasant; but I failed completely in the attempt. The young birds, which had been hatched under a domestic hen, soon became very tame, and would even receive food from the hand when it was cautiously offered to them. They would fly up to the window, and would feed in company with the common poultry; but, if anybody approached them unawares, off they went to the nearest cover with surprising velocity. They remained in it till all was quiet, and then returned with their usual confidence. Two of them lost their lives in the water by the unexpected appearance of a pointer, while the barn-door fowls seemed scarcely to notice the appearance. The rest took finally to the woods at the commencement of the breeding season." For more extended information on this subject, consult Loudon's Magazine of Natural History; Mowbray's Treatise on Breeding and Rearing Domestic Poultry; and the Rural Sports of Mr. Daniel.

Pheasants have, in many instances, been collected in considerable numbers; and under the name of batteaux, have served for gala days of sport to the nobility and gentry. These exhibitions were painful, and totally opposed in principle to the real spirit of English sports. We never could comprehend a man's feelings in making a great slaughter of game under such circumstances. Sport it certainly is not. To enjoy and obtain this, there must be a given portion of uncertainty and trouble connected with its prosecution. If a man could kill all the game of an extensive and well-stocked preserve in an hour, there would be no sport in the case, in the true sense of the word. It would be one of the dullest and most uninteresting acts of his life; but where he has to seek, and to find, and to ramble for miles through a thickly-wooded or moorish country, there is pleasurable excitement produced; and this is the sustaining principle of pure sport, and the true source of all the enjoyments which the pursuit of wild animals can confer on man. It is to wander about; a constant prey to the alternations of hope and fear; the disappointments met with on the eve of realised advantages, that constitute the current of exhilarating feeling and lively sentiment, which we connect with the healthy and natural indulgence in field sports generally. It is a bad spirit for a real sportsman to cherish, to be always craving for great success, and to be perpetually out of humour both with himself and every one about him, if he does not get his bag sooner and better filled than his neighbours and competitors. There is an exclusive and selfish bitterness lying at the root of all such trains of thought, and the habits they engender; and the best receipt for eradicating this pernicious principle is, to look lightly and carelessly on the sport, and to make it a means, and not an end.

Indeed, we know from experience, as well as from what is daily passing around us, that it is impossible to keep large collections of pheasants from depredations. The slightest noise disturbs them in the night-time, and induces them to crow; and this discovers the places in which they are congregated, when they become the easy prey of the poacher. "When once they are frightened from their roost," observes Mr. Waterton, "they never perch again during the remainder of the night, but take refuge among the grass, and underneath the hedges, where they fall an easy prey to the fox, the cat, and the stoat. A poacher armed with a gun, finds a cloudy night fully as good for slaughter as one on which the moon shines;"
and if larch trees grow in the wood, to these
be resorts, knowing, by experience, that the
pheasant prefers this kind of tree to any
other." And then—

"What avails his glossy, varying dyes,
His purpl'd crest, and scarlet circled eyes,
The vivid green his shining plumes unfold.
His painted wings, and breast that flames with gold!"

Pheasants are subject to considerable
changes; one of which is, that in certain cases, and in
certain years, the female bird assumes
the appearance of the male. This curious fact
induced Dr. John Hunter to make a series
of experiments, with a view of ascertaining
whether there was in reality any transfer of
gender accompanied by this change of plumage
and outward appearance. But he found no
organic change whatever in the generative
organs. The diseases to which the pheasant is
subject are but little understood. It is said
that they die off suddenly about the time they are
being denuded of their crest and tail feathers,
without any apparent illness, having an abun-
dance of food, of which ants and their eggs
form a part. Good air, exercise, and even
choice grass plots, will not arrest the ravages
of the complaint. It has been recommended,
by way of cure, that, as in Asiatic countries,
of which the bird is a native, it lives very much
on aromatic plants, all remedial measures
should take this circumstance into considera-
tion. Spices and stimulants are recommended,
with nutritious diet, chopped eggs, and shred
beef. Pepper pods, and other aromatics, are
likewise used, in small quantities. In spite,
however, of all care, great mortality sometimes
prevails among the pheasants of particular
localities.

**PHEASANT SHOOTING.**

On the 1st of October—which is an inter-
esting day to aristocratic sportsmen, with their
well-trained dogs—pheasant shooting begins,
and there are a variety of opinions among
sportsmen as to the case with which this spe-
cies of bird may be shot; some averring that it
is difficult to bring it down; whilst others
hold that there is no difficulty whatever.
Much, however, depends upon the tempera-
ment or nervous system of the shooter, his
experience, and his practice.

The noise which a pheasant makes when it
takes wing—the whirr with which it rushes
through the leaves, sends a momentary thrill
through the frame of some men, quite suffi-
cient to shake their steadiness of aim, and
send their shot nowhere, after it has been
ejected from the muzzle of the gun. Steadi-
ness is the great matter in exploits of this
kind; it determines the relative portion of
skill which a man throws into such pursuits.
The spaniel is much recommended for pheas-
ant shooting; and Mr. Daniel considered any
other kind of dog out of place when this
sort of game was the object of pursuit.
"Spaniels," says this authority, "for pheas-
ant or cock shooting cannot be too strong,
too short upon the legs, or have too much
courage; the thickness of the coverts will
oppose, and, sometimes, almost overpower
even this combination of form and spirit.

* * * Should the woods be very extensive
when spaniels are steady from hares, they
cannot well be too numerous; but if given to
hunt hares, they disturb the pheasants. Upon
no account accept or keep a spaniel—it is
needless to tell a sportsman not to breed from
such—which has any taint of the blood in his
pedigree, although for generations back; they
will be sure to hunt hare in preference to
winged game; and the stock may be crossed
everlasting, may attain beauty, strength,
symmetry, yet this latent spark of the harrier
will never be extinguished." Some shooters
use beagles in pheasant shooting with good
effect; and even terriers are employed in some
districts. But much depends on locality. In
thick hedge-rows, young woods, furze planta-
tions, and entangled underwood of any kind,
such dogs as the beagle and terrier may be
better suited for pheasant sporting than the
spaniel; but where the grounds are com-
paratively open, the latter are to be pre-
ferred.

For pheasant shooting the sportsman should
be early in the field, and he should scour the
stubbles of wheat, barley, and bean fields well.
In very bright days, the woods should be care-
fully explored, for the birds often betake them-
selves to them in such weather. Cover beat-
ing is very essential, and the grounds should
be thoroughly tried both with the dogs and
the beaters. A nye of pheasants are often
found huddled together within a very small

549
SHOOTING, [PEHAANT SHOOTING.

compass. Every section and crevice of a cover should be run over, as birds are frequently found when the sportsman is not expecting them. We have already remarked, that no sportsman will kill a hen pheasant if he can help it. As she is the rearer of the stock, she ought to be most carefully preserved.

"But when the hen, to thy discerning view,
Her sable pinions spreads, of dusker hue,
The attendant keeper's prudent warning hear,
And spare the offspring of the future year;
Else should the fine, which custom laid of old,
Avenge her slaughter by the forfeit, gold."

The veteran Daniel is very particular in reference to the proper training of the dogs to pheasant shooting, as they are very apt to disturb the game, if not completely reduced and brought to a knowledge of their duties. "They disturb the pheasants," he says, "who first fly up, and perch upon the lower boughs; and the ground of the covert is in vain traversed, and beat for birds that are already some yards above it; in short, a spaniel that follows a hare further than whilst in view, is never worth keeping. Other circumstances to be minded are, that when a spaniel is once put into covert, he is never to quit it to range in the fields, which some slippery ones will do, whilst their owners are beating within it. When a spaniel owns a haunt, and quests freely, there should be no disappointment; whenever the notes are doubled, their master should be certain there is game, and accordingly press forward. Much depends upon the practice which spaniels have, the constant use, and the killing of game to them, are as essential to the steadiness of a high-mettled spaniel as to a high-bred fox-hound; neither can be worked too hard, if kept well in blood." The writer then goes on to state, that one of the chief conditions of obtaining this desirable end is, that the dogs be of pure breed. There must be no crossing, no contamination of the hound in their blood, as we have already observed, or they will be ill-adapted for the duties they are expected to perform. As an instance of an evil of this kind, he gives the following:—"A stronger instance," says he, "could not well be exhibited than in the spaniels which belonged to Lord Waltham and Mr. Hoare. A road only parted the seats of these two gentlemen, and their gamekeepers frequently shot in the woods together; their dogs were equally handsome; but those of the former would drive hares the whole day through, and consequently sprung everything that accidentally lay in their course; whilst those of the latter no more ran hares than they did sheep; they would indeed find hares, but follow no further than they saw them. They were always in their places, twisting round every stub with that agility, and possessed of such fineness of nose, that neither woodcock nor pheasant could escape their search. Lord Waltham's spaniel bitches had originally a cross of the beagle; and although this was tried to be remedied by resorting to the best dogs, the tendency to hare could never be subdued."

A similar case occurred in the north of England, among the dogs of the late Ralph Lambton, Esq. He had some favourite spaniel bitches that had originally a cross with a bloodhound; and this corruption was continually manifesting itself in the conduct of his shooting dogs, whenever sheep or domestic animals of any kind thwarted their movements. That old and excellent sportsman used jealously to observe, that they would retain their taint, as mankind are doomed to bear the weight of their original transgression, till the end of their existence.

Whether it be the particular nature of the ground on which pheasants locate themselves, or whether there be anything peculiar in their scent, we cannot determine; but, even the best dogs are often in fault whilst engaged in pheasant shooting. Without attempting anything like a solution of this singularity, we give the fact for the benefit of the reader.

The season of the year has a great influence upon the success of pheasant shooting, and there is a considerable difference between the character of October and January birds. At the fall of the leaf the birds are scarcer, and a vast deal more cunning, taking the alarm at the slightest noise made, by the approach of the sportsman. In the opinion of many experienced pheasant shooters, December ought to close the season; for it is contended that, if prolonged later, the birds will fly off and mate with other birds, and will not be likely to remain, if the noise made by the reports of the gun be long continued in every direction around them.
We have already alluded to battue shooting, which was formerly common in all parts of Europe, as well as in Great Britain; and must again characterise it as a murderous proceeding, which fills us with horror, rather than admiration, on account of the indiscriminate slaughter perpetrated upon the game races on such occasions. In most books on shooting, relative to the most distinguished of these gatherings among the nobility and gentry, they are minutely detailed; but they are of little or no interest now to the real sportsman.

In Sweden there is something of the battue shooting prevalent; but it differs, in some essential particulars, from what was, and, in some instances, still is, followed in France and Germany. Indeed, all over the continent there are innumerable traces of this kind of sporting with the gun; but not of the kind which can add much to a true sportsman's knowledge, or his love for his favourite amusement. In every kind of sports, there should, at least, be some portion of reason and sentiment thrown into them, or they will soon excite disgust, rather than pleasure, in the breasts of all who have any pretensions to humanity, or are even a little removed above the brutal biped, who is guided in his pleasures neither by the laws of reason nor the sentiments of humanity.

In India, even, they have their batteaux; and as long as these are confined to the destruction of such animals as are destructive to man, they are excusable, and may, by many, be considered even laudable. Mr. Johnson, in his Indian Field Sports, gives us a description of the manner in which one of these celebrations is conducted. “The day before the hunt, or driving commenced, several hundred people were sent to the farthest extremity of the reserved cover, where they fixed on a proper place, and set the nets, which extended about a mile, not in continuation, but at intervals. They required four or five elephants, and twenty or thirty bullocks to carry them. Each net was about forty feet long, and seven feet high; the cords being of the size of a man's little finger, lightly twisted, with meshes about eight inches square, made without any knot whatever, simply by twisting the cords into one another, by which they were rendered more elastic, less visible to the animal, and not so cumbersome and heavy as if made with knots. Sometimes three or four knots were placed in succession, touching, or overlapping one another; but more frequently they were intercepted by jungle, which was made almost impenetrable, by stakes driven down in the midst of it, and thorns twisted between them.”

Such are the preparations for an Indian battue, which is attended by men, women, and children, all armed with some kind of instrument, either of offence or terror. The children and the women, no doubt, carry the instruments of terror, which are such as will make the loudest noise, in order to frighten the horned beasts from the jungle into the nets laid to entrap them. The slaughter, on these occasions, is sometimes immense; but, as it is generally perpetrated upon the most ferocious and dangerous animals, it excites emotions of a very different kind from those that arise in witnessing the ignoble slaughter of beautiful and unoffending birds. In the destruction of the former, the inhabitants of a village or town, secure with greater certainty the safety of themselves and their property. In the destruction of the latter, it deprives the forest of one of the most beautiful of the ornithological species, and retrenches the pleasures of the naturalist, as well as those of the true and considerate sportsman.
CHAPTER VII

THE QUAIL.

The Quail (Tetrao Coturnix, Linn.) is described as being fully seven inches long. The bill is dusky; the irides hazel, and, in old males, yellow; the crown of the head is black, transversely marked with rufous brown; and down the middle is a yellowish-white line. Above the eye, in a backward direction, is another line of the same colour; and on the chin and throat is a black mark, which has a turn upwards towards the ears. The remaining parts are white, and the hind portion of the neck is black. The scapulars and tail-coverts are of a rufous-brown tint, and the middle of each feather is streaked with yellowish white, surrounded more or less with black. The sides are of the same colour, but not having quite so much of the white streaks. The breast is light ferruginous brown; shafts white; belly paler. The wing-coverts are pale rufous brown, streaked like the back, but more minutely distributed. The quills are dusky; the outer webs more or less mottled with yellowish white. The tail is dusky, tipped with white, and consists of twelve short feathers hidden by the coverts. The hen bird is distinguished by having little or no black on the chin or throat, and by a dusky mark passing from the ears downwards. Some black spots are likewise seen on the chest, and the coverts of the wings are barred with yellowish-white streaks.

The quail is very widely distributed, being known almost throughout the world, with the exception, it is said, of America, where it has not hitherto been discovered. In the countries of the European continent it is very numerous; much more so than in England, Wales, and Scotland. It is often met with in Ireland in large numbers.

This bird has been called the dwarf partridge, from its great resemblance in figure, colour, and habits, to the true bird of that name. "These birds," says Mr. Daniel, "resemble each other by being both pulverulent, having short wings and tail, and running very swiftly; they feed, copulate, build their nests, and raise their young nearly in the same way. Both are salacious, inordinately lustful, and the males quarrelsome; but numerous as are the points of resemblance, they are more than balanced by a number of disparities, which render quails a distinct species; for, omitting the peculiar incident of their migration, quails are universally smaller; they have not the bare space between the eyes, nor the figure of the horse-shoe impressed on the breast of the males, as in the partridge; the quail's eggs are smaller, and of an entirely different colour; their notes are unlike: the flesh of the quail is also of a different flavour, and more loaded with fat; the period of their life is shorter, for the quail does not live more than five years. They are less cunning than the partridge, and much more easily ensnared, especially when young; their dispositions are not so gentle, and it is extremely rare to see them tamed. Quails seldom form themselves into covesys, except when their wants unite the feeble family to their mother, or some powerful cause urges, at once, the whole species to assemble and traverse together the extent of the ocean, holding their course to the same distant land; but this forced association does not subsist after they have alighted, and find in their adopted country that they can live at will. The appetite of love is the only tie, and even this is momentary: so soon as passion has spent its force, the male abandons his mate to the labour of raising the family. The young quails are hardly full-grown when they separate; or, if kept together, they fight obstinately; and their quarrels are terminated only by their mutual destruction."

The quail is migratory in its habits; and though many attempts have been made to naturalise it in this country, the instinctive desire to migrate, has bitherto frustrated all such attempts. This bird has engaged the attention of the naturalist and the sportsman from the earliest times. Pliny says—"Quails alight in such numbers on ships (and which is
always in the night), by their settling on the masts, sails, &c., as to bear down barks and small vessels, and finally sink them; and, on that account, the sailors have a great dread of them, when they approach near to land." In the autumn, large flocks of them cross the Mediterranean from Italy to Africa, taking in their route, both in departing and returning, the various islands of the Archipelago as their resting-places. They are often in such prodigious numbers as absolutely to cover the entire face of the country. In Alexandria they are so common, that they can be readily bought for a farthing each. Many of the crews of merchant vessels have been so much confounded to feeding on its flesh, that it has been the cause of certain diseases breaking out among them, and complaints have formerly been made on the subject to the British consul at Alexandria. These birds assemble in autumn on the northern shores, to emigrate southward; and it has often been remarked, that they delay their departure until the north wind rises, when, towards sunset, the entire body take wing, and display such swiftness as to traverse one hundred and fifty miles by break of day. In Italy, Sicily, and most of the Greek islands, they arrive at a stated season in immense numbers, and with singular punctuality, not differing, in the average of years, above a day or two at the utmost. One hundred thousand have been known to be taken in a day. They are run after during the night, and great numbers perish in the chase. In Sicily, there is quite a sensation produced when they arrive. Crowds, of all ages and ranks of life, are assembled to witness the sight. The number of boats is likewise astonishing; and their passengers all carry guns and pistols, to have a shot at the flustered strangers. Ortygia was named from them; and so abundant were they on the island of Capri, at the entrance of the Gulf of Naples, that they constituted the chief source of revenue of the bishops of the place. There were a hundred and sixty thousand captured in one season. In China, and in many of the islands in the Eastern Archipelago, they are also extremely plentiful.

With respect to these birds having an instinctive knowledge of the precise time for emigration, we have a very singular fact in some young quails, which, having been bred in cages from the earliest period of their lives, had never enjoyed, and, therefore, could not feel, the loss of liberty. For four successive years they were observed to be restless, and to flutter with unusual agitations regularly in September and April; and this uneasiness lasted thirty days at each time. It constantly began about an hour before sunset. The birds passed the whole night in these fruitless struggles, and always, on the following day, appeared dejected and stupid.

It is observed in the Rural Sports, that they are birds of passage, some entirely quitting our island; others shifting their quarters, as it is said, from the neighbouring inland counties, into the hundreds of Essex, in October, where they continue all the winter. If frost or snow drive them out of the stubble-fields and marshes, they retreat to the sea-side, shelter themselves among the weeds, and live upon what they can pick up from the algea, &c., between high and low water-mark. Their appearance in Essex coincides with that of their leaving the inland counties; and this same observation has been made in Hampshire. The quail, like the partridge, makes no nest, except a few dry leaves or stalks scraped together may be so called; and sometimes a mere hollow in the bare ground suffices: in this the female lays six or seven eggs, of a whitish colour, marked with irregular rust-coloured spots. Mr. Holland, of Conway, once found a nest with twelve eggs, eleven of which were hatched; and Mr. Daniel saw a bevy of nine young ones.

In combative qualities the quail holds distinguished eminence. He fights long, and dies hard. The Greeks and Romans cultivated the pugnacity of this bird to a great extent; and the conqueror in a regular pitched battle was highly prized. Indeed, in such estimation was he held, that Augustus put a prefect of Egypt to death for having brought a conqueror to the table to be eaten—a singular act of imperial justice, that estimated the life of a man as of no more value than that of a bird. During the middle ages, quail-fighting was common; and Henry III., king of Castile, devoted much of his time to the catching of quails for the purpose of matching them in fights. His subjects usually hunted them morning and

553
evening, and had regular combats with them at places adapted for the purpose. Scaliger informs us, that the Italians have costly gardens purposely laid out to hunt them, by means of quail-pipes, with which they pursue the birds as a great amusement.

In some countries the quail is said to be more prolific than in others. In Italy and France, from fifteen to twenty is a common produce; but, in hotter climates, twenty-five and thirty are sometimes found in one nest. This large number of eggs accounts, in some degree, for the numbers of the birds. Some sportsmen maintain that they hatch twice a year; but this does not appear to be satisfactorily proved. This subject is touched upon in a communication inserted in the *New Sporting Magazine*, vol. v.; wherein it is said—"This place (the Isle of Thanet) was formerly so famous for them (quails), either from its vicinity to the French shore, or the quantity of grain which is cultivated, that people come from great distances for the express purpose of quail shooting; of late years, however, their numbers have considerably decreased; but still the sportsmen, in the beginning of September, may commonly kill from two to three brace a day. Along the banks of the Thames, below Purfleet, several farmers and sportsmen have assured us, that, about the beginning of November, a time at which the departure of the main body has taken place, a small number of quails make their appearance, and continue during the winter, always at a short distance from the river's edge; these are evidently the young birds of the second bay, who, for some reason, seek that particular situation after the migration of the rest of their species."

Respecting the abundance of these birds in the East, we find it related in a work, entitled *Letters from the Campagne Felice*, that, during the time when the Capitani Bay blockaded the harbour of Alexandria, one of his Greek seamen caught two or three that had perched on the rigging of the ship. They were presented to the capitani; and he was so pleased with them, that he offered a piastre for every one that should be brought him. The price was a great temptation; and, in a few days, the sailors found means to cover the rigging with flocks of quails. Every one caught, was, as a matter of course, brought to the capitani, who, to escape impending ruin, was forced to stand out to sea, or break the promise he had made to the captors of the birds. He preferred the former alternative.

Quail shooting is, in this country, principally confined to the counties of Essex, Kent, Cambridge, Suffolk, and Norfolk; and the bevy's seldom exceed ten in number, and are generally under that figure. They are to be found in the evenings, feeding in corn-fields, and sometimes they lie remarkably still, and may be readily approached. At other times, however, they are as wild as possible. A steady dog is indispensable; but it must be remarked, by way of caution, that most dogs are apt to be spoiled for some time after they have been employed in tracing these birds. Common partridge shot is recommended; but some quail shooters prefer No. 7.

These birds usually sleep during the day, concealed in the tallest grass, lying on their sides, with their legs extended, in the same spot, even for hours together. So very indolent are they, that a dog will sometimes absolutely run upon them before they are flushed; and when they are forced to take wing, they seldom fly far. They are easily drawn within reach of a net, by a call imitating their cry, which is not unlike the words *whit, whit, whit*: this is done with an instrument called a quail-pipe.

Great numbers of these birds are imported from France, for the table; all of which are males. They are conveyed in large square boxes, divided into five or six compartments, one above another, just high enough to admit of their standing upright. Each of these boxes contains about a hundred. Were the birds allowed a greater height, they would soon kill themselves; and, even with this precaution, the feathers on the top of the head are generally beaten off. These boxes have wire on the fore part, and each partition is furnished with a small trough for food. Quails may be forwarded in this manner, without difficulty, to great distances.
CHAPTER VIII

THE WOODCOCK.

Woodcock shooting has been called the "Fox-hunting of shooting"—a phrase at once descriptive of its character and dignity.

The Woodcock (Scolopax Rusticola, Linn.) is placed by naturalists at the head of the snipe genus. It is thus described by Bewick and others:—"Its length is about fourteen inches; twenty-six in breadth; and its weight about twelve ounces, though sometimes it is found to the extent of fourteen. The shape of the head is considered somewhat curious, being more obtusely triangular than round; and the eyes are placed very forward, near the top of the ears, and nearly in a line with the corners of the mouth. The upper mandible, which measures about three inches, is furrowed nearly its entire length; and at the tip it projects beyond, and hangs over the under one, ending in a kind of knob, which, resembling those of others of the same genus, is susceptible of the finest feeling, and calculated by that means for aiding, perhaps, by an acute sense of smell, to find the small worms in the soft and moist grounds, from whence it extracts them with its sharp-pointed tongue. By means of its bill, it likewise turns over and tosses about the fallen leaves, in search of insects which take shelter underneath. By the entire conformation of the bird, and particularly for the structure of its head, we have an opportunity of displaying some of the wonderful contrivances which Nature has instituted for the sustenance and preservation of her various orders of animated beings. From the extreme sensibility of the mouth of the woodcock, some structural peculiarities are required to gain a given end or object—the capture of insects deeply embedded in either mud, earth, or decayed wood."

The woodcock, it has been said, is naturally of a shy and retiring disposition, rarely taking wing by day, unless disturbed; but just as twilight begins, it quits the woods, and, nearly at the same instant, wanders over the meadows in search of wet and splashy places, and moist grounds, in quest of food. As the day dawns it retires to its hiding-place. Thus, when most other birds are recruiting exhausted nature by sleep, the woodcock is roaming through the dark, directed by an exquisite sense of feeling, which it experiences by means of its long and singularly-constructed bill. The eye is not called into use; and, like the mole, it may be said to feed beneath the surface; and by the sensibility of the instrument, which is thrust into the soft earth, not a worm, however small, can escape that is within its reach.

The eyes of the woodcock are of large dimensions in proportion to its general bulk of body; and, like those of some other nocturnal birds, have the capacity of collecting the faint rays of light, in the darkened vales and sequestered woodlands, during its nocturnal excursions. Thus, likewise, it is enabled to avoid coming in contact with trees and other obstacles, which are continually offering impediment to its flight. The nerves on the bill, like those of the duck tribe, are very numerous, and have a highly sensible power in discriminating between objects by the sense of touch. A woodcock, in a menagerie, has discovered and drawn forth every worm in the ground, which was dug up to enable it to bore with its bill; and worms put into a large garden-pot, covered with earth, live or six inches deep, wholly disappear before the ferocity of the woodcock by the next morning. The enormous quantity of worms which woodcocks devour is scarcely credible; indeed, it would be the constant labour of one person to collect such food in sufficient quantity for two or three of these birds. The difficulty of collecting a sufficiency of such precarious aliments, has led the interested to try if bread and milk would not be a good substitute; and it has been found that, by placing clean-washed worms into the mess, the bird soon acquires the taste for its new food, and would eventually eat a basin of bread and milk in twenty-four hours, besides the worms it could obtain.
The digestive powers of the woodcock are remarkably vigorous, and work with great rapidity. On anatomical examination there is very little found in its stomach and intestines, save a few fibres of a vegetable texture, mixed with some sand, small stones, and gravel.

Of the British species of woodcock there are three varieties. "In the first," says Dr. Latham, "the head is of a pale red, body white, and the wings brown; the second is of a dun, or rather cream colour; and the third of a pure white." Dr. Hesham, in his Catalogue of Cumberland Animals, mentions having met with one, the general colour of which was a fine pale ash, with frequent bars of a very delicate rufous; tail brown, tipped with white; and the bill and legs a flesh colour." In addition to these, some other varieties are taken notice of by Marmaduke Tunstall, Esq., of Wy-cliff, in his interleaved books of Ornithology. Mr. Daniel seems likewise to be aware of such a difference; for he observes that there are different sizes of woodcocks. Those found in the first part of the season are of the largest size, fly heavily, and their heads appear to be muffled, especially the under parts, with short feathers. The most numerous tribe, which arrive in November and December, are rather smaller, their heads less, the feathers smoother, and the bills shorter. Woodcocks that arrive in this country about Candlemas, are likewise small, and differ in their manner of flying; are quicker of wing, take pretty long flights, and are well known to be very difficult to shoot, on account of their not rising above the spray, like the larger muffled woodcocks, but make their way for some distance, as it were, among the boughs. Mr. Baillon also notices two kinds of woodcocks. "The largest arrive first, and may be distinguished from the others by the colour of their legs, which are of a greyish tint, inclining to rose colour. The smaller kind have a coating similar to that of the common woodcock, but their legs are blue. Variegated plumage, and other anomalies, now and then occur among these birds; thus, a pure white one has been seen; and we can only wonder that still greater variations do not frequently take place; for although most sporting works, in their account of the woodcock, usually confine his foreign residence to the north of Europe, yet it should be known that he is likewise found in all the climates, both hot and cold, in the old continent, as well as in North and South America. It is, however, a curious fact, that he is everywhere an emigrating bird. His migrations in some countries appear, however, to be confined to a journey from the plains to the mountains, and vice versa. In Europe he is located during the summer on the Alps, Pyrenees, and other lofty mountains, from whence he migrates to the regions below, and probably some reach us. His universality thus established, we need not be surprised that he should thus sport into varieties, seeing that every locality, according to its proximity or remoteness from what may be considered as his attracting spot for domestication for the time, has its influence over the size, colour, and even the aptitudes of the bird."

The sex of the woodcock has been considered as entirely unmarked by any external signs; but internally it can be readily detected. Mr. Pennant thinks, from the examination of the bird's feathers, which in the hen present a narrow stripe of white along the lower part of the exterior veil of the feather, would be sufficient to do away with all doubt upon the question as to which is the cock and which is the hen. In the male bird, the same feather, at the same part, is beautifully and regularly spotted with black and reddish white. Many sportsmen maintain that there is another criterion—namely, the greater size of the female bird; but this is not invariably to be depended on.

The female woodcock makes a very careless nest, consisting of some dried leaves and fibres, on the bare ground, and very often chooses the root or stump of a decayed tree for the locality. She commonly lays four or five eggs, a shade larger than those of pigeons, and of a rusty green colour, blotched and marked with dusky ill-defined spots. The young quit the nest as soon as they are freed from the shell; but the parent bird continues to attend them until they can provide for themselves. Buffon informs us that the mother will sometimes take a weak bird under its throat, and carry it more than a thousand paces.

The flesh of this bird is, by gastronomes, held in high estimation; and it is eagerly sought after by many sportsmen. In cooking
it, the entrails are not drawn, but roasted within the bird, whence they drop out with the gravy, upon slices of toasted bread, and are relished as a delicious kind of sauce. The Italians and French have each particular modes of preparing this bird for the table, which they do in such excellent style as to leave an impression on the palate of the eater for some time after.

The woodcock is migratory in its habits, and generally arrives in the south of England during the month of October. It does not come in large flocks, but in ones or twos, till about the month of December. They are, very probably, much influenced in their movements by the wind, which, if it blow from a continental quarter, is more likely to aid their flight than when it comes from the opposite direction. The birds have a singular instinct of landing only in the night, or in dark misty weather; for they are never seen to arrive by day, but are frequently found next morning in any ditch which could afford them shelter, particularly after the great fatigue they must have undergone in buffeting the adverse winds which they must frequently have to encounter in their aerial voyages. They do not remain on the shores to take their rest longer than a day, but proceed inland to the very same haunts which they occupied during the preceding season. In stormy weather they retire to the moors and mountains; but as soon as the frost sets in, and the snow begins to fall, they return to lower and more congenial situations, where they meet with boggy grounds and springs, and little oozing moss-fringed rills which are rarely frozen, and seek the shelter of the close bushes of holly, furze, and brakes in the glens, or dells which are covered with underwood. There they remain concealed during the day, and remove to different haunts, and feed only in the night. From the beginning to the end of March, or sometimes to the middle of April, they gradually approach the coasts, and avail themselves of the first fair wind to return to their native woods. Should the weather be unfavourable to their migrating, they will delay their departure, when their numbers increase by degrees, and when they are more easily found and destroyed by their numerous enemies.

Other accounts say that they leave the north with the first frost, and travel slowly southwards till they come to their accustomed winter quarters. They do not usually make a quick voyage, but fly from wood to wood, reposing and feeding on their journey; selecting such woody haunts as are in the vicinity of moist and marshy springs. They conceal themselves under thick bushes by day, and fly abroad to feed in the dusk of the evening. A laurel or holly-bush forms a favourite place for their repose. The thick and glossy leaves of these trees prevent the radiation of heat from the soil, and they are less affected by the refrigerating influence of a clear sky, so that they afford a warm and comfortable retreat for the woodcock. These birds usually take to the north on the first approach of spring, and their flights are generally longer, and their rests fewer at this season than in autumn. In the latter they are driven from the north to the south by the want of food, and they stop wherever they can find it. In the spring there is the influence of another powerful instinct added to this—the sexual feeling. They migrate in pairs, and pass as speedily as possible to the place where they are likely to find food, and where they can rear their young with the probability of being unmolested, of which the old birds have already had the experience of former years. Scarcely any woodcocks winter in any part of Germany. In France there are a few found, particularly in the southern departments; and in Normandy and Brittany. The woods of England, especially of the west and south, contain always a certain number of these birds; but there are far more in the moist soil and warmer climate of Ireland. In the woods of southern Italy and Greece, near marshes, they are still more abundant; and they are generally diffused over the Greek islands, Asia Minor, and Northern Africa.

Woodcocks have been known to settle upon a vessel at sea. Mr. Travers, of Cornwall, records an instance of this, when at such a distance from land as to make it rare for birds to be seen. When first discerned, it was high in the air, hovering above the ship, but gradually descended; and, after making several circuits round the vessel, at length alighted on the deck. Its exhaustion was so great, that it allowed itself to be taken up by the hand.

In their flight, woodcocks, like other birds,
are attracted by a glare of light; and many instances have occurred, at the Cromer and Eddystone lighthouses, of their falling victims when dashing against the windows of these structures. At the lighthouse upon the Hill of Howth, the man who attended it on one occasion, was surprised by a violent stroke against the windows, which broke a pane of plate-glass, more than three-eighths of an inch thick. On examining the balcony which surrounds the light, he found a woodcock, which had flown against the window with such violence as to break his bill, head, breast-bone, and both wings. The man had often found birds which had killed themselves by flying against the glass, but had never before known of a pane to be injured.

Woodcocks have been seen at their first arrival, in considerable numbers, on the coast of Sussex, in the church-yard, and even in the streets of Rye; but during the night, the usual time of their flying, they have betaken themselves to less dangerous and more natural quarters. At their first visit for the season to the coast, they are commonly poor in condition, weakened and wasted through great exertion, and, likewise, sometimes scurvy, though not so much so as before their return in the spring. The taste of the flesh has also become quite metamorphosed. On their arrival, this is usually marked by insipidity of flavour; but when they have been a short time feeding in the country, it greatly improves, both in point of richness and delicacy. If a woodcock is shot just before its departure, it bleeds plentifully; whereas, at the beginning of winter, it yields hardly any blood at all. From this circumstance it would seem, that in those countries where they have their summer residence, they live on a different kind of food to what they find here. Probably the luxuriant and succulent aliment which they meet with among us, prepares them for breeding in those countries to which they retire with the companions of their choice.

The time when the woodcock appears and disappears in Sweden, agrees exactly with the periods of their arrival in, and departure from, our own island. Their autumnal and vernal appearance on the coast of Suffolk have been accurately noticed. They come over sparingly in the first week of October, the greater number not arriving till November and December, and always after sunset. It is the wind, and not the moon, which determines the time of their arrival; and it is probable that this should be the case, as they come hither in quest of food, which fails them in the places they leave. If the wind has been favourable for their flight, and if they remain at all on the coast where they alight, it is but for a very short time; but if they have been forced to struggle with an adverse gale, they rest a day or two to recover their strength. In such cases they have been known to be so much exhausted, that they have been taken up in Southwold streets, nearly dead. They do not come in flocks, but separately, and disperse like so many feathered skirmishers making their way through the fields of air.

France, Germany, and Italy are treated in the same manner as we are, when the proper season arrives. They visit Burgundy in the latter end of October, but continue there only four or five weeks; it being a dry country, they are forced from it, for want of sustenance, by the first frost. In the winter they are found in great abundance as far south as Smyrna and Aleppo. During the same season they appear in vast quantities in Barbary, where the Africans call them the "ass of the partridge." It has been asserted that some have been seen as far south as Egypt, which is the remotest migration to which they can be traced on that part of the African coast of the Mediterranean; on the other side of Asia they are common in Japan. The woodcocks that resort to the countries of the Levant, probably come from the deserts of Siberia, or Tartary, or the old mountains of Armenia. In the neighbourhood of Athens, woodcocks abound, descending, after snow on the mountains, into the plains, and suddenly retiring if the weather continues severe. They enter the gardens of the town in great distress, rather than cross the sea, and are sometimes caught with the hand.

It is now fully ascertained that they occasionally breed in this country, and even as far north as the Orkney Islands; but it is maintained that these birds are not nearly so plentiful as they were half a century ago, amongst us. Perhaps this may really be the case; but the fact has been doubted. It is the common failing of some minds to exaggerate the
past at the expense of the present. It is therefore safe to be somewhat incredulous in this matter, in order not to attach so much credit to these statements as some writers do. There is a greater number of sportsmen now than formerly, at least in the shooting art; and this may account for fewer woodcocks being killed by any single person. The sport, we believe, is more generally diffused, but not seriously, if at all, diminished from former times.

In regard to the kind of dogs which should be used by the woodcock shooter, spaniels are the best. Pointers and setters are taken by some; but they are considered inferior to the spaniel where the woods are extensive and thickly set with underwood, brambles, and thorns. The spaniel should, however, be well trained, and should be taught both to hunt close or wide, as circumstances require. Both beaters and markers are requisite in extensive woods. The employment of beating and marking necessitates a regularly digested plan of operations, and a minute regard to instructions previously agreed upon among the parties. Those engaged in it must take their stations at a given spot, and pay attention to each other's signs and movements, otherwise they will be working at cross purposes, and prove worse than useless. Many beaters take sticks to beat the bushes and underwood; while the markers take up their position on some elevated piece of ground, or even some tree, that they may the better see the birds, and mark accurately where they drop, in order to be able to give correct instructions to the sportsman.

Large numbers of woodcocks are taken by means of nets and traps, and find their way to the London markets, where they generally bring tolerably high prices. It is said that, in the neighbourhood of Torrington, in Devonshire, these birds are so numerous throughout the season, that they have been killed to the value of nearly two thousand pounds in one year. Catching them by nets and springs is common in the hilly counties of Cumberland, Westmoreland, and Durham. The same practices are in operation in Wales to a great extent. Mr. Dobson, in his *Kunapedia*, says—

"The poacher's dog in Wales is an ugly, raw-boned, cross-made derivation from the light setter, degraded through half-a-dozen genera-

tions of bastardy, with a view of being made into pointers. Than this, it is not possible to conceive more unpromising materials; and if such be the effects producible upon this stock, it is fair to conclude what a similar discipline is capable of doing with superior natures. By hunger and hard work, of both of which they have plenty, they are brought down to obedience; and their draw upon a cock in a wood, under the dread of their master's arm, with the power of which they soon become acquainted, is wrought into a full stop."

Formerly there was a regular system of shooting and entrapping woodcocks pursued in Scotland, for the Edinburgh and Glasgow markets. In some localities of that country the birds are very common, and there is a varied abundance of food for their support, particularly on the western side of the island, where the winter season is comparatively mild and open, and the springs and boggy grounds are not so liable to be frozen. In a letter written by Sir Walter Scott, to a friend, he says—"I have been out for two or three days endeavouring to obtain a shot or two at a woodcock, but I have not been successful; the fact is, these birds are now taken off wholesale by a band of men who do nothing else for the season but kill them, and they find a ready and profitable market for them in all our large and populous Scottish cities and towns. I was lately informed, by one poulterer of Edinburgh, that he had paid one man nearly a hundred pounds last season for woodcocks, which he had chiefly shot in the western parts of Argyllshire and Inverness-shire. This seems prodigious." It is likewise stated, in the work from which this letter is taken (*Annals of Sporting, Edinburgh*), that formal applications had been made to the magistracy of several districts in Scotland, to endeavour to put a stop to this wholesale destruction and traffic.

Ireland is highly praised for its woodcock sporting. Colonel Hawker says, "that a real good sportsman feels more gratified by flushing and killing a woodcock, or even a few snipes, than bags-full of game that have been reared on his own or his neighbour's estate. Localities of cock shooting are widely distributed over the British dominions. Ireland, throughout, is unquestionably the very best spot for a zealot in cock and snipe shooting; the natur
of the ground, inclined as it is to bog and
marsh, suits the one and the other of these
birds." On the same subject, the Colonel
remarks—"If a sportsman is fond of cock
shooting, it will repay him well for his trouble
to take a trip to Ireland; it is not material
what part to recommend, as it is impossible
almost to go to a bad place for sport. As to
asking leave, it is needless; as the only cause
of jealousy that can subsist between the visitor
and the owner of the ground, will be, for not
acquainting him of his coming, in order that he
might have had it in his power to receive him
in the usual hospitable manner, by providing
beaters to show him sport, giving him the best
of fare, a good bottle of claret, a sincere and
hearty welcome; assuring his guest, the longer
he stays and honours him with his company,
the more welcome he is, and the happier he will
make him."

CHAPTER IX.

THE SNIPE.

Snipe shooting can be enjoyed in almost all
parts of the kingdom; but we do not think
that it is a sport calculated to be so attractive
to the generality of shooters as the pursuit of
the game of the mountains and the moors.
To many, however, it affords a sufficiency of
excitement; whilst it always secures them as
much exercise as will add to their health, and
helps to render them cheerful companions
whilst sitting at the fireside of their homes.

There are three different kinds of snipes
known to the British sportsman.

The Great Snipe (Scolopax Major, Linn.) is
a comparatively rare bird; the upper portion
of its plumage nearly resembling that of the
common snipe. The breast, sides, belly, and
vent, are white, spotted, barred, and undu-
lated with black. Its weight is about eight
ounces; and length sixteen inches. The bill
is like the shape of the woodcock's, and about
four inches long. The crown of the head is
black, and divided down the centre by a pale
stripe; and over and beneath each eye there is
another of the same colour. The upper parts of
the body resemble those of the common snipe;
the feathers on the neck, breast, and sides, are
edged with a dusky white, and those of the
belly spotted with the colour. The middle,
however, is quite plain. The quills are dusky;
and the tail reddish; the two middle feathers
of which are plain, and the others barred with

560
black; the first edged with white, and the secondaries are tipped with the same. Those next to the body are, with their coverts, striped and barred with an iron-grey colour. The lower breast and belly are white; upper tail-coverts brown, barred with black. The tail consists of fourteen black feathers, barred and spotted with dull orange red towards the end, and with a narrow bar of black near the tip, where it is of a pale rufous colour. The legs vary; in some they are dusky, or lead-coloured, and in others black.

The Jack Snipe (Scolopax Gallinula, Linn.) This species is described, in the Ornithological Dictionary, as nearly half the size of the common snipe, and weighs about two ounces. Its length is about two inches and a-half. The bill is nearly two inches long, of a lead colour, black at the point, and the upper mandible of a light colour, and the irides black. The crown of the head is black, and slightly edged with rusty brown, bordered on each side with a yellowish streak, beneath which is a dusky one; and close above the eye is another streak of a light colour. From the bill to the eye is a dusky stroke. The black is varied with ferruginous brown, and dusky. The back, rump, and scapulars are of a fine, glossy, changeable green and purple; the exterior webs of the latter, deep buff colour, forming the two conspicuous lines from the shoulder to the tail. The quills are dusky, and so likewise are the wing-coverts, bordered with brown. The lower breast, and all beneath, is white. The tail is cuneiform, consisting of twelve pointed dusky feathers, dashed more or less with an iron-grey. The legs are of a greenish hue. The jack snipe comes later in the season than the common snipe; and no instances are known of its ever having remained in this country during the breeding season. It is very common in most countries of Europe, as well as in the various states of North America.

We have already said that snipes are found in tolerable abundance in all the old countries of Europe, in Africa, Asia, and the islands of the Eastern Archipelago. In the American continent they are very numerous, especially in the states of North and South Carolina. In Egypt, they frequent the rice-fields or plantations in such swarms, that it is no uncommon circumstance for a man to shoot a basketful in a day. It is said, however, that the sport here is fatiguing, from the light earth of the rice-grounds being so deeply mixed with water, that the shooter sinks, at every step he takes, often above the knees. Snipes arrive in Lower Egypt at the beginning of November, and pass the entire winter there.

'The snipe is hardly ever found
In woods; he's fond of open ground,
The rusty pond, the quiet brook,
But chieflv to the marshes look;
The plashy heath and boggy moor
Yield frequently an ample store;
Stick to them well when this the case is,
They very quickly change their places;
To-day the sportsman can pursue
The numerous game till all is blue.
To-morrow he goes out again,
But mayn't a single shot obtain;
Affected by the wind and weather,
They often flock away together;
Sometimes they to the hills repair,
Rising in whirls all wildly there;
Vain the pursuit, but if a gale
Should quickly from the east prevail,
Or even from the boisterous north,
Again you ought to sally forth.'

These lines, though scarcely poetical, are valuable, on account of the truthfulness of their directions. They are taken from Remarks on Shooting, by Mr. Watt.

The snipe begins to pipe in the first week of April. Many breed in this country. Their nests are composed of dried grass and plants, now and then intermixed with feathers. They lay four or five eggs—sometimes six are found—of a dirty olive-colour, marked irregularly with dusky spots. The young have an ill-formed, shapeless appearance. It has been well ascertained that the mother never deserts them until their bills have become long, and of sufficient firmness to enable them to seek and procure food for themselves. When disturbed much in the breeding season, the parents soar very high, and the male bird will keep on the wing for an hour together, mounting like a lark, and uttering a shrill and piping noise. It then descends with great velocity, and makes a bleating sound, resembling that of a goat, which is repeated alternately round the spot which the female occupies, especially if she is then hatching her eggs. This sound, in the days of superstition, was called the campana celestis.
Snipes of all kinds feed mostly on worms and insects, which abound in moist grounds and marshy localities. Snails have occasionally been found whole or undigested in their stomachs. Their flesh is fat and savoury; and they are cooked in the same manner as woodcocks, without extracting the entrails.

From observations made by a gentleman in Norfolk, and furnished by Mr. Daniel, it appears that the common snipe arrives in the vicinity of Norwich in the early part of September, and stops for a day or two, or perhaps only for a few hours. They often come in large flocks, and lie very light on the ground. At the end of October the greatest numbers make their appearance; but as soon as the cold weather commences, they almost entirely disappear, and return no more until March, previous to their final departure. During the frost, the spring ditches are, when free from ice, carefully examined; but, excepting on two or three early days of frost, very few birds are found. The forwardness or backwardness of spring seems invariably to regulate their movements, which induced this gentleman to remark the coincidence of the time of the flowering of wild plants, and that of the reappearance of the snipes. In February, a few punctually arrived; but on frost setting in, they departed again. The marshes were searched, but not a snipe could be seen. In March they again visited the moist grounds and springs, in considerable numbers, in company with a large flock of lapwings; but in a few days they left for other countries. The next spring being a very early one, many made their appearance in the first week of March. They came in flocks, but in a fortnight they had all gone away. It would appear from this, that the weather has a great deal of influence in determining the movements of the snipe which has a very powerful and an unerring instinct.

SNIPESHOOTING.

Snipe shooting is considered by Mr. Thornhill to be no bad test of a man's love of genuine sport, if he feel a strong partiality for this kind of shooting. He observes—"Snipe shooting is a sport the best calculated (grouse excepted) to try the keenness of the sportsman, to ascertain his bottom, and if he can stand labour, water, mire, swamps, and bogs. He should be possessed of a strong constitution, not liable to take cold, and have all the fortitude, as well as exertion, of a water-spaniel; he should be habitually inured to wet, dirt, and difficulty, and not be deterred by cold or severe weather." Mr. Daniel says—"Snipe shooting, when the birds are plentiful, is an excellent diversion: they are said to puzzle the marksman by the irregular twistings of their flight when first sprung; but this difficulty is soon surmounted if the birds are suffered to reach to a certain distance, when their flight becomes steady, and easy to traverse with the gun. There is no reason to be apprehensive of their getting out of the range of the shot, as they will fall to the ground if struck but slightly with the smallest grain. Snipes, like woodcocks, and many other wild birds, always fly against the wind; therefore, by keeping the wind at his back, the sportsman has this advantage of the bird when it rises—that it presents a fairer mark. These birds are scarcely good till November, when they get very fat. In hard, frosty, and more particularly in snowy weather, snipes resort in numbers to warm springs, where the rills continue open, and run with a gentle stream; these, on account of their long bills, are then the only places where they can hunt for food. Snipes will generally lie well to a pointer; and some dogs have a singular knack of finding and standing to them."

Regarding the difficulty of shooting snipes, some affirm that it is very great, whilst others affirm quite the contrary. To be cool and collected is a great point gained; for where there is hurry and trepidation, the chances are greatly against the shooter. The motion of the bird is irregular, and is supposed to arise from the nature of its visual organs, being so constructed as to see things in daylight very indistinctly and obscurely; and this is supposed to be the cause of that unsteadiness of flight so embarrassing to the sportsman. It must be remembered, that in snipe, as well as in woodcock shooting, there is what is called a knack to be obtained; a rapidity of action, and promptness of aim, which practice, joined to a particular temperament of body and mind, alone secure. It is remarked by Mr. Blaine, that it has been said, "in some writings,
that the snipe is the hardest to hit of all birds; whereas, in others, it is said to be anything but difficult to bring down a snipe. In our opinion, however, there are two methods of hitting him with moderate certainty: the one is by snap-shooting, which is a habit gained by some, but not to be critically described by any, except we regard it as a conscientious action of eye and hand at the same moment. The other certain mode of snipe shooting is to put the gun into the hand of the cool and deliberate marksman, who, nothing flurried, waits his opportunity, and the moment the bird settles into its course, arrests that course by a shot." The Oakleigh Code affirms, that "the shooter will bring down a snipe with much less difficulty at from fifteen to twenty paces, than at any other distance. The aim is thus taken just before the bird begins to make its cross-flights, but before it has attained its full speed. The irregularity of its flight is of little consequence during the first and second twisting, before the bird is safely on the wing, since its flight is then comparatively tardy. But let the snipe fly ten yards from whence it sprang—let it be, for instance, twenty-five paces distant from the gun—it is then at the top of its speed, and in the very midst of its sidelong, elliptical gyrations, and more than a match for the majority of shooters."

Whether dogs should be employed in snipe shooting is another point of dispute; but where there are many men there must be many minds; and if these were to agree in all things, they would soon become rusty and useless. Accordingly, some maintain that dogs are useless in snipe shooting; whilst others consider them as highly necessary. "Who shall decide when doctors disagree?" Mr. Blaine tells us, that he shot snipes in England, Ireland, and Scotland, and never did so without a dog, if he could get one. In Ireland, snipe shooters not only have dogs, but beaters and markers in addition.

We believe that snipes were, in this country, much more abundant than they now are. Mr. Daniel tells us, that snipes, in the Cambridgeshire fens, were, at one period, most abundant; those brought to Cambridge market, which at that time were all shot birds, sold at threepence to fivepence each. One season he killed, in three mornings, thirty-three couple of snipes; and from having known his father's men catch them by drawing with a net in the night-time, he mentioned to a person near Milton Fen, his surprise that this mode of taking them had not been resorted to. The fenman inquired what sort of net was to be used, and was told a lark-net would answer the purpose of a trial. This the fenman soon borrowed, and, the first night of his making the experiment, caught as many snipes as a small hamper could contain. The practice soon became general; and the netted were so much better than the shot birds, that the latter could scarcely find a purchaser in the market. The price at Cambridge afterwards increased to a shilling, and sometimes to eighteen-pence a-piece. The Duke of Marlborough's gamekeeper, on one occasion, killed twenty-two snipes at one shot.

A French sporting writer says, that, in the year 1793, there were such immense flocks of snipes settled along the south-eastern coast of France, that they were taken in cart-loads. They were so weak and feeble, that the peasants used to knock them down with their hands or their hats. As this occurred when the revolutionary frenzy was at its height, the country people thought the presence of these birds, in such multitudes, was a miracle; and very few, in consequence of this notion, were eaten.

The localities for good snipe shooting are, in England, Cambridgeshire, Lincolnshire, and Northamptonshire; and the Essex marshes have been long known and celebrated for this sport. The birds are likewise to be found in Yorkshire, Durham, Cumberland, and Westmorland. In Scotland they are, on the whole, more numerous than in England. In the former country wisps of thirty and forty are not uncommon in the boggy and marshy lands, near the lochs and rivers which there abound. Ireland, however, carries off the palm in point of abundance. There it is no uncommon achievement to kill forty or fifty brace of these birds in a few hours. They are to be met with in every section of the country. In North and South Wales there is likewise good sport. Twenty brace have been killed among the mountain bogs there in four hours; and this, too, in comparatively unfavourable weather.
THE BUSTARD.]

We can scarcely move in any direction in South Wales, without meeting with vast numbers of these birds; but they must be sought after and followed in very odd places; and we must never scruple to plunge up to the middle to gain our object. This sport is undoubtedly a very exciting one, but it must be purchased at a certain cost of bodily labour, privation, and discomfort; and only those individuals possessing sound and vigorous constitutions, should follow it.

The time of the arrival and departure of migrating birds, has been thus noted by Mr. Markwright, whose observations extended over a period of twenty-six years:

CHAPTER X.

THE BUSTARD.

The greater bustard (the Otis Tarda of Linnaeus) is one of the largest of British game-birds; but it is now rarely met with. It is about four feet long, and from twenty-five to thirty pounds weight; its bill is strong, and rather convex; its eyes are red, and its head and neck are ash-coloured. On each side of the lower bill is a tuft of feathers, from five to nine inches long, the back of which is barred transversely with black and rust colour; the large quill feathers are brown, and the belly white. There are twenty feathers in the tail, those of the middle being of a rust colour, barred with deep black, and those on each side white. The legs are long and naked beyond the knees, and are of a dusky colour. The bird has no hind toe; its nails are short, strong, and of considerable convexity, both above and below, and the bottom of the foot is furnished with a callous prominence, which serves the purpose of a heel. The female bird is smaller in size than the male. The crown of the head of the former is of a deep orange, crossed with transverse black lines; the rest of the head is brown. The lower part of the fore-side of the neck is ash-coloured, and she is destitute of the tuft on each side of the head; in other respects her plumage resembles that of the male, with the exception that the colours of the back and wings are less vivid and glossy. The male is furnished with a kind of pouch, capable of containing nearly seven pints of water, the entrance to which is immediately under the tongue. It is supposed that the bird fills this to supply its wants in those dry and thirsty plains which it inhabits. Some naturalists say that the male supplies the female with a portion of the liquid when she is sitting on her eggs. In Morocco, where the hawk is employed to capture the bustard, he makes use of his pouenful of water as a means of defence; for, whenever the hawk is coming upon him, he spirits it out upon his foe, and thus endeavours to escape the consequences of his capture. The female bustard makes no kind of nest, but simply scratches a hole in some dry field, and drops two eggs upon the ground, as large as those of a goose, and of a pale olive brown, dotted irregularly with a number of small dark spots, resembling the brown colour of the plumage. She sits thirty days, and watches them with great jealousy; and it is said, if any one handles them in her absence, she immediately abandons them.

Bustards feed on corn and vegetables of various kinds; they likewise devour great quantities of earthworms. Like the ostrich, they even swallow small pebbles, and bits of
metal. Bulfin relates a somewhat strange story of one that was opened before the Royal Academicians of France; in the stomach of which there were ninety doubloons, all worn and polished by the attrition of the coats of the stomach.

Shooting the bustard was once a very favourite sport with the gentlemen of England. Then, however, they were more plentiful. In autumn they appeared in the largest numbers. Sometimes as many as fifty or more would be seen together near the Downs in Wiltshire. In Scotland the bird is supposed to be quite extinct. In former days, all sorts of contrivances were invented to gain upon the wary bird; carts and coaches, in which gunners were concealed, was a favourite plan; and Markham tells us, that in his time (nearly two centuries and a-half ago), the stalking-horse was the surest mode of capture. It was a great achievement to get a shot at the bird, and a still greater to kill him. It was not an uncommon thing for even greyhounds to course the bustard—as it displays always a great reluctance to take wing, and is often successfully overtaken by the dogs, and secured.

About thirty years ago, two fine male birds were shot in Northumberland, which weighed nearly twenty-five pounds each. Salisbury Plain has long been noted for them; but we believe, at the present hour, they are but seldom seen, even in this favoured locality. There have been a few stray birds taken in the high grounds in Wales, within the last ten years. They are very common in Russia, Germany, and Tartary.

The Little Bustard (Otis Tetrax, Linnaeus).

This is a smaller species of the bird, being sixteen inches in length, and thirty-five in breadth, with outstretched wings. Its weight is about twenty-five ounces. Bewick says—“It is very uncommon in this country; we have only seen two, both of them females. It is, however, common in France, where it is taken in nets, like the partridge; but it is not an easy prey, being a very shy and cunning bird; if disturbed, it flies two or three hundred paces, not far from the ground, and then runs away much faster than any one can follow on foot. The female lays in June, to the number of three or four eggs, of a glossy green; and, as soon as the young are hatched, she leads them about as the hen does her chickens, and they are able to fly about the middle of August.”

In India the bustard is a favourite table bird; but even thousands of gastronomes in this country, if it were brought to table, would be at a loss to know what it was. Colonel Montague tells us that, in 1804, one was shot and taken to Plymouth market, where a publican purchased it for one shilling—what would have fetched two or three guineas where its value was known. This rare wanderer was, however, so entirely unknown, that it was rejected at the second table as improper food, in consequence of the pectoral muscle differing in colour from the other parts of the breast—a circumstance not unusual in birds of the grouse kind. Some country gentlemen supping at the inn the following evening, and hearing of the circumstance, desired that they might be introduced to the princely bird, and, at their repast, partook of it cold.

CHAPTER XI.

FEN-BIRDS.

The term “fen-birds” embraces a numerous class, all breeding in the fens—which, by the way, are fast disappearing before the march of progress—but roving into different localities, especially during the first part of the year. They consist of wild ducks, geese, gargories,
or summer teal, pochards, shovellers, teals, pewits, gulls, terns, herons, bitterns, coots, water-hens, water-rails, ruffs and reeves, knobs, redshanks, lapwings, and many others. This enumeration is sufficiently full to indicate the varied character of the feathered population of the fens.

THE BITTERN.

This bird is the Ardea Stellaris of Linnaeus, and bears a strong resemblance to the heron family, only it is smaller, and has a different plumage. The feathers on the top of its head are black; and those on the hind part of the head, neck, and breast, are long and loose. The general colour of the bird is a dull, pale yellow, but variegated with spots and bars of black. The greater covert and quill feathers are ferruginous, and regularly barred with black. The tail is short, and the legs of a pale-green hue; the toes and claws are very long and slender, and the middle claw is serrated on the inner edge. The female is somewhat less than the male, with a plumage less bright, the feathers on the neck not being so long and flowing. Its bill is considerably shorter than the bill of the heron, and likewise weaker. She makes her nest in April, among rushes and sedges, and is, in all respects, a regular visitor of the fen districts. She lays from four to six eggs, which are of a pale greenish ash colour, and sits twenty-five days. When they are hatched, the young have the appearance of being all legs and neck, and never venture from the nest until about twenty days after they are hatched, during which time they are carefully watched and fed by the old birds. Their common food are slugs, small fish, and frogs. In February and March, the male bitterns make a deep hollow noise, morning and evening, which ceases after the breeding season commences. This is called the booming of the bittern, and has been often noticed both by poets and naturalists. It is observed, in the Ornithological Dictionary, that “those who have walked, on a summer’s evening, by the sedgy sides of unfrequented rivers, must remember a variety of notes from different water-fowl, the loud scream of the wild goose, the croaking of the mallard, the whining of the lapwing, and the tremulous neighings of the jack-snipe. But of all these sounds there is none so dismally hollow as the booming of the bittern. It is impossible for words to give those who have not heard this evening call, an adequate idea of its solemnity. It is like the interrupted bellowing of a bull, but lower and louder, and is heard at the distance of a mile, as if issuing from some formidable being that resided at the bottom of the waters. This is the bittern, whose windpipe is fitted to produce the sound for which it is remarkable—the lower part of it, dividing into the lungs, being supplied with a thin loose membrane, that can be filled with a large body of air, and exploded at pleasure. These bowing explosions are chiefly heard from the beginning of the spring to the end of autumn, and are the usual calls during the pairing season. From the loudness and solemnity of the note, many have been led to suppose that the bird made use of some external instrument to produce it, and that so small a body could never eject such a volume of tone. The common people are of opinion that it thrusts its bill into a reed, which serves as a pipe for swelling the note above its natural pitch; while others imagine that the bittern puts its head under water, and then, by blowing violently, produces its boominings. The fact is, that the bird is sufficiently provided by nature for this call, and it is often heard where there are neither reeds nor water to assist its sonorous invitations. It hides in the sedges by day, and begins its call in the evening, booming six or eight times; and then, discontinuing for eight or ten minutes, it renewes the same sound. In Scotland, the sound of the bittern is so very common, that every child is familiar with it, though the birds, from being shy, are not often seen. The poet Thomson seems to have had a very erroneous opinion of the manner in which the bird produces this noise, when he says—

"So that scarce
The bittern knows his time, with bill engulphed,
To shake the sounding marsh."

On the contrary, we have repeatedly remarked that the bittern usually booms while flying high in the air. Its lofty spiral flight is, indeed, a matter of common remark—

"Swift as the bittern soars on spiral wing."

A line which, we may remark, is not very ornithological, inasmuch as neither the bittern nor
any other kind of bird has spiral wings. Southey, however, seems to have been well acquainted with the boom of the bittern—

"At evening, o'er the swampy plain,

The bittern's boom came far."

The shooting of the bittern scarcely merits the name of sport, as their numbers are limited, and they are seldom sought for as especial objects of game. They are easily brought to the ground. They rise heavily on the wing, and move forward with a slow and deliberate motion, and are, therefore, a good mark for theowler. Sometimes, however, they will rise rapidly, with a spiral motion; and when this is the case they are not so readily shot. A double gun is of advantage in seeking for this shy bird. When wounded it fights hard; and when driven to extremity, will attack a man with vigour, striking his legs with its bill, and even in some cases aiming a blow at his head. This bird was once held in high esteem at the tables of the great, and is still highly prized by the real sportsman.

THE HERON.

This noble-looking bird is the Ardea Major of Linnaeus; and has been described by Buffon as "a picture of wretchedness, anxiety, and indigence, condemned to struggle perpetually with misery and want, and sickened by the restless cravings of a famished appetite." How such a description could have fallen from the pen of the great French naturalist we are at a loss to divine; as, throughout the whole scheme of creation, there is no animal, in a natural state, doomed to a life of perpetual wretchedness. The bird is just as happy as any other bird; and it follows its instinctive habits with the same unerring regularity as do the members of every other tribe of the feathered creation. It is seen to stand for hours fixed like a stake to a given spot—no evidence of life in it—waiting patiently for the moment to arrive when the trout or the minnow shall come within the range of its long cranked neck. Its movements are among the wonders of this class of fen-birds; and if patience is a virtue, then the heron is abundantly endowed with it.

The heron has a wonderful capacity of stomach. It may be said literally to swallow no end of fish. Some young birds have been known to consume fifty small roach in a day. These birds make their nests of pieces of stick, lined with wool and feathers; and the female lays five or six eggs, of a pale green colour. During incubation, the male bird passes much of his time perched by the side of the female. They abandon their nests during the winter season, except in the month of February, when they return to them, and put them into a state of repair.

In the sport of hawking, the heron, in ancient times, was a frequent victim; but it had a means of defending itself which may not be known to the generality of our readers. A note in the Book of St. Alban's, says—"The heron, or heronsew, is a fowl that liveth about waters, and yet she doth so abhorre raines and tempests, that she seeketh to avoid them by flying on high. She hath her nest in very lofty trees, and showeth, as it were, a natural hatred against the gosse-hawk, and other kinds of hawks; and so, likewise, doth the hawk seek her destruction continually. When they fly above in the air, they labour both especially for this one thing, that the one might ascend and be above the other. Now, if the hawk getteth the upper place, he overthroweth and vanquisheth the heron with a marvellous earnest flight; but if the heron get above the hawk, then with his dung he debilith the hawk, and doth destroyeth him, for his dung is a poison to the hawk, rotting and putrefying his feathers."

The heron seldom weighs more than three or four pounds, notwithstanding it measures about three feet in length; and the breadth of its wings, from tip to tip, is above five feet. The bill is full six inches long, straight, pointed, strong, and serrated; and the upper mandible is of a yellowish horn colour, dark towards the ridge, whilst the under one is yellow. A bare skin is extended from the beak towards the eye, the irides of which are yellow, which imparts to them a fierce and penetrating look. The brow and crown of the head are white; the eyes bordered by black lines, which stretch to the nape of the neck, where they join a long, flowing, pendent crest of the same colour. The upper part of the neck, in some birds, is white; in others pale ash colour; and the fore part, lower down, is spotted with a double row of black feathers; those falling
over the breast being long, loose, and unwebbed. The shoulder and scapular feathers are likewise of the same kind of texture, of a grey colour, generally streaked with white, and spread over its down-clothed back. The ridge of the wing is white, the coverts and secondaries lead-coloured, and the bastard wings and quills are of a bluish black, as are also the long soft feathers which take their rise on the sides under the wings. These fall down, meet their tips, and hide all the under parts; the latter, next the skin, being covered with a thick, matted, dirty-white down, except about the belly and vent, which are almost bare. The tail is short, and consists of twelve feathers of a brownish-red colour. The legs are a dirty green, long, bare above the knees, and the middle claw is jagged on the inner edge.

The female differs from the male in not possessing the long flowing crest, or the long feathers which adorn the breast of the male. The entire plumage of the female is comparatively subdued and uninteresting.

Shooting the heron may generally be referred more to chance than any settled plan of sporting with the gun. The extreme shyness of the bird renders it difficult to be got at; and it is commonly only by accident that the sportsman falls upon it and secures it. When not fatally wounded at first, it will turn upon both the shooter and his dog, if he has one; and, with its hard-pointed bill, it can inflict a sharp wound. One that was shot in the north of England, dropped a trout of ten inches out of its mouth. On the dog approaching it, he was struck upon the forehead by the bird’s bill, and a wound more than half an inch deep was inflicted. Such occurrences are far from being rare in the shooting annals of this curious specimen of the fen-birds.

In England, herons were, for centuries, considered royal game, and protected as such by the law. Whoever destroyed their eggs was liable to a penalty of twenty shillings for each offence. When heron-hawking was a favourite diversion among the nobility and gentry, the bird was considered a rich dainty at their tables. The heron has been partially tamed. Sir John Sebright knew of a full-grown one taken in a decoy, and brought to J. D. Downes, Esq., at Old Gunton Hall. At first, it was crammed with food, and at length became so tame as to follow him on the wing to the distance of some miles, to come into the house when called, and to take food from the hand.

**THE GREAT WHITE HERON.**

The *Ardea Alba* of Linnaeus is seldom found in Great Britain. It is about the same size as the common heron, but stands higher, being longer in the legs. It is devoid of crest, and its plumage is entirely white; its bill is yellow, and its legs black. It is found in considerable numbers in the Russian dominions, and in most of the countries contiguous to the Caspian and Black Seas, and the lakes of Tartary. It is met with in the United States of America from June to October, and is often shot in these parts.

**THE NIGHT HERON**

Is only about twenty inches in length. The bill is nearly four inches long, slightly arched, strong, black, and inclining to yellow at its base. The skin from the beak round the eye is bare, of a greenish hue, and its irides are yellow. A white line is extended from the beak, and over each eye a black patch, glossed with green, covers the crown of the head and nape of the neck, from which three long and narrow white feathers, tipped with brown, hang loose and waving. The hinder part of the neck, coverts of the wings, sides, and tail, are ash-coloured, and the throat is white. The fore part of the neck, breast, and belly, are of a yellowish white, approaching to buff; the back is black, and the legs a greenish yellow. The female bird is nearly of the same dimensions; but she differs considerably in her plumage from the male. The former is less bright, distinct, and vividly portrayed; neither has she the delicate plumes which flow from the head of the male. It is unnecessary here to describe the "Stork" and the "Crane;" for, although they are birds similar to the heron, they are now rarely met with in this country.

This bird frequents the sea-shores, rivers, and inland lakes and marshes, and lives upon crickets, slugs, frogs, reptiles, and fish. During the day it lies concealed, and does not roam abroad until the approach of nightfall. It is known by its rough, harsh, discordant cry,
which is by some compared to the noise made by a person trying to vomit. The female builds her nest on rocky cliffs, and lays three or four white eggs. Both male and female are very difficult to shoot, on account of their extreme wariness.

THE RUFF AND REEVE.

The Ruff is the Tringa Pugnax of Linnaeus, and is the name given to the male; whilst the Reeve designates the female of this species of fen-bird. The length of the ruff is about twelve inches, and its weight ranges between six and eight ounces. The bill is about an inch long, and is tipped with black, but reddish at the base. The distinctive mark which separates the male from the female is a singularly wide-spreading, variegated tuft of feathers, which, in the breeding season, grows out of his neck. This tuft, a portion of which stands up like ears behind each eye, is in some black, in others black and yellow, and, in rare cases, white, russet, or barred with glossy violet, black and white. The entire face of the bird is covered with reddish tuberces, or pimples; the wing-coverts are brownish ash-colour; the upper parts and the breast are generally marked with transverse bars, and the scapulars with roundish shaped, glossy black spots, on a rusty-coloured ground. The quills are dusky; the belly, vent, and tail-coverts are white. The tail is brown, and the four middle feathers in it barred with black. The legs are of a yellowish hue. The male does not acquire the ornament of his neck till the second season, and, before that time, is not easily distinguished from the female, except by being larger. After molting, at the end of June, he loses his ruff and the red tuberces on the face; and, from that time, until the spring of the year, his plumage again resembles that of his mate. This singular tuft in the male bird, it has been remarked, is not a warlike ornament, but only a kind of defensive armour, fitted, by the length, stiffness, and closeness of the feathers, to palliate the blows of an assailant.

The Reeve is smaller than the ruff, and has no collar round the neck. She is brown in the upper parts, and the middle of each feather is dusky, and the larger quills are of the same hue. The secondaries are of rufous brown, and the legs are yellowish. She lays four eggs in

the grass, the ground-colour of which is white, with iron-coloured spots. Among sportsmen it is a rule, understood, not to take the reeves, but to spare them for breeding purposes. When the reeves arrive, the ruff takes to what is called hilling; which is selecting a suitable place for pursuing his loves, and which is generally some elevated locality. Each ruff is said to take possession of some small mound, or part of a hill, which he wears quite bare by hilling, or breeding upon it.

An erroneous opinion prevails very generally, that ruffs, when in confinement, must be fed in the dark, lest the admission of light should set them to fighting. The fact is, that every bird, even when kept in a room, takes its stand, as it would in the open air; and if another invades its circle, a battle ensues. A whole room full of them may be set into fierce contest by compelling them to shift their stations: but, after the disturber has quitted the place, they have been observed to resume their circles, and become again pacific. In confinement, their quarrels originate in the circumstance of the pan containing their food not being sufficiently large to admit the whole party to feed without touching each other. When the food has been divided into several pans, the birds have remained perfectly quiet.

These birds migrate in the winter, and are then supposed to associate with others of the fen-bird species, among which they are no longer recognized as the ruff and the reeve. In the spring, when they return, they take up their residence in the fenny districts, where they were bred, when they, as a matter of course, become the objects of the fowler's sport.

About Michaelmas is the time for taking these birds; but as few old males are caught, an opinion has been formed that they migrate before the females and young. Is it not, however, more probable that the few which are left after the spring fowling, like other polygamomous birds, keep separate from the female and her brood till the return of spring? That some old ruffs are occasionally taken in the autumnal fowling is, perhaps, true; but others declare that none are taken at this season. It must, however, be recollected, that, in the autumn, the characteristic long feathers have been discharged, and, consequently, young and
old males have equally their plain dress; and this circumstance may tend to give rise to the contrary judgments on the matter. It does not appear to be the opinion of fowlers that the males take longer than one season to arrive at maturity; because the ruffs taken in the spring, being without the long feathers, which constitute the principal distinction between them and the reeves, are comparatively few to those possessing the ruff; the opinion, therefore, that these ruffless males are birds of a very late brood of the preceding season, is sufficiently reasonable.

The shooting of the ruff and reeve is principally restricted to the fens of Lincolnshire and Cambridgeshire, and to the Isle of Ely, and the East Riding of Yorkshire. There are likewise a few to be found in the fenny districts in the neighbourhood of Bridgewater, in Somersetshire; but these having been considerably drained of late years, the birds are now scarcer. In the marshy lands between Boston and Spilsby, they may yet be met with in considerable numbers.

THE KNOT.

This is the Tringa Canutus of Linnaeus, and has a claim upon our notice independent of its being a fen-bird. This claim arises from the derivation of its name. It seems that the Danish king, Canute, was very partial to the flesh of this bird—a circumstance that caused it very often to be served up to him. It therefore came to be known as the bird of Canute, which was pronounced by his subjects knute, which, in the course of time, for brevity, and greater facility in the pronunciation, was corrupted to knot. It measures about nine inches, and has a tail of a dusky brown colour, of rather more than an inch long. The extent of its wings is about fifteen inches; and its weight is about two ounces eight drachms. The bill is one inch and three-eighths long, black at the tip and dusky, fading into orange towards the base. The tongue is nearly of the same length, and is sharp and horny at the point. The sides of the head, neck, and breast are cinereous, edged with ash-coloured grey; and the chin is white, with a stroke of the same colour passing over each eye. All the upper parts of the plumage are darkish brown, but deeper and glossier on the crown of the head, back, and scapulars; and each feather is edged with ash or grey. The under parts are a cream-coloured white, streaked or spotted with brown on the sides and vent. The great coverts of the wings are tipped with white, which form a bar across them when extended. The legs are of a yellowish hue, and do not measure more than two inches and an eighth, from the middle of the toe to the knee. The thighs are feathered nearly to the knee; and the toes are divided without any connecting membranes.

When the sportsman follows these birds with the gun, they generally run very fast; and it always requires considerable labour and time before he can make them rise within a fair range. Their flight is quick and unsteady. When severe frost sets in, they betake themselves to the sea-shore, where they are more readily brought down than upon the fenny marshes. In Lincolnshire, they are, in large numbers, decoyed into nets, by carved wooden figures painted to represent themselves, and placed within the nets, much in the same manner as the ruff is taken. The knot is likewise fattened for sale, and esteemed by many equal to the ruff in delicacy of flavour. The best season for its capture is from August to November.

THE RED SHANK.

This bird is also called the Pool Snipe, and is the Scopelopus Calidris of Linnaeus. It is a favourite with many sportsmen, as it affords them a good deal of amusement at certain periods of the year. Its length is twelve inches, its breadth twenty-one, and its weight about five ounces and a-half. The bill, from the tip to the corners of the mouth, is nearly two inches long, blackish at the point, and red towards the base. The feathers on the top of the head are dark brown, edged with a pale rufous hue. Over each eye there is a whitish line, from the corners of which, dark brown spots extend to the beak. The irides are hazel. The back part of the neck is obscurely spotted with dark brown, on a rusty ash-coloured ground. The throat and fore part are more distinctly marked, or streaked with spots of the same colour. The breast and belly are white, tinged with an ash colour; the spots are thinly distributed, and are shaped something like the heads of arrows or darts. The general
appearance of the upper parts of the plumage is glossy olive-brown; and those on the shoulders, scapulars, and tertials are transversely marked with the same coloured waved bars, on a pale rusty ground. The bastard wing and principal quills are dark brown; and the inner webs of the latter are deeply edged with white, flecked with brown; and some of those quills next the secondaries are beautifully marked, near their tips, with narrow brown lines, exactly pointed, and shaped to the form of each feather. Several of the secondaries are barred in the same manner, and some are white. The back is white; the tail-feathers and coverts are elegantly marked with alternate bars of dusky grey and white. The middle ones are slightly tinged with russet. The legs are red, and measure, from the end of the toes to the upper bare part of the thigh, four inches and a-half.

This bird is solitary in its habits, being usually found alone, or in pairs only. Its habituation is among the fens, or in wet or marshy lands, where it rears its young. It lays four eggs, of a whitish hue, tinged with olive, and flecked with irregular spots of black, chiefly on the broad end of the egg. When disturbed, it wheels round its nest in the air, and utters a cry similar to the lapwing. It is not very easily shot, on account of the spiral motion it makes, and the rapidity of its flight; but it gives excellent sport to a young shooter.

THE GODWIT.

This is the Scolopax Rreocepala of Linnaeus, of which there are several varieties: its difference of plumage is to be regarded as a mark sufficiently strong to determine this. Its length, from the extreme end of the bill to the tip of the tail, is twelve inches, and to the end of the toes, nearly fifteen. Its breadth is twenty-one inches and a quarter, and its weight is five ounces and two drachms. The bill is slenderly formed, measuring two inches and a-half from the corners of the mouth to the tip, and is, for half its length nearest to the base, of a reddish hue, and the other part black. The irides are hazel. The head, breast, neck, and belly, have spotted streaks, mottled and barred with dingy ash-brown and dull white, which become darker towards the hinder part of the neck. The throat is white; and lines of the same colour pass from the upper sides of the beak over each eye, from the corners of which two brown ones extend to the nostrils. The shoulders, scapulars, lesser coverts, and tail, are of a glossy olive-brown. The feathers on all these parts are indented on the edges, in a greater or less degree, with triangular-shaped white spots. The back is white, and the rump barred with waved lines of ash-coloured brown and dingy white. The feathers about the vent are marked in a similar manner, but they have a larger proportion of white. The tail and coverts are likewise barred with narrow waved lines, of a dull ash-colour; and, in some specimens, are nearly black and white. Five of the principal quills are dark brown, tinged with olive; the shaft of the first quill is white; the next six are, in the male, rather deeply tinged with white, and slightly spotted, barred with brown. The secondaries, as far as uncovered, when the wings are extended, are of the same snowy whiteness as the back. The feathers which cover the upper part of the thighs, and those near them, are bluish, with a reddish or vinous hue. The legs are of a deep orange red, and measure, from the end of the middle toenail to the upper part of the thigh, five inches and a-half. Colonel Montague says there is a larger kind of godwit than this, weighing twelve ounces, and measuring about eighteen inches in length.

This bird was known formerly as a permanent resident amongst us, resorting to the fens from the moors, where they were taken by means of a stale or stuffed bird, after the manner of the ruff and reeve. Towards the winter the godwit may be seen at the mouths of many of our large rivers, and it is then a very popular object of pursuit to water-fowl shooters. At Hudson's Bay, it packs in such numbers, that there have been fifty and sixty of them killed at one shot.

There is another variety of the above. This has the greater covert of its wings so deeply margined with light grey-brown as to appear almost all white at a distance, and the sides of the body have a few long streaks of brown. The bird is met with in various parts of Europe, Asia, and America; and in Great Britain, in the spring and summer, it takes up its residence in the fenny districts and marshy grounds, where it feeds upon small worms and insects.

571
During these seasons it only removes from one boggy locality to another; but when severer frosts set in, it betakes itself to the salt-marsches and sea-shores. The flesh of the godwit is highly esteemed by epicures, and sells at a high price.

**THE WHEAT-EAR.**

This small bird is known in the Linnean System as the *Motacilla Enanthe*, and is often shot on Brighton Downs: it is taken in some neighbouring localities in great numbers. This is accomplished by means of two turfs placed on edge, at each end of which a small horse-hair noose is fixed to a stick, which the bird, either in search of food or to evade a storm of rain, attempts to get under, and is caught. Colonel Montague says—"In confinement they are almost continually in song, and sing by night as well as day; they have a very pleasant, variable, and agreeable song, different from all other birds: sometimes it is very loud; and they continue it a great length of time, not continually breaking off like a robin-redbreast and some other birds; but their winter song is best and most varied." In allusion to the migratory habits of this bird, Miss Charlotte Smith has written some beautiful lines; but we have room only for one stanza, which is sufficient to indicate the happy spirit in which they were composed:—

"From that deep-sheltered solitude
Where, in some quarry, wild and rude,
Your feathered mother reared her brood,
Why, pilgrim, did you brave
The upland winds, so bleak and keen,
To seek these hills, whose slopes between,
Wide stretched in grey expanse, is seen
The ocean's toiling wave?"

**THE LANDRAIL.**

The landrail is also called the corncrake, and is the *Rallus Crex* of Linnaeus. Bewick describes it as rather more than nine inches long, and its general bulk of body as considerably compressed. The bill is light-brown, and the eyes hazel. Most of the feathers on the upper part of the plumage are of a dark-brown hue, edged with pale rust; both winged coverts and quills are of a deep chestnut colour. The fore part of the neck and breast are pale and ash, and a streak of the same colour extends over each eye, from the bill to the side of the neck. The belly is a yellowish white, and the thighs, sides, and vent, are marked with faint rusty-coloured bars. The legs are a pale flesh-red.

The landrail is migratory in its habits, and makes its appearance in this island about April. Corncrakes, says Mr. Daniel, "are plentiful in these realms, and in Ireland particularly so, where it is probable they pass the winter. They are in the greatest plenty in the Isle of Anglesea, where they appear about the third week in April, supposed to come there from Ireland. At their first arrival it is common to shoot seven or eight in a morning. They abound in the county of Caithness, in Scotland, and are found in most of the Hebrides and the Orkneys. Few places in England are destitute of them in summer; but they are nowhere what may be called common. It is observed, that wherever quails are in plenty the corncrakes abounds. On their first appearance in England, they are so lean as to weigh less than six ounces; but, before their departure, have been known to exceed eight, and are very fat. Their flesh is considered excellent."

The cry of the landrail is well known, and when once heard, cannot be readily forgotten. It shelters among the long grass, and is rarely seen, for it invariably hides among the thickest parts of the herbage, and runs so quickly, that it is, in nine cases out of ten, impossible to overtake it. When hard pressed by a dog, it will sometimes instantaneously stop and squat down, by which device the dog runs past, and loses the trace of it. It seldom springs but when driven to extremity, and generally flies with its legs hanging down, but never to any great distance. When it alights, it begins to run with surprising speed; and before the fowler gains the spot, is far out of his reach.

The nest of the bird is formed of dry grass, a few soft leaves, and a little moss mixed up with the whole. It is commonly imbedded in some hollow part of the surface of the ground, but occasionally is met with on high and even places. The female lays ten or twelve eggs, of a dull white colour; and the young, as soon as they escape from the shell, are capable of running with wonderful swiftness.

The landrail departs from England before
the winter, and repairs to other countries in search of its food, which principally consists of slugs, of which it destroys a prodigious quantity. It likewise devours worms and insects, as well as seeds of various kinds. Mr. Pennant thinks that most of the birds which leave us in spring, to spend the summer elsewhere, have been traced to Lapland—a country of lakes, rivers, swamps, and alps, covered with thick and gloomy forests, that afford shelter during summer to the fowls which, in winter, disperse over the greater part of Europe. In these arctic regions, in consequence of the thickness of the woods, the ground remains soft and penetrable to the woodcocks, and other slender-billed fowl. Some, on the other hand, think that they take the opposite direction, and in place of flying to Lapland, make their way to Africa. The cause of the migration of birds is ascribed, by Pennant, to the deficiency of food at certain seasons, or the want of a secure asylum from the persecutions of man during the time of courtship, incubation, and nutrition.

It is difficult sometimes to get a shot at this bird, from the peculiarity of its habits.

**PLOVERS.**

The Great Plover is the Charadrius edinencus of Linnaeus; but by some writers it is called the stone curlew, and Norfolk plover, and considered a diminutive type of the bustard. It is about sixteen inches long, with a bill of moderate length; eyes and eyelids of a pale yellow hue, with a pale streak above and below, which forms a very characteristic mark. The upper parts of the body are tawny brown, and, on each feather, there is a dark streak down the centre. The fore part of the neck and breast are nearly of the same colour, but much paler. The belly, thighs, and vent are of a pale yellowish white, and the quills are black. The tail is short and rounded, and a dark band crosses the middle of each feather. The tips are black, and the rest white: the legs are yellow, and naked above the knees, which are very thick, as if swollen; and its claws are black.

This bird is very frequently found in Norfolk; and Mr. White observes, that the district of Selborne, in Hampshire, is one of its favourite spots. In the north of England it is little known. It frequents dry and stony places, by the sides of sloping banks, and makes no nest. The female lays two or three eggs on the bare ground, sheltered by a stone, or in some small hole formed in the sand. These are of a dirty-white colour, marked with deep-red spots, mixed with slight streaks. Although this bird has great power of wing, and flies with great strength, it is seldom seen during the day, unless surprised, when it springs to some distance, and commonly makes its escape before the sportsman gets within gun-shot. It runs along the ground nearly as swiftly as a dog. After running some time, it suddenly stops, holding its head and body still, and, on hearing the least noise, squats close to the ground. In the evening it comes out in quest of food, and may then be heard at a great distance. Its cry is singularly hoarse, and has been compared to the turning of a rusty handle. Its food consists chiefly of worms. It is said to be tender and savoury eating when young; but, when aged, to be hard, dry, and black. In White's History of Selborne, it is stated that the young run immediately from the nest as soon as they escape from the shell, and that the female leads them to some stony field, where they bask among the stones, to which they bear so close a resemblance, in point of colour, as not easily to be discovered.

The Great Plover is migratory in its habits, and arrives in this country in April. It remains with us all the spring and summer, and, at the commencement of autumn, prepares to take leave by getting together in flocks. It is supposed that these plovers retire to Spain, and frequent the sheep-walks with which that country abounds.

Like the Landrail, it is difficult to obtain a shot at it, from the celerity with which it runs over the ground.

**THE LAPWING, OR PEWIT.**

This is the Fringilla Veselius of Linnaeus, and is a common bird among sportsmen. It falls in his way in every direction, where there is poor, barren, and moist land. Its weight is about eight ounces. The plumage, taken altogether, is beautiful, and the male and female greatly resemble each other; the latter, however, being rather the smaller of the two. It is a well-known bird, chiefly by its singular
cries when flying, and its motions are full of variety. The female lays four eggs, of a dirty-olive colour, spotted with black, which she deposits in some small indentation in the ground, having previously made a rude nest of a little dry grass and heather. The young brood, as soon as they leave the shell, are capable of using their limbs, and the parent bird displays a great deal of tenderness and solicitude over them.

The Lapwing is found in most parts of Europe, as far northward as Iceland; and, in the winter, it is met with in Persia and Egypt. Its chief food is worms; and sometimes flocks of this bird may be seen covering low marshy grounds in search of these, which they draw with great dexterity from their holes. When the bird meets with one of those little clusters of pellets, or rolls of earth, that are thrust out by the perforations of worms, it first gently removes the mould from the mouth of the hole, then strikes the ground at the side with its foot, and steadily and attentively waits the issue: the reptile, alarmed by the shock, emerges from its retreat, and is instantly seized. In the evening the birds pursue a different plan. They run along the grass, and feel under their feet the worms, which now come forth, invited by the coolness of the air. Thus they obtain a plentiful meal; and afterwards wash their bill and feet in the small pools or rivulets.

"I have seen this bird," says Dr. Latham, "approach a worm-cast, turn it aside, and, after making two or three turns about, by way of giving motion to the ground, the worm came out, and the watchful bird, seizing hold of it, drew it forth."

The Lapwing remains in England the whole year. The parent exhibits the greatest attachment to her young; and the arts she employs to allure boys and dogs from the place where these are running, are extremely amusing. She does not wait the arrival of her enemies at the nest, but boldly pushes out to meet them; when, as near as she dare venture, she rises from the ground with a loud screaming voice, as if just flushed from hatching, though probably, at the same time, not within a hundred yards of her nest. She now flies, and makes a great clamour, and appears extremely disturbed; whining and screaming round the invaders, striking at them with her wings, and sometimes fluttering as if she was wounded. To complete the deception, she becomes still more clamorous as she retires from the nest. If very near, she appears altogether unconcerned; and her cries cease in proportion as her fears are augmented. When approached by dogs, she flies heavily, at a little distance before them, as if maimed; still vociferous, and still bold, but never offering to move towards the quarter where her young are stationed. The dogs pursue, in expectation, every moment, of seizing the parent, and, by this means, actually lose the young; for the cunning bird, having, by her stratagems, drawn them off to a proper distance, exerts her powers, and leaves her astonished pursuers to gaze at the rapidity of her flight.

There are few readers acquainted in any degree with the country, who will not recollect how justly the following lines describe the manners of this bird:—

"Hence, around the head
Of wand'ring swains, the white-wing'd plover wheels
Her sounding flight; and then directly on,
In long excursion, skims the level lawn,
To tempt him from her nest."

At certain seasons these birds search the dry heathery of the downs for insects and grubs; and, not long after, they are found feeding on shell-fish in the moist and swampy ditches. They are fine eating, and their eggs bear a high price in the market.

To shoot them with certainty requires considerable practice; but, on the whole, when on the wing, their mode of flight is favourably to the shot telling upon them in vital quarters. No. 4 shot is generally recommended for this bird.

THE GOLDEN PLOVER.

This is the Charadrius Pluvialis of Linnaeus, and is described as being about seven or eight ounces in weight, and its length about ten inches and a-half. The bill is a little more than one inch in length, dusky in its hue. The irides are hazel. The general plumage above is dusky, spotted with greenish yellow, brighter on the back and scapulars, and palest on the wing-coverts. The sides, head, and neck of the body are lighter-coloured; and the middle of the belly and vent are white. The
quills are dusky, slightly margined at the tip with grey. The tail is also dusky, spotted with yellow, and of a white hue. The legs are black.

The golden plover is very common in this country, and is pretty generally distributed over Europe. In America it is very numerous, from Hudson's Bay as far as Carolina, migrating from one locality to another, in accordance with the seasons that produce its food. The male and female are very nearly alike in size and plumage. In young birds the yellow spots are not very strongly marked, as the plumage, during the time of their growth, inclines more to a grey hue.

These plovers were formerly taken in great numbers by means of a stalking-horse. When fired at, they fly over you, darting down for the moment, and separating in every direction; so that by taking a random shot with the first barrel, you may often bring them down to get a fair shot with the second.

**THE GREY PLOVER.**

This is the Tringa Squatarola of Linnaeus, and is about eleven or twelve inches long, and varying from twenty-four to twenty-five broad. Its general weight is about seven ounces. The bill is black: the head, back, and wing-coverts are of a dull dusky brown, edged with greenish ash-colour, and some with white. The cheeks and throat are white, and marked with oblong dusky spots. The belly, sides, and rump are white, the sides being marked with a few scattered dusky spots. The outer web of the quills is black; and the lower parts of the inner webs of the first four are white. The feathers of the tail are marked with alternate bars of black and white. The legs are of a dull green hue, and the hind toe is small.

This bird is not very common in Great Britain, but is occasionally met with in large flocks on the sea-coast. Its flesh is esteemed a great delicacy. In cold and frosty weather, grey plovers seek their food on lands near the sea-shore; and when the sky is clear they frequent ploughed fields, especially if sown with grain. After feeding they make for some water, in which they wash their beaks and feet, and seem to take great delight in so doing. In the night they run up and down, feeding on worms, which they devour in large numbers. The bird is very common in Ireland, where it is found in immense numbers. Being a shy bird, it is difficult to get near enough to shoot it.

**THE WATER-RAIL.**

This is the Rallus Aquaticus of Linnaeus, and is a curious specimen of the rail-bird. It resembles the landrail in general appearance and figure, but is quite distinct in habits and instincts. The water-rail is one day couch'd in the long grass of a high district, and in the next is squatted on, or flying about, the marshy and boggy grounds. When hunted closely it may be readily sprung, and makes a passable shot. Colonel Montague thus writes of it:—

"It seldom takes wing, but dives on the least alarm, and will remain under water, amongst the reeds or other aquatic plants, with only its bill above, for respiration. Its nest is formed, like the rest of the grebes, of a prodigious quantity of flags, or other water-plants, but is generally fastened to the reeds, or flags, in order to prevent its being carried away by the current. Temminck gives a similar statement. The eggs are five or six in number, of a dirty white; the shape oblong, and less than those of the pigeon. These are generally covered with weeds, so that when the bird quits her nest suddenly, they are not exposed to view. In large rivers, these birds are frequently devoured by pike and trout while they are diving in pursuit of small fish. We once took from the stomach of the last, a water-rail weighing fifteen ounces, the trout only weighing four pounds. After the breeding season, the bird is frequently found in some of our inlets of the sea, where it is said to feed on shrimps."

**THE GALLINULE, OR MOOR-HEN.**

This is the Tortice Chloropus of Linnaeus, and in many of its habits, it is very like the water-rail. It is not met with in any great numbers; but its species are scattered, here and there, over almost every country. We believe it is not positively ascertained whether they are migratory; but it is well known that they change their place according to the seasons of the year; frequenting elevated tracts in summer, and more sheltered parts in winter. It is very common in Britain; and sportsmen fall in with it mostly on the borders of rivers and ponds, where willows and sedges grow.
Mr. Daniel says—"It is like the water-rail; it conceals itself during the day; and in the evening it runs and skulks by the margin of the waters, among the roots of the bushes, oxiers, and long loose herbage which overhang the banks, in quest of its food, which consists of insects, worms, aquatic plants, and seeds. It will likewise pick up corn from the neighbouring stubbles, and is at all times very good eating; but from September to December the flesh is extremely delicious."

The nest of the female moor-hen is composed of reeds and rushes woven closely together, and is placed in some corner or chink by the side of water, or upon the stump of an old root. She lays seven eggs, which are about two inches in length, of a yellowish-white hue, marked with a goodly number of irregular spots, of a reddish colour. Some writers affirm, that during incubation, she never leaves the nest without covering the eggs with leaves. She has two, and sometimes three, hatchings during the summer; and the young take to the water very soon after they leave the shell.

The length of the bird is about fourteen inches; the breadth twenty-two; and the weight from twelve to fifteen ounces. The bill is red, with a greenish-yellow tip, and about an inch long. The head is small and black, with the exception of there being a white spot under each eye. The irides are red. The colour of the plumage is sooty black, tinged with shining olive-green. The outer edge of the wing, outside feathers of the tail, and under-tail coverts, are of a dull or dingy white. The colour of the legs is of a pale yellow, often shading off to a dark green. The toes are very long; sides broad; and these are furnished with membranous edgings, which enable the moor-hen to swim, and run rapidly over the surface of slimy mud. Its feathers are thickly set, and bedded in down.

This bird is difficult to shoot in the water, as it dives the moment it sees the flash of the gun. The best method of killing it is to aim a little below it in the water. This plan is often successful.

THE COOT.

This is the Fulica Atra of Linnaeus, and is well known throughout England, as it per-576manently resides here. Its usual weight is about twenty-eight ounces; and it is fifteen inches in length. The bill is of a greenish-white hue, and about an inch and a quarter long. The irides are red. The upper portion of the plumage is black, except the outer edges of the wings, and a spot under each eye, which are white. The under parts of the body are of a hoary dark ash or lead colour; and the skin is protected with a coat of thick down, coated with feathers closely bedded together. The thighs are placed far behind, and are strong, fleshy, and yellow above the knees.

The common coot has, in many of its characteristics, so striking a resemblance to the water-rail and moor-hen, that many writers have considered them as belonging to the same species. Others, however, think it a distinct genus, chiefly on account of its being fin-footed, and from its great attachment to water, whith it seldom leaves. With this bird naturalists commence to arrange the general tribe of swimmers, and place it among those that mostly depend on the watery element for their subsistence. It swims and dives with as much ease as almost any other of the aquatic tribes; and, like those which seldom venture on land, it is a bad traveller, and may be said not to walk, but to splash and waddle between one water and another, with a laboured, ill-balanced, and awkward gait.

THE GREATER COOT.

This bird is of a larger size than the last, and differing little in colour or plumage, except in being a shade darker. It is found in Lancashire and in Scotland. In many sections of the European continent it is abundant. There is a curious anecdote told of a bald coot, that built her nest in Sir William Middleton's lake, at Belsay Castle, in the county of Northumberland. The rushes amongst which its fragile home was constructed, having been loosened by a high wind, the nest was forced from its Moorings, but floated upon the surface of the water, in every direction. Notwithstanding this unexpected event, the female continued to sit, and brought forth her young upon her movable habitation.

For the sake of the culinary department of the household, we give the following recipe for
cooking these birds, as it is from a high authority. After picking them, take off the black down, by means of powdered black rosin and boiling water, and then let them soak all night in cold spring-water. This process makes them look as delicate as a chicken, and become tolerably tender and juicy. Unless this be done, the skin, in roasting, will be oily, and have a strong fishy taste and smell; and when taken off it will become dry, and good for nothing. But, perhaps, the best method is to skin them at once; and after soaking them twenty-four hours in cold spring-water, repeatedly changed, they can be made into a pudding or pie, or into soup. By these means, the skin is got rid of, without losing the juice of the flesh; and their fishy taste is, in a great degree, drawn off by the steam.

The cook is difficult to be flushed, consequently a fair flying shot at it is not always to be obtained. Its suspicious habits: keep it from frequently showing itself, and dogs are seldom able to make much impression upon it in rousing it from its lurking-places. They are sometimes pursued in France by two shooters— one on each side of a narrow and sedgy stream—when, with the addition of a couple of industrious dogs, execution is occasionally done, and a few brace bagged in the course of a day. It is, however, only in some favourite locality that success can be realised even in that country, where the birds are more numerous than they are with us. It is not often that these birds are regularly sought after by sportsmen in England; the shooting of them being rather a chance affair than a purposely sought-for sport.

In many of the sedgy and sluggish rivers that lie along the south-eastern portion of the coast of France, coots are very numerous; but the inhabitants in rural districts consider them as birds of evil omen; and whenever they see one fly out from its hiding-place, they cross themselves, and consider the circumstance as portentous of some unhappy event. This may, perhaps, be susceptible of some degree of explanation, when the shy and retiring habits of the bird are taken into account.

**THE CURLEW.**

The *Scopola Aquata*, of Linnaeus, is a shy bird, and requires some manoeuvring to get within range of him. He measures about two feet in length, and, from the tip of each wing, averages about three feet. The bill is full seven inches long, and curved, with a somewhat tender and blunt point. The upper mandible is of a blackish hue, gradually shaded off to a brown towards the base; and the under one is flesh-coloured. The head, neck, and upper part of the back, and wing-coverts, are of a pale brown; and the middle of each feather is black, fringed and deeply indented with pale rust, or light grey. The breast, belly, and lower portion of the beak, are of a dull white, sparsely spotted with black; and the two former with oblong strokes of the same colour, mathematically set. The quills are black, and the inner webs are crossed, or spotted with white. The tail is barred with black, on a white ground tinged with red. The legs are bare a little above the knee, and of a bluish hue; whilst the toes are thick and strong, and flat on the under side.

These birds vary considerably, not only in point of size, but in regard to the colours of their plumage. Their weight ranges from twenty-four to upwards of thirty ounces. In some, the white portions of the plumage are much more distinct and clearly defined than in others, which are more uniformly grey, and tinged with pale brown. The female has a great resemblance to the male, and makes her nest upon the ground, in a dry tuft of rushes or grass, or of such withered materials as are found near the spot. She lays four eggs, of a greenish hue, with brown spots irregularly distributed over them.

The food of these birds consists of worms, insects, and flies, which they pick out of the soft mossy ground, by the pools or water in such parts of the country as they frequent. In winter they seek the sea-shores, where they appear in great numbers, picking up worms, marine insects, and other fishy materials, on the beach, and among the loose rocks and pools left by the retiring tide. The flesh of the curlew has been characterised by some as very good, and of a fine flavour; while others have unceremoniously condemned it. The truth is, when it lives in the moors, and feeds on insects, and such fare as it can gather in the boggy ground, it is excellent eating; but after it has been a short time by the
sea-coast, and obliged to put up with such diet as it can find there, its flesh becomes strong and unsavoury. In former times, the curlew enjoyed a high reputation, as the old proverb tells us:—

"A curlew, be she white, or be she black,
She carries twelvetimes on her back."

We have already observed that this bird is shy and suspicious, and very difficult to be approached with the gun and dog. The only chance is to steal a march upon it, by getting round some hill, or elevated piece of ground. To bring it down requires rather heavy shot; such as No. 3 and No. 2.

In some districts of Ireland, and in the boggy moor-grounds in all the counties of Yorkshire, Durham, Cumberland, Westmoreland, and Northumberland, the curlew is found in considerable numbers; but as it tries to deceive the sportsman as the plover does, the unwary are often cheated out of their anticipated sport by it. The only way of getting near it, as we have said, is to take the advantage of some cover—a hill, a wall, a bush, or something of the kind; but even with all or any of these screens or aids, it is often surprising to witness with what keenness of sight it will espy an enemy, and how rapidly it will wheel round and get out of the reach of his weapon. What we now state has reference to the birds in the moors and spongy grounds, where, during the summer months, they have taken up their habitat for greater safety during the process of incubation. They are more easily approached when they frequent the seaside in winter. When they are pursued in the moors, dogs are useless; nay, worse than useless, as they disturb the birds long before the sportsman himself makes any impression upon them. In curlew shooting by the seaside, dogs are entirely unnecessary.

Punt-shooting for this bird by the seaside is sometimes followed, and has its share of excitement. It is pursued in autumn, when the birds assemble in large numbers, and roost in some favourite localities, not far distant from each other. These spots require to be well known by the shooters previous to their operations. When they are approached by means of a punt or boat, it should be done in fine frosty weather, and just after or before daybreak. The party should conceal themselves by stooping or lying down in the punt, and then, when within range, a raking fire from each gunner should be made. Sometimes a good bag of birds is obtained in this way.

Besides the curlew proper, there is a species called the little curlew, which affords some sport. It is found in considerable numbers on the Essex coast, and in some parts of South Wales. Colonel Hawker says, Langston Harbour, in the Poole district, and Romney Marsh, yield them in abundance; and, therefore, afford good sport.

CHAPTER XII.

SEA-FOWL SHOOTING.

SEA-FOWL shooting is attended with little profit to the sportsman beyond what it adds to his health, in the air and exercise which it calls him forth to enjoy. As there are many, however, who take great delight in its pursuit, who love to hear the report of their fowling-pieces awakening the echoes of the crags and cliffs that rear their rugged forms as guardians of the land, against the inroads of the waters of the great deep, we have deemed it worthy of introduction into these pages. It has not much to recommend it in the way of supplying the table with something good; but it has associated with it much that is grand and sublime. There is the sea, upon which time, that touches everything else, makes no impression,
and which has been aptly considered as an emblem of eternity. There are, also, the golden sands of the pearly beach, which glitter in the rays of the sun, or glance in the beams of the moon, as the ocean rolls its melodies over their surface; and there are the giant rocks, which, for thousands of years, have frowned defiance to the sea, and which, mayhap, for thousands more, will present their grim fronts to the tempest, whilst sheltering the gull and the guillemot. These are all impressive objects; and, in sea-fowl shooting, are to be taken into the account, when estimating the amount of pleasure which this pursuit may afford.

THE STORMY PETREL.

The Procellaria Pellagicca of Linnæus, is about the size of the common swallow, and the smallest web-footed bird known. When crossing the Atlantic, we ourselves can well remember the ominous prognostications which a flock of these birds would often draw from the mariners, when the clouds were gathering in darkening masses over us, and portending storms collecting their strength, as it were, with no other object than to doom our ship, and ours alone, to destruction. They are heard generally at night, and are recognised by their shrill and piercing cry. The following description is taken from Loudon’s Magazine of Natural History:—“As the stormy petrel is scarcely ever seen near the land, except in very boisterous weather, one of the natives of the island of St. Hilda, for a trilling remuneration, agreed to traverse the face of a huge rock, and fetch me some petrels out of its fissures. Accordingly, accoutred with a rope of hemp and hog’s bristles coiled over his shoulders, he proceeded to the cliff. Having made one end fast by means of a stake, he threw the coil over the face of the rock, and gradually lowered himself down, but with the utmost caution and circumspection, carefully pressing his foot hard upon the narrow ridges before he at all loosened his firm grasp of the rope, which he never altogether abandoned. I had previously thrown myself upon my chest, to enable me to have a better view of him by looking over the cliff; and certainly, to see the dexterity and bravery with which he threw himself from one aperture to another, was truly grand. The trembling surface of the

Atlantic was foaming many hundreds of feet beneath, and dashing its curling, cream-like surge against the dark base of the cliff, in sheets of the most beautiful white; while the heron and black-backed gulls, alternately sweeping past him, so as to be almost within reach of his arm, threw a wildness into the scene by the discordant scream of the former, and the laughing, oft-repeated bark of the latter. This, however, he appeared entirely to disregard; and, continuing his search, returned, in about half-an-hour, with seven or eight of the stormy petrels, tied up in an old stocking, and a pair of the Manx puffins, together with their eggs. The birds, he told me, he had no difficulty in capturing. The eggs of the stormy petrel are surprisingly large, considering the diminutive size of the bird—being as large as those of the thrush. The female lays two eggs, of a dirty or dingy white, encircled at the larger end by a ring of fine rust-coloured freckles. The birds merely collect a few pieces of dried grass, with a feather or two, barely sufficient to prevent the eggs from rolling or moving on the rock.”

The rope alluded to in this passage is of great value to the St. Kildan. Indeed, he could not pursue his vocation without it; consequently, it often makes the first article in the testament of a father. Of the manner in which it is used, Mr. Macauley gives the following instance, of which he was an eyewitness:—“One of them fixed himself to a craggy shelf; his companion descended about sixty feet below, and having directed himself away from the face of a most frightful rock hanging over the sea, began to play his gambols. He swung merrily, and laughed very heartily; and, after some time, having afforded all the entertainment he could, he returned in triumph, full of his own merit, with a large string of birds about his neck, and a number of eggs in his bosom. When aowler is under the necessity of descending the rocks, without any assistance from his fellows, he drives a post sloping into the earth, and, by fastening the rope to it, lets himself down thereby, without the help of any person whatever.”

THE GULL FAMILY.

It is maintained by some sportsmen that there are eleven species belonging to this
family; but Colonel Hawker extends them to thirteen. They have all a striking resemblance to each other; and their principal characteristics are a compressed bill, elongated and pointed, with the upper mandible turned towards the end, and the lower, underneath, forming a salient angle. Their nostrils, placed towards the middle of the bill, are long, narrow, and bored through. Their tail is full; the legs rather long, and the thumb short. All the gull tribes are more or less objects of the gunner's sport, and the shooting of them is often attended with considerable excitement and pleasure. These birds generally congregate in vast flocks in those parts of the coast that are high, abrupt, and little frequented by either boats or land travellers; where, in fact, the rugged nature of the cliffs, and the air of solitude and desolation around, seem to secure to them comparative safety and retirement. To a man susceptible of the wild and grand in scenery, and with a rambling-piece in his hand, we know of no more attractive pursuit than a ramble along the headlands of the coast, in quest of these birds. Everything around is vast and imposing. The ocean casts a solemn shade over the most volatile mind, and lifts the thoughts to objects of contemplation, that strikingly impress it with the majesty of the Supreme Power. In such sporting rambles among the feathered tribes in this section of Nature's vast domains, the sportsman scans the singular economy that prevails in the congregated families that are here bred and nourished by her paternal hand. He scrambles from one cliff to another, sometimes with fear and trepidation; while he often recognises birds of which he knew little or nothing before; and, perchance casts his eye on the nest of the eagle, whose marauding flights are marked in every direction with blood and rapine.

"High from the summit of a craggy cliff,
Hung o'er the deep, such as, amazing, frowns
On utmost Kilda's shore, whose lonely race
Resign the setting sun to Indian worlds,
The royal eagle draws his vigorous young.
Strong pounced, and ardent with paternal fire,
Now fit to raise a kingdom of their own,
He drives them from the fort, the towering seat,
For ages, of his empire; which in peace
Unstained he holds, while many a league to sea
He wings his course, and preys in distant isles."

These birds abound in far greater numbers in the northern parts of Britain than in the southern. In the Farn Islands, off the coast of Northumberland, and all around the northern and western parts of Scotland, they are to be found extremely numerous, especially in rocky localities. In the Orkney and Hebrides Islands, they afford plenty of good sport; for we conceive that most sportsmen, who have had opportunities of enjoying this species of shooting, must have remarked, that the farther north they went, and the more unfrequented the parts into which they travelled, the less shy the birds became, and the richer the harvest that awaited them.

The weather has a great influence over this sport. All the different kinds of sea-fowl are more approachable in stormy than in calm weather; only the former is not so pleasant to the sportsman himself. But there is no getting all matters to square evenly in sporting practices. The fair must be blended with the foul, even to impart a relish to sport.

THE SWAN FAMILY.

The Anas of Linnæus have long held a distinguished place in the eyes of sportsmen. The ancients consecrated them to Apollo and the Muses. Callimachus, in his hymn upon the island of Delos, celebrates them:—

"When from Patoius' golden banks,
Apollo's tuneful songsters, snowy swans,
Steering their flight seven times their circling course,
Wheel round the island, carolling meantime
Soft melody, the favourites of the nine,
Thus ushering to birth with dulcet sounds
The god of harmony, and hence seven strings
Hereafter to his golden lyre he gave;
For ere the eighth soft concert was begun
He sprung to birth."

These birds are considered at the head of the web-footed tribes; and to shoot them is, among sportsmen, esteemed a great achievement. The hoovers, or wild swans, are very easily killed, if the fire be directed towards the head, or under the wing; but they are almost shot-proof in other parts of their body. The flight of the swan is very rapid. Hearne says—"Notwithstanding their size, these birds are so extremely swift on the wing when in full feather, as to make them more difficult to shoot than almost any others, it being frequently necessary to take sight, say twelve feet before their
bills. This, however, is only when they are flying before the wind in a brisk gale, at which time they seldom fly at a less rate than a hundred miles an hour: but when flying across the wind, or against it, they are not able to make any great progress."

The swan is five feet long, above seven broad, and weighs from thirteen to sixteen pounds. The bill has a length of three inches, and is of a yellowish hue from the base to the middle, and thence to the tip, black. The bare space from the bill over the eye and eyelids is yellow; and the entire plumage, in adult birds, is of a pure white. They are clothed, next to the skin, with a thick fine down. The legs are black.

This species usually congregate together—keeping in groups or families, except at the pairing season, and when the severe frosts set in. In winter they assemble in prodigious numbers, near great rivers and lakes, situated in thinly inhabited countries in the northern parts of Europe, Asia, and America. When the weather becomes very severe, they take their flight very high in the air, and divide their number in quest of a more genial temperature. In such hard winters they are sometimes met with in various sections of Great Britain, and in other more southern countries of Europe. The rule as to their migrations has been observed in America. They do not, however, remain longer than towards the approach of spring, when they retire northward to the arctic regions, to breed. In these movements to and fro, a few straggling birds stop short, and perform the offices of incubation by the way; for it has been ascertained that they breed in the Hebrides, the Orkney, Shetland, and other solitary isles. The great body of them, however, go far north, and are to be met with in the large rivers and lakes near Hudson's Bay, and those of Kamtschatka, Lapland, and Iceland. They are said to return to the latter place, in flocks of about a hundred at a time, in the spring, and also to pour in upon that island from the north, in nearly the same manner, on their way southward in the autumn.

Martin says, that in the month of October, swans arrive in great numbers at Lingey, one of the Western Isles, and continue there till March, when they return northward to breed. A few continue in Mainland, one of the Orkneys, and breed in the little islands of the fresh-water lochs; but the principal part of them retire on the approach of spring. They are called the Countryman's Almanack; for their quitting the isle is said to presage good weather; and their arrival, the reverse.

In Iceland, these birds are an object of chase. In the month of August, they lose their feathers to such a degree as not to be able to fly. The natives, at that season, resort, in great numbers, to the places where they most abound; and are accompanied with dogs, and active and strong horses, trained to the sport, and capable of passing nimbly over the boggy soil and marches. The swans will run as fast as a tolerably fleet horse. The greater number are taken by the dogs, which are taught to seize them by the neck—a mode of attack that causes the birds to lose their balance, and become an easy prey.

This species has several distinctions from that called by us the Tame Swan: but the most remarkable one is the strange form of the windpipe, which falls into the chest, then turns back like a trumpet, and afterwards makes a second bend to join the lungs. By this curious construction, the bird is enabled to utter a loud and shrill note. The other swan, on the contrary, is the most silent of all the feathered tribes. It can do nothing more than hiss, which it does on receiving any provocation. The vocal swan emits its loud notes only when flying, or calling: its sound is, whoop, whoop, very loud and shrill, but not disagreeable when heard high in the air, and modulated by the winds. The Icelanders compare it to the notes of the violin. As they hear it at the end of their long and gloomy winter, when the return of the swans announces also the return of summer, every note must be melodious which presages a speedy thaw, and a release from their tedious confinement.

It was from this species alone that the ancients derived their fable of the swan's being endowed with the powers of melody. Embracing the Pythagorean doctrine, they made the body of this bird the mansion of the souls of departed poets; and then attributed to the birds the same faculty of harmony which they had thus possessed in a pre-existent state. The common people, not distinguishing
between sweetness of numbers and melody of voice, imagined that to be real which was only intended figuratively. Our own Shakespeare is called the "Swan of Avon." The Mute or Tame Swan never frequents the Padus; "and I am almost equally certain" says Mr. Pennant, "that it never was seen on the Cayster, in Lydia; each of these streams being celebrated by the poets for the great resort of swans. The Padus was styled Oloriferus, from the numbers of these birds which frequented its waters; and there are few of the poets, either Greek or Latin, who do not make them its inhabitants."

**THE SWAN GOOSE.**

This is the *Anas Cynoidee* of Linnaeus, and is another interesting species of the web-footed family. In point of size, it stands between that of the common duck and the swan; whilst its length is fully a yard. It is known from the goose by its stately carriage, and by its having a large knob at the root of the upper mandible, and a skin almost bare of feathers, hanging down under the throat. A white line extends from the corners of the mouth over the front of the brow. The hue of the bill is orange, and the irides a reddish brown. A dark brown or black stripe runs down the hinder part of the neck, from the head to the back. The fore part of the neck and the breast are yellowish brown; and the back, and all the upper parts, brownish grey, fringed with a light colour. The legs are orange.

Some writers maintain that these birds were originally natives of Guinea, in Africa. They are now, however, very common everywhere, being widely and numerously dispersed, both in a wild and domestic state. They are found in great numbers about Baikal, an eastern section of Siberia, and likewise in Kamtschatka; and are kept in a state of domestication in most of the Russian provinces.

**THE MUTE SWAN.**

The plumage of the *Anas Cygnus Mansuetus* of Linnaeus, is of a snowy whiteness, and the bird itself is much larger than the wild swan; often weighing twenty-five pounds, and measuring three feet and a-half in length. The female makes her nest among the rough herbage, near the water's edge, and lays from six to eight large white eggs. She sits for the space of six weeks—some say eight—before they are hatched. The young do not acquire their full plumage till the second year.

Swans, from the earliest period of our history, have been protected on the river Thames as royal property; and it continues, at this day, to be accounted felony to steal their eggs. By this means their increase is secured; whilst they prove highly ornamental to the river scenery. In the reign of Edward IV., the estimation in which they were held was such, that no one who possessed a freestone of less than the clear yearly value of five marks, was permitted even to keep them. In those times hardly a piece of water was left unoccupied by these birds, as well on account of the pleasure they gave to the eye of their lordly owners, as that which they afforded when they graced the sumptuous boards at the splendid feasts of that period. The manners of those days, however, have passed away, and swans are not now so common as they were formerly, being by most people considered a coarse kind of food, and consequently held in little estimation; but cygnets (young swans) are still fattened for the table, and are sold for a guinea each, and even more. Hence we may infer that they are better food than is generally imagined.

This swan is a bird beautifully formed. In it we see no broken or harsh lines, no constrained or abrupt motions, but the roundest contour and the easiest transitions imaginable. The eye wanders over every part with pleasure, and each portion takes new grace with new postures.

"The swan, with arched neck

Between her white wings mantling, proudly rows

Her state with airy feet."

It exhibits, however, but an inelegant appearance on land.

The swan will swim faster than a man can walk. It is very strong, and at times extremely fierce; it has not unfrequently been known to throw down and trample upon youths of fifteen or sixteen years of age; and an old swan, we are told, is able to break the leg of a man with a single stroke of its wing. A female, while in the act of sitting, observed a fox swimming towards her from the opposite shore: she instantly darted into the water;
and, having kept him at bay for a considerable time with her wings, at last succeeded in drowning him; after which, in the sight of several persons, she returned in triumph. This circumstance took place at Pensay, in Buckinghamshire.

Swans are very long-lived, sometimes arriving at the age of one hundred years.

**WILD GEESE.**

Six different species of wild goose are said to visit the British shores in winter. The *grey-lag* is one, and is the original of our common domestic goose. Its flocks are well-known to all country people, from the circumstance of their always flying in a particular figure—that of a wedge. They are difficult to approach in regular hunting form, being shy and wary to a proverb. When they arrive in winter, they frequent the sea-coast, and little rivulets and creeks, feeding on marine and other grasses, and display a great partiality to green wheat. The only mode of getting within range of them is by ambush, or advancing upon them under cover of some kind. Colonel Hawker recommends, that we “ascertain, in the watery meads, what part they have used (which we shall be able to see by their dung and feathers); and then we should wait for them, at dusk, in some ambush that commands the fresh places adjoining. Contrive, if possible, to get the line of a dyke or drain, so as to take their company in the flank.” Mr. Daniel likewise says—“Their flight is always (except in thick fogs) very elevated; their motion is smooth, accompanied with little rustling, and the play of the wings seems never to exceed two or three inches; the regularity with which they are marshalled, implies a sort of intelligence superior to that of other birds, which migrate in disorderly bodies. The arrangement observed by the goose, is at once calculated to preserve the ranks entire, to break the resistance of the air, and to lessen the exertion of the squadron. They form two oblique lines, like the letter V; or, if their number be small, only one line. Generally they amount to forty or fifty, and each keeps its rank with admirable exactness. The chief, which occupies the point of the angle, and first cleaves the air, retires, when fatigued, to the rear, and the rest by turns assume the station of the van. Pliny describes the wonderful harmony that prevails in these flights, and remarks that, unlike the cranes and the storks, which journey in the obscurity of the night, the goose are seen pursuing their route in broad day.”

The wild goose generally weighs about ten pounds; and is two feet nine inches long, and five broad. The bill is thick at the base, tapers towards the tip, and is of a dullish-red hue, with the nail white. The head and neck are brown, tinged with dull yellow, and, from the separation of the feathers, the latter appears striped downwards. The upper part of the plumage is of a deep brown, mixed with ash-grey. Each feather is lighter on the edges, and the lesser coverts are tipped with white. The shafts of the leading quills are white; the webs grey, and the tips black. The secondaries are black, tinged with white. The breast and belly are crossed and clouded with dusky and ash colours on a whitish ground; the tail and vent are of a snowy whiteness. The middle feathers of the tail are dusky, tipped with white; those adjoining, more deeply tipped; and the exterior ones are nearly all white. The legs are pale red.

During any succession of frosty days, especially if accompanied with a snow-storm, there are few places, on the British coast, which will not afford more or less wild goose shooting. If going on the water, or into the marshes, after these birds, does not suit the convenience or choice of the sportsman, by visiting the brooks and small rivers that are only partially frozen, and following their course, he may be almost certain of meeting with some of these birds. There are many localities in the moor districts of the north of England where they are found in winter, even when it has not been either very cold or stormy.

**THE SIBERIAN GOOSE.**

The *Anser Ruficollis* of Linnaeus, also called the Laughing Goose, is white fronted. It is seldom seen in Britain. Colonel Hawker tells us, that it was unknown here till the frost of 1830, when there were eighty of them alighted in a field near the village of Wilford, where, he says, they were beset by a swarm of gunners, and attacked, but only with very moderate success. The colonel himself succeeded, however, on the following day, in...
THE CORMORANT.

The three varieties of the Pelicanus Corbo, known to sportsmen, are the crested, the black, and the cole-goose. The common cormorant weighs from four to seven pounds; and the size varies from about three feet to four feet six inches in breadth. The bill, to the corners of the mouth, measures four inches, and its ridge two-and-three-quarters. It is of a dark horn-like consistency, and the tip, or nail, of the upper bill is considerably hooked and sharpened. From the base of this it is furrowed on each side, nearly to the top, without any visible appearance of nostrils. The lower bill is compressed, and covered, about the gape of the mouth, with a naked yellowish skin, extending under the chin and throat, where it hangs loose, and forms a kind of pouch, which, together with the springing blade on each side forming its rim, is capable of great expansion, and by it the bird is enabled to swallow prey apparently too large to be admitted into its throat. The skin about the eye is naked, and of the same colour as the pouch. The eyes, which have a remarkably wild stare, are placed near the bill. The crown of the head and neck are black; and on the hinder part of the former the feathers appear elongated, and form a sort of loose crest. In some species the throat is white, with a kind of stripe passing from it, upwards, behind each eye. In others the cheeks and throat are mixed with brown and white; while, in other species, the head and neck are streaked with scratches of the latter colour. The middle of the belly is white, with a patch of the same colour over each thigh. All the under parts, however, together with the back and rump, are commonly of a glossy blue-black, with green shades. The shoulders, scapulars, and wing-coverts, are of a bronze-brown hue, tinged and glossed with green; and each feather is bordered with shining bluish-black. The secondary quills are nearly of the same colour. The coverts and primaries are dusky. The tail consists of fourteen stiff feathers, which look as if they were discoloured by being dipped in mud or dirty water. The legs are thick, and black, and about two inches and a-half long.

The cormorant is a native of almost every climate. It abounds in large numbers in Greenland and Nova Zembla, and parts adjacent; and the natives have a curious method of taking them, by means of lures or decoys. They make use of the jugular pouch of the bird for a bladder to float their fishing-darts, after they are thrown; whilst their skins, which are tough and leathery, are used for garments, and their flesh for food. It is said, however, that the eggs of the bird are too fœtid even to be eaten by Greenlanders.

These birds usually assemble in flocks, on the summits and inaccessible parts of the rocks which overhang or are surrounded by the sea, upon which the female makes her nest of the withered sea-tang, weeds, sticks, and grasses, which are cast on shore by the waves. She lays four or five greenish-white eggs, of the size of those of a goose, but of a longer shape. Many writers and naturalists assert that, in some parts of the world, these birds build their nests on trees, like the rook and the heron; others, again, forming their opinions from the singular conformation of the feet and the serrated claws, ascribe properties to them which they do not possess, and maintain that they hold their prey in one foot, while, with the other, they push forward to the shore, or carry it thither in the same manner on the wing. This is, however, fancy, unsupported by any evidence of fact. The truth is, the feet of these birds are not adapted for any such purposes. They are, like those of all the expert diving tribes, placed far behind; and while, by their position and the powerful stroke from their broad webs, the birds are able to pursue and overtake their prey, the hooked sharp-edged beak is the only instrument they have fitted both to catch and secure it, and there is no need to use the awkward expedient of removing it afterwards to the foot.

At sea, or in the inland lakes, cormorants prove themselves great gluttons. From the loftiest heights they drop down upon the object of pursuit, dive after it with the rapidity of a dart, and, with an almost unerring certainty, seize it. They then emerge with the fish across the bill, and, with a twirl, throw it up into the air, and dexterously catch it as it descends head foremost, and swallow it whole.
While at rest on shore, these birds sit, more or less, in an erect posture, and are propped up by the stiff feathers of the tail. In places where they have not been disturbed by firearms, they have been known, however wary at other times, to sit and receive repeated shots, without offering to move out of the danger. At other times and places, while they sit in a dosing and stupefied state, from the effects of one of their customary surfeits, they may easily be taken, by throwing nets over them, or by putting a noose round their necks, which they endeavour to avoid no further than by slipping the head from side to side as long as they can.

Whatever may be the wild disposition of these birds, we have authentic accounts that certain species of them were formerly tamed, and rendered subservient to the purposes of man, both in this and other countries. Among the Chinese, they have frequently been trained to fish, and fishermen have kept many of them for that purpose, and by their skill have gained a good livelihood. A ring placed round the neck prevents the bird from swallowing what it catches; whilst its natural appetite, joined to the will of its master, induces it instantly to dive at the word of command; but, unable to gorge the fish it has taken, it returns to the keeper, who secures it himself. Sometimes, if the fish be large, and difficult to manage, two will act in concert—one bird taking it by the head, and the other by the tail. Willoughby informs us, that in England, when these birds are brought to the rivers, their heads are taken off, and then a leather thong is tied round the lower part of their necks, that they may not swallow the fish they take. The birds are then thrown into the water, when they immediately dive; and, for a time, with remarkable swiftness, pursue the fish with great ardour. When they have caught any, they rise to the surface, and pressing them lightly with their bills, swallow them, each to the extent of five or six; then the keepers call them to the fist, to which they readily fly, and little by little, one after the other, vomit up all their finny captures, which appear sometimes a little bruised with the nip the bird has given them with its hooked bill. When the fishermen have done, they set the birds on some high place, and then loosen the string from their necks, which leaves the passage free of air to the stomach; and, by way of encouragement, part of the prey is given back again to each bird. Whitlock tells us, likewise, that he had several cormorants tamed like hawks, which would come to hand. He took great pleasure in them; and relates, that the best he had was one presented to him by Mr. Wood, master of the cormorants to Charles I.

Dr. Heysham relates, that, on a certain occasion, one of these birds perched upon the castle at Carlisle, and soon afterwards removed to the cathedral, where it was shot at upwards of twenty times, without effect. At length, a person got upon the cathedral, fired at, and killed it. In another instance, a flock of fifteen or twenty perched, at the dusk of evening, on a tree, on the banks of the river Esk, near Netherby, the seat of the late Sir James Graham. A person who saw them settle, fired at random at them, in the dark, six or seven times, without either killing or even frightening any of them away. Surprised at this, he came again at daylight, and succeeded in killing one, when the rest took to flight.

Colonel Hawker says, that cormorants may be seen in the evening, pursuing a regular course towards the cliff, on the sea-coast, where they roost, and that, in their flight, they are often mistaken for Brent geese, and shot at by the inexperienced. They are likewise sought after by adventurous persons, who are able to reach the middle of the rocky heights. In attempting to shoot them in such positions, much caution is requisite in secreting the sportsman from observation. So keen-sighted are these birds, and so jealous of any object that bears even the semblance of a weapon, that they immediately take the alarm at the slightest appearance of an enemy, and thus elude the devices of the best sportsman. Shooting them is considered an excellent exercise for young gunners.

The wild duck. The *Anas Boschas* of Linnaeus is the parent of our domestic duck, and, in point of size, is a little less. The wild mallard, or drake bird, has a length of about twenty-three inches, and a breadth of about thirty-five. It usually
SHOOTING,

in vast numbers, leave the north at the end of autumn, and, flying southward, arrive in Great Britain in the beginning of winter, and spread themselves over all the lakes and marshy wastes. They pair in the spring, when the greater part of them again return to the north, to breed during the summer months of comparatively warm weather and long days. A few straggling birds remain every season with us, and breed.

It is not at all times that wild duck shooting can be pursued with success. These birds being very shy, considerable art must be employed in endeavouring to bring the shot within range of them. They have fixed times of feeding and visiting certain localities; and the only way for the sportsman to make sure of them, is to watch their movements, and conceal himself from observation. He may thus often intercept their flight when congregated in considerable numbers, and bring down several at a shot. They are sometimes very easily killed, and sometimes not. All depends upon the part of the body which the pellets have struck. Regular wild duck shooters are often very successful in moonlight nights. The birds are then less shy and suspicious.

Wild ducks frequent the marshy places of many parts of this kingdom; but nowhere in greater plenty than in Lincolnshire, where prodigious numbers were wont annually to be taken in the decoys. In only ten decoys in the neighbourhood of Wainfleet, as many as thirty-one thousand two hundred have been caught in one season.

To those who may not know what a decoy is, we may say that it is a pond generally situated in a marsh, so as to be surrounded with wood or reeds, and, if possible, with both, to prevent the birds which frequent it from being disturbed. In this pond the birds sleep during the day; and as soon as the evening sets in, the decoy rises (as it is termed), and the wild fowl feed during the night. If the evening is still, the noise of their wings during flight is heard at a great distance, and is a pleasing though somewhat melancholy sound. The decoy-ducks (which are either bred in the pond-yard, or in the marshes adjacent, and which, although they fly abroad, regularly return for food to the pond, and mix with the
tame ones that never quit the pond) are fed with hemp-seed, oats, and buck-wheat. In catching the wild birds, hemp-seed is thrown over the screens to allure them forward into the pipes, of which there are several, leading up a narrow ditch, that closes at last with a funnel-net. Over these pipes, which grow narrower from the first entrance, there is a continued arch of netting, suspended on hoops. It is necessary to have a pipe for almost every wind that can blow, as on that circumstance it depends which pipe the fowl will take to. The decoy-man likewise always keeps to the leeward of the wild fowl; and burns, in his mouth or hand, a piece of Dutch turf, that his own smell, if he have any, may not reach them; for, if they once discover by their scent that a man is near, they all instantly take flight. Along each pipe are placed reed screens, at certain intervals, to prevent him from being seen till he thinks proper to show himself, or the birds have passed up the pipe, to which they are led by the trained ducks, which know the decoy-man's whistle, or are enticed by the hemp-seed. A dog, which is taught to play backwards and forwards between the screens, at the direction of his master, is sometimes used. The fowl, roused by this new object, advance towards it, while the dog is playing still nearer to the entrance of the pipes. At last the decoy-man appears from behind the screens, and the wild fowl, not daring to pass by him, and unable to fly off on account of the net covering the hoops, press forward to the end of the funnel-net, which terminates upon the land, where a person is stationed ready to take them. The trained birds return past the decoy-man into the pond again, till a repetition of their services is required. The general season for catching is from the latter end of October till February.

It was formerly customary to have, in the fens, an annual driving of the young ducks, before they took wing. Numbers of people assembled, who beat a vast tract, and forced the birds into a net placed at the spot where the sport was to terminate. By this practice—which, however, has been abolished—as many as a hundred and seventy-four dozen have been known to be taken in one day.

Wild ducks do not always build their nests close to the water, but often at considerable distance from it; in which case the female will take the young in her beak, or between the legs, to the water. They have been known sometimes to lay their eggs in a high tree, in a deserted magpie's or crow's nest; and an instance has likewise been recorded of one being found at EtchingHAM, in Sussex, sitting upon nine eggs, in an oak, at the height of twenty-five feet from the ground. The eggs were supported by some small twigs laid crossways.

We are informed, that at Bold, in Lancashire, there were formerly great numbers of wild ducks, during the summer-time, in the ponds and most near the hall. These, it is said, used regularly to be fed. A man beat with a stone on a hollow wooden vessel, and immediately the ducks would come round him. He scattered corn among them, which they gathered with as much quietness and familiarity as might be expected from tame ducks. As soon as they had finished their repast, they returned to their accustomed haunts.

Prodigious numbers of these birds are taken by decoys, in Picardy, in France. It is customary there, to wait for the flock's passing over certain known places; when the sportsman, having a wicker cage, containing a quantity of tame ducks, lets cut one at a time, which enticing the passengers within gun-shot, five or six are often killed as once by an expert marksman. They are also, now and then, taken by hooks baited with raw meat, which the birds swallow while swimming on the water.

Other methods of catching ducks and geese are peculiar to certain nations. One of these, from its singularity, seems worth mentioning. A person wades into the water up to the chin; and, having his head covered with an empty calabash, or gourd, approaches the place where are the ducks; which, not regarding an object of this kind, suffer him freely to mix with them. He then has only to pull them by the legs under the water, one after another, and fix them to his belt, till he is satisfied; returning as unsuspected by the remainder as when he first went among them. This curious method is frequently practised on the river Ganges, the earthen vessels of the Hindoos being used instead of calabashes. These vessels are what the Hindoos boil their rice in. After having been once used, these vessels are looked upon as defiled, and are thrown

557
into the river as useless. The duck-takers find them convenient for their purpose, as the ducks, from seeing them constantly floating down the stream, esteem them as objects not to be regarded.

The Chinese make great use of ducks, but prefer tame to wild ones. It is said that the greater number of the ducks in China are hatched by artificial means. The eggs, being laid in boxes of sand, are placed on a brick hearth, to which is given a proper heat during the time required for hatching. The ducklings are fed with craw-fish and crabs, boiled and cut small, and afterwards mixed with boiled rice; and, in about a fortnight, they are able to shift for themselves. The Chinese then provide them an old step-mother, who leads them where they are to find provender; being first put on board a sampans* or boat, which is destined for their habitation; and from which the whole flock, often to the amount of three or four hundred, go out to feed, and return at command. This method is used nine months out of the twelve; for in the colder months it does not succeed, and is so far from a novelty, that it may be everywhere seen; but more especially about the time of cutting the rice, and gleaning the crop, when the masters of the duck-sampans row up and down the river, according to the opportunity of procuring food, which is found in plenty, at the tide of ebb, on the rice plantations, as they are overflowed at high water. It is curious to observe how the ducks obey their masters; for some thousands, belonging to different boats, will feed at large on the same spot, and, on a signal given, will follow their leader to their respective sampans, without a single stranger being found among them. This is still more extraordinary, if we consider the number of inhabited sampans on the Tigris, which have been supposed to be not less than 40,000, moored in rows, close to each other, with, here and there, a narrow passage left for boats to sail up and down the river. The Tigris, at Canton, is somewhat wider than the Thames at London; and the whole river is there covered in this manner for upwards of a mile.

* Sampans is a common name for boats: the inhabited ones contain each a separate family, of which they are the only dwelling; and many of the Chinese pass almost their whole lives in this manner on the water.
such is the form and shortness of the wing of pochards, that they cannot ascend again from these little inclosures if they would; besides, the numbers which are usually knocked into these pens, preclude all chance of escape from them by the wing. A decoy-man will sometimes allow the haunts of dun-birds to be so great, that the whole surface of the pond will be covered with them previous to his attempting to take one. Upon such occasions he bespeaks all the assistance he can get, to complete the slaughter by breaking their necks. When all is ready, the dun-birds are roused from the pond; and all wild fowl rise against the wind, the poles in that quarter are unpinned, and fly up with the nets at the instant the dun-birds begin to leave the surface of the water, so as to meet them in their first ascent; and they are thus beat down by hundreds. At the pond of Mr. Baxton, at Goldhanger in Essex, as many pochards have been taken at one drop as filled a waggon, so full as to require four stout horses to carry them away; and the lower birds in the pens have been known to be killed and pressed entirely flat, from the numbers of their companions heaped up above them by the fatal stoppage of the poles and nets. The few attempts made to domesticate the pochard have been hitherto unsuccessful. They do tolerably well where there is plenty of water, but cannot bear walking about on hard, pebbly grounds."

The pochard leaves the northern regions at the commencement of winter, and directs its course southward. It is said that it frequents Egypt, also the entire section of the Holy Land; and is very numerous in some of the lakes and marshy districts in America, especially in Carolina and Louisiana. In France it makes its appearance about the month of October, in large flocks; and about the same period it may be found in all the low and feney districts of Great Britain.

In shooting this bird, especially in a severe snow-storm, accompanied with a hard frost, it is found not to be so difficult to bring to the ground with tolerably sized shot as some other wild fowl; it is, however, always a matter of difficulty to get within range of it, for it is very shy, and remarkably quick in recognising an enemy, when it immediately takes wing to some safe retreat.

THE WIDGEON.

This well-known bird is the Anas Penelope of Linnaeus, and has a length of about twenty inches, a breadth of from two to three feet, and a weight of about twenty-two ounces. The bill is an inch and a-half long, and narrow, with its outer edges serrated. The upper mandible is of a dark leaden hue, tipped with black. The crown of the head is very high and narrow, and is of a cream colour, with a small spot of yellowish white under each eye. The rest of the head, the neck, and the breast, are of a bright rufous chestnut, faintly freckled on the head with black spots, and darkest on the chin and throat, and tinged with a vinous colour. A band, composed of beautifully waved or indented narrow ash-brown and white lines, separates the breast and neck. The scapulars and back are marked with similar feathers, as are also the sides of the body under the wings, even as low as the thighs. These, however, are paler. The belly, to the vent, is white, and the ridge of the wing and adjoining coverts are of a dusky ash-colour, approaching to brown. The great coverts are brown, fringed with white, and tipped with black, which forms a border to the changeable green beauty-spots of the wings, which are likewise bordered on the under side by the deep velvet black tips of the secondary quills. The exterior webs of the adjoining quills are white; and those next the back, which are very long, are of a deep brown, fringed with yellowish white. The greater quills are brown; the vent and upper tail-coverts are black.

During the night, whilst widgeons are taking their course through the air, they may be distinguished from other wild fowl by the peculiar whistling note they use. They have been domesticated, and are generally much admired on account of their liveliness and beauty.

On the approach of frosty weather, they leave the desolate regions of the north, and direct their course to the south, breaking into detached and diverging lines, and spreading themselves along the shores, and over the morasses and lakes of different countries. Large numbers of them are found in the East, particularly in Egypt, and in the islands of the Mediterranean. They remain in these
parts during the winter, at the end of which the old birds pair; and the whole flock, in full plumage, take their departure northward about the end of March. While the widgeon remains in Britain, it frequents the same places, and feeds in the same mode as the mallard, and is often taken in the decoys, along with different species of the duck tribe.

There are a great number of birds called divers; and among the number are the scap, golden-eye, and morillon. Colonel Hawker says there are seven kinds of these divers to be found in Great Britain, exclusively of other six, which are separately classed as the genus Mergus. Mr. Daniel observes, that "they vary much both in plumage and size; some weighing two pounds and a-half, and others a pound less, and are caught in the decoys with the ducks. In hard weather, they frequent the shores and tide rivers in great plenty, and are almost always, at that season, fat and in good condition. They do not fly in such large flocks as many of the duck species, but usually close to the surface of the water, and bear very hard blows from the shot without dropping, unless struck upon the head or wing. The scap is seen in prodigious numbers, from November to March, on the French coasts, especially if the wind be to the north, or north-west. The day seems to be spent by these birds between diving and flying to small distances over the water, which they do so low as often to dip their legs in it. They swallow their food whole, and soon digest the shells, which are found crumbled to powder among their excrescences. They have been kept tame for some time, and will feed on soaked bread. The flesh tastes fishy in the extreme; and, from this cause, is allowed by the Roman Catholics to be eaten on fast days and in Lent; and, indeed, to say the truth, must be a sufficient mortification."

However amusing the shooting of these birds may be, it is not attended with much profit, as they are very difficult to hit. They are wonderfully quick in diving; for the moment the gun is pointed, down they go. In stormy weather—that is, with the wind from the north-east, cold and frosty—a sportsman on the east coast of Britain, may now and then waylay these birds on their flights, and succeed in bagging a few brace; but even to do this, great exertion, patience, and the concurrence of favourable circumstances, are required.

THE TEAL.

The Anas Crecce of Linnaeus is a great favourite with many sportsmen, and is considered both a beautiful and handsome bird. It is about twelve ounces in weight, fifteen inches in length, and twenty-four in breadth. The bill is dark, tipped with white. The irides are pale; and a glossy bottle-green patch, fringed on the upper side with pale brown, and beneath with cream-coloured white, covers each eye, and extends to the nape of the neck. The rest of the head, and the upper part of the neck, are of a deep reddish chestnut, darkest on the forehead, and freckled on the chin and about the eyes with cream-coloured spots. The hinder part of the neck, the shoulders, part of the scapulars, sides under the wings, and lower belly towards the vent, are pencilled with black, ash-brown, and white traversed waved lines. The breast is of a pale brown or reddish yellow, and each feather is tipped with a roundish heart-shaped black spot, having a resemblance to the markings of the Indian shell. The belly is a cream-coloured white. The quills, lesser and greater coverts, are brown, and the last are deeply tipped with white, which form a bar across the wings. The first six of the secondary quills are of a fine velvet black; while those next to them, towards the scapulars, are resplendent glossy green; and both are tipped with white, forming the divided black and green bar, or beauty-spot of the wings.

The tail consists of fourteen feathers, of a whitish brown colour, with pale edges; and the legs and feet are of a dingy lead. The female, which is less than the male, has its head and neck prettily freckled with brown and white. She has not the green patch between the eyes, but a brown streak supplies its place, and extends to the nape of the neck. The crown of the head is dark brown. The upper mandible yellow on the edges, olive green on the sides, and olive brown on the ridge. The nail is black, and the under bill yellow. The breast and belly are of a glossy yellowish white, irregularly spotted with brown. The upper plumage is dark brown, each feather being bordered with rusty brown, and fringed with grey. The wings are like those of the male bird.
In most parts of Great Britain, during winter, teal are common; but it is not very well ascertained whether they remain throughout the year to breed, as they do in France. The female makes a large nest, composed of soft dried grasses, lined with feathers, concealed in a hole among the roots of weeds and bulrushes, near the edge of the water; and some naturalists have asserted, that the nests, in several instances, have been found entirely to float on the surface of the water, so as to rise and fall with it. The eggs are of the size of those of a pigeon, and amount to six or seven in number. They are of a dull white colour, freckled with small brownish spots. Their numbers vary. Some have been known to lay twelve eggs. Buffon says, that numbers of young teal are seen in pools, feeding on cresses, wild chervil, &c.; and, unquestionably, as they grow up, they feed, like other ducks, on the various seeds, grasses, and water-plants, as well as on the smaller living things with which all stagnant waters are so abundantly stored. The bird is highly extolled for the excellence of its flavour.

Teal are seldom found in large numbers; scarcely ever more than ten or twenty are seen together, and this only in stormy weather, and in certain favourite localities near the coast, or by the edges of a sheet of water, where they are fringed with long grass, or brushwood. They are comparatively solitary birds, confining themselves chiefly to families; and it is only in this way that they are interesting to the sportsman. A man may range a considerable section of marshy country, and not see more than a pair or two at a time. In all the moor and boggy districts, in the north of England, they are to be met with; but never in great numbers.

There is a large portion of wild-fowl shooting pursued as a matter of business and traffic, and, consequently, with a view to filling the coffers rather than furnishing sport. This is chiefly confined to the low districts of the coast, where birds of the duck kind, especially, congregate in immense flocks at certain seasons of the year. Many persons gain a good livelihood by this kind of shooting as it is followed on the Hampshire coast, and the Isle of Wight. The coast between these localities consists, at ebb tide, of vast muddy flats, covered with green sea-weed; and affords the fowler an opportunity of practising arts perhaps not elsewhere resorted to. Fowling and fishing are, indeed, on this coast, commonly the employments of the same person. He who in summer, with his line or net, plies the shores when they are overflowed by the tide, in winter with his gun, as evening draws on, runs up in his boat among the little creeks, which the tide leaves in the marshlands, and lies in patient expectation of his prey. Sea-fowl usually feed by night, when, in all their multitudes, they come down to graze on the savannahs of the shore. As the sonorous cloud advances (for their noise resembles a pack of hounds in the air in full cry), the attentive fowler listens which way they bend their course: perhaps he has the mortification to hear them alight at too great a distance for his gun (though of the longest barrel) to reach them; and if he cannot edge his boat round some creek, which it is not always in his power to do, he despair of success that night; perhaps, however, he is more fortunate, and has the satisfaction to hear the airy noise approach nearer, till at length the host settles on some plain upon the edge of which his boat is moored. He now, as silently as possible, prizes both his pieces anew (for he is generally doubly armed), and listens with all his attention. It is so dark, he can take no aim; for, if he could discern the birds, they would also see him, and, being extremely timorous, would seek some other pasture. Though they march with noise, they feed in silence; some indistinguishable noises, however, if the night be still, issue from so vast a concourse. He directs his piece, therefore, towards the sound, fires at a venture, and instantly catching up his other gun, discharges it where he supposes the flock to rise on the wing. His gains, for the night, are now decided, and he has only to gather his harvest. He immediately puts on his mud-pattens (flat, square pieces of board, which the fowler ties to his feet that he may not sink in the ooze), ignorant yet of his success, and goes grooping about in the dark in quest of his booty, picking up sometimes many, and perhaps not one; so hardly does the poor fowler earn five shillings, exposed in an open boat, during a solitary winter night, to the weather as it comes—rain, hail, or snow, on a bleak coast—a league

591
probably from the beach, and often liable, without great care, to be fixed in the mud, where he would become an inevitable prey to the returning tide. We have heard of a poor fellow who never took a dog with him in these expeditions, because no dog could bear the cold which he was obliged to suffer. The tide often throws, next day, on different parts of the shore, many of the birds which he had killed on the previous night, but could not find them.

This is the account given by Mr. Gepin, of this kind of sport; but, since his time, the mode of pursuit has been greatly improved.

The danger, Mr. Daniel tells us, of fowlers attacking the wild fowl in small boats, arises from the circumstance, that when there happens to be ice in the river, they get encircled by it, and can only hope to extricate themselves by following the current, wherever it may take them. It not unfrequently happens that the men are detained two or three tides, before they can work their way out of the icy entanglement. They also suffer much, in such cases, from cold and privation.

On and in the vicinity of the Fern Islands, near to Berwick-upon-Tweed, wild fowl congregate, and breed in surprising numbers. It is impossible, in walking on the ground, to step upon a single square foot of space without crushing eggs beneath your feet. In the winter season, when there is a storm from the east or north-east, with a heavy sea breaking on the shore, the wild fowl may be shot, even on the mainland, in considerable quantities, by artfully concealing oneself along the beach. Storms have sometimes so bewildering an effect, even on these hardy birds, that they seem quite stupid, and will sometimes come within twenty yards of the gun, in daylight.

LAKE AND POND SHOOTING.

This sport can only be followed in certain parts of the kingdom, as, where there are neither lakes nor ponds, it cannot be pursued. In the fenny districts of Lincolnshire and Cambridgeshire, however, where the various kind of wild ducks breed among the reeds and long grass in the boggy grounds, this sport is to be obtained. Here the young are hatched, and, in the month of August, receive the name of flappers; and the shooting of them then commences, and is found to be excellent sport.

This kind of shooting is altogether different from that which is practised on the coast, where the birds only come to feed at particular seasons, and where they never breed. These fens, mere, or broads, are sometimes amazingly stocked with birds of all kinds; and great numbers are shot, or taken in traps and nets for the London market.

For Hampshire coast-punt shooting, a gun of fifty pounds weight is that which is found to be the most suitable. The old heavy pieces of seventy and eighty pounds, rendered the punt immovable when fouled on grass and winkle, which are shells strewed over the oozes in countless myriads. The sportsman, in such a punt, rows with his back to the gun, until he sees the fowl, when he turns on his face, and works himself along with a kind of prong, weighted to catch the ground. When the water is too deep for the pushing-pole readily to reach the ground, two paddles are made use of to help the fowler forward.

Having given these general instructions, the reader is referred to the work of Colonel Hawker for further information. There he will find all that relates to mud-pattens, mud-boards, and to several modifications of the launching-punt, the launching-sledge, the Sussex mud-boat, and the Poole canoe—all devices and instruments made to facilitate the capture of the wild fowl in the creeks and oozes of this part of the British coast.

There are other matters connected with this sport sufficiently important to demand a slight notice, amongst which is the dress of the wild-fowl sportsman. Respecting this, Mr. Daniel says—"To be properly equipped for this sport in severe weather, it is essentially requisite to be well clothed. Flannel shirt, drawers, and additional exterior and warm garments, will not be found unpleasant to those who face the cold winds upon the marshes, or sit fixed in a punt alongside the oozes; thick yarn stockings, and, over them, what are termed wads by the fisherman (knit woollen stockings that come up to the middle; and, however inelegant in their appearance, prove very solid comforts to the wearer); and over these double defenders of the legs, a pair of waterproof boots will also be found indispensable. A cap must be worn, made of skin, instead of a hat; as the wild fowl will not approach near the latter."
Wild-fowl shooting being a severe and much-exposed amusement, ought not to be engaged in by young men of a consumptive habit. Indeed, we have heard of many a man possessed of what is called an iron constitution, sinking under long-continued exposure to night air, want of sleep, with, perhaps, a too great indulgence in tipping, to keep the cold out. The best means for this is to go out to the sea-shore in a frosty night, pretty well soaked with warm tea; it will enable the sportsman to stand longer uninjured by cold and damp than anything he can take. We have found this to be true from personal experience, as well as from the testimony of others.

Wild-fowl shooting can be obtained in almost every section of the coast of Great Britain and Ireland, and in most of the mountainous and moorish districts of both islands. North and South Wales present some fine lakes for this kind of shooting; and so likewise do all the Highland localities of Scotland. The whole coast of this part of Britain offers a large field for this sport; and to one who wishes to enter zealously into it, we would recommend him to take a tour round the western isles, by the north cape, returning by the eastern side of the island. In such an excursion he will find sport enough to satisfy the most ravenous appetite.

In India, wild-fowl shooting is zealously followed, both by British residents and natives. "The English," says Mr. Pennant, "send out their servants as well as Indians to shoot these wild fowl on their passage. It is in vain to follow them; they therefore form a row of huts made of boughs, at musket-shot distance from each other, and place them in a line across the parts of the west marshes of the country where the fowl are expected to pass. Each stand is occupied by a single person; these, on the approach of the birds, mimic their cackle so well, that they will answer, wheel, and come near the hovel. The sportsman keeps motionless, and on his knees, with his gun cocked, and never fires till he has seen the eye of the wild fowl. He fires as they are going from him; then picks up another gun that lies by him, and discharges that. The fowl killed he sets up on sticks, as if alive, to decoy others; he also makes artificial birds for the same purpose. In a good day (for they fly in very unequal numbers), a single Indian will kill two hundred. Notwithstanding every kind of wild fowl has a different call, yet the Indians are admirable in their imitation of every one."

There is a kind of shooting called flight-shooting, which is thus spoken of by Mr. Blaine. "The uninitiated in this sport," he says, "without other company than one friend or his servant, may commence with this shooting by following these instructions:—By either a punt or canoe, provided you can pitch on a retired spot, not followed up either by the fishermen or the rattle of the neighbourhood. In a canoe, either by rowing or pushing yourselves along between the banks of a creek, being well screened from observation, your chance of success is in the proportion of your prudence in keeping yourselves completely concealed, and in the dexterity of your manipulations, when the fowl begin to arrive in small tribes towards nightfall. Being provided each with a handy duck gun, wait their arrival patiently. Now, as Colonel Hawker most descriptively expresses it, you will probably soon hear the whistle of the approaching widgeon, the stormy rush of the dun-birds, the plaintive notes of the plover, and the shrill sound of the approach of the wild ducks. It will offer you more chance of success should the weather be somewhat boisterous, and still more, if the birds are forced to fly against the wind, which not only makes them fly low, but pretty closely together also. Be particularly careful that nothing you have on can make a glare; be as still as death, yet watchful as life can make you; and as the birds, in the flight up the creek, lower themselves, shoot well forwards—say one or two feet, before their heads, according to the rate at which they fly. If you can find or even make any screen, one may leave the boat, and wait the flight of a tribe coming on the marsh to feed; the other may wait his own chance with patience in the boat. This shooting may also be attempted, and often successfully, when alone, and likewise without a boat, provided you have the means of concealing yourself, which will, in all probability, happen, by taking advantage of some of the deep indentations made by storms, currents, or under the banks of a brook. Wait patiently in such a situation, and you will be almost
certain of success, particularly about the dusk of the evening; and, if you are as great a zealot as we have been at the sport, try the grey of the morning, which we have commonly found the best time, because the best employed for this purpose."

CHAPTER XIII.

ROOK SHOOTING.

Rook shooting is excellent sport, and is followed in the month of May. The rook is about the size of the carrion crow, and is very like it, except in its glossy plumage. The base of the bill and nostrils, as far as the eyes, is covered with a white skin, which constitutes one of the points of difference between it and the common carrion crow. It is gregarious, and collects in vast multitudes at morning and evening, to repair and return to its feeding and resting-place. During the breeding-time rooks live together in large societies, and build their nests on trees close to each other, and, not unfrequently, even in the heart of populous cities, says Mr. Hone, in his Every-Day Book.

Besides insects, rooks feed on different kinds of grain, and cause some inconvenience to the farmer; but to whatever extent this may be, it seems greatly repaid by the good they do to him, in extirpating the maggots of some of the most destructive of the beetle tribe. In Suffolk, and in some parts of Norfolk, the farmers find it beneficial to encourage the breed of rooks, as the only means of freeing their ground from the grub which produces the cockchafer, which, in this state, destroys the roots of corn and grass to such a degree, that there are some pieces of pasture-land where you might turn up the turf with your foot.

These birds are sometimes seen in flocks so great as to darken the air in their flight. They build their nests on high trees, close to each other; generally selecting a large clump of the tallest for this purpose. When once settled, they, every year, frequent the same place. They are, however, bad neighbours to each other; for they are continually fighting and pulling to pieces each other's nests. These proceedings seem unfavourable to their living in such close community; and yet, if a pair offer to build on a separate tree, the nest is plundered and demolished at once. Some unhappy couples are not permitted to finish their nests until the rest have all completed their buildings; for, as soon as they get a few sticks together, a party comes and demolishes the whole. It generally happens that one of the pair is stationed to keep guard, while the other goes abroad for materials. From their conduct in these particulars, our cant-word rooking, for cheating, originated.

As soon as the rooks have finished their nests, and before they lay, the cocks begin to feed the hens, who receive their bounty with a fondling tremulous voice, fluttering wings, and all the little blandishments that are expressed by the young while in a helpless state. This gallant deportment of the males is continued throughout the whole season of incubation.

There seems to exist a wonderful antipathy between these birds and the raven. It is said, that as soon as a raven builds her nest in a tree adjoining a rookery, all the rooks immediately forsake the spot. At a rookery at Broomham, near Hastings, upon a raven building her nest in one of the trees, all the rooks forsake the spot; they, however, returned to their haunts in the autumn, and built their nests there the succeeding year. It is not difficult to account for this antipathy. The raven will scarcely suffer any bird whatever to come within a quarter of a mile of its own nest, being very fierce in defending it. Besides, it seizes the young rooks from their nests, to feed its own young.
Rooks begin to build in March; and, after the breeding season is over, forsake their nesting trees, and, for some time, roost elsewhere; but they have always been observed to return in August. In October, they repair their nests. When the first brood of rooks are sufficiently fledged, they all leave their nest-trees in the day-time, and resort to some distant place in search of food: but return regularly every evening, in vast flights, to their domiciles; where, after flying round several times with much noise and clamour, till they are all assembled together, they take up their abode for the night.

In parts of Hampshire, adjacent to the New Forest, after the rook has reared its progeny, and has carried off such of them as have escaped the arts of men and boys, it retires every evening, at a late hour, during the autumn and winter months, to the closest coverts of the forest, having spent the day in the open fields and enclosures in quest of food. Its late retreat to the forest is characteristic of the near approach of night.

"Retiring from the downs, where all day long
They pick their scanty fare, a black-wing train
Of loitering rooks thick urge their weary flight,
And seek the shelter of the grove."

But although the forest may be called its winter habitation, it generally, every day, visits its nursery; preserving the idea of a family, which it begins to make provision for very early in the spring.

Dr. Darwin has remarked, that a consciousness of danger from mankind is much more apparent in rooks than in most other birds. Any one who has in the least attended to them, will see that they evidently distinguish that the danger is greater when a man is armed with a gun, than when he has no weapon in his hands. In the spring of the year, if a person happen to walk under a rookery with a gun in his hand, these inhabitants of the trees rise on their wings, and call to the unfledged young to shrink into their nests from the sight of the enemy. The country-people, observing this circumstance so uniformly to occur, assert that rooks can smell gunpowder.

In England these birds remain during the whole year; but both in France and Silesia they migrate. It is said that there are no rooks in the island of Jersey, although they frequently fly over from Britain into France. The young birds, when skinned and made into pies, are much esteemed by some persons; they are, however, very coarse meat, and far from being universally relished.

CHAPTER XIV.

THE PIGEON.

Pigeons form a tribe which are considered to be the connecting link between the passerine birds and the poultry. They are much dispersed over the world, some of the species being found even in the arctic regions. Their principal food is grain: they drink much—not, however, at intervals, like other birds, but by a continued draught, like quadrupeds. During the breeding-time they associate in pairs, and pay court to each other with their bills. The female lays two eggs, and the young which are produced, are, for the most part, a male and a female. They usually breed more than once in the year; and the parent birds divide the labour of incubation by sitting alternately on the eggs.

Both the male and female assist in feeding their young. This, in most of the species with which we are acquainted, is done by means of a substance in appearance not unlike curd, and analogous to milk in quadrupeds, that is secreted in their crop. During incubation, the contents of the crop are gradually enlarged and thickened, like what happens to the udders of

595
female quadrupeds during the time of uterine gestation. On comparing the state of the crop when the bird is not sitting, with its appearance on these occasions, the difference is found to be very remarkable. In the first case it is thin and membranous; but when the young are about to be hatched, it becomes thicker, and takes a glandular appearance, having its internal surface very irregular. Whatever may be the consistence of this substance when just secreted, it probably very soon coagulates into a granulated white curd; and in this form it is always found in the crop. If an old pigeon be killed just when the young ones are hatching, the crop will be found as above described, having in its cavity pieces of white curd mixed with the common food of the bird, such as barley, peas, &c. The young pigeons are fed for a little while with this substance only; about the third day some of the common food is to be found along with it. As the pigeon grows older, the proportion of common food is increased; so that by the time it is seven, eight, or nine days old, the secretion of the curd ceases in the old ones, and of course no more is found in the crop of the young. It is a curious fact, that the parent pigeon has, at first, power to throw up this curd without any mixture of common food; although afterwards both are thrown up in the proportion required for the young.*

THE STOCK-DOVE.

This is the Columba oenas of Linnaeus; and, from being the parent stock whence all the varieties of the domestic pigeon are derived, is often called the stock-dove. It is still found in many parts of our island in a wild state; forming its nest in holes of rocks, and old towers, and in the hollows of trees; but never, like the ring-dove, on the boughs.

There is considerable uncertainty about the identity of this bird. Bewick calls it the wild pigeon; and Colonel Montague the rock-dove, or rockier; and he says that ornithologists seem to differ concerning the rock and the stock-pigeon, though it appears almost impossible to conceive them a distinct species. Bewick says, that the stock-dove, rock-pigeon, and wood-pigeon, with some small differences, may be included under the same denomination. The wood-pigeon ought to be taken entirely out of this class, because it is well known never to produce any sexual intercourse with the domestic pigeon, though every effort has been tried which ingenuity could suggest. The stock-dove is very generally diffused throughout all the countries in Europe. It is said to be migratory; but this is not well ascertained. The nest of the female is very loosely and rudely put together; so much so, that the eggs can be distinctly seen from the under part of the nest. She lays two white eggs. These birds live on wild fruits, herbs, and on all kinds of grain. They are very partial to peas, and are themselves delicate eating, except when they have been for some time feeding on turnips; they then acquire a strong and rancid flavour. In habit they are shy, but are somewhat more easily killed with shot than the common wood-pigeon. When they assemble in large flocks, they set scouts to watch; but, by a little care, and keeping perfectly still, if possible, the sportsman may succeed in getting at them. Some writers say they are more common in the southern counties of England than in the northern. They are likewise numerous in some districts of Wales. In some of the continental states, particularly in Hungary, Bohemia, and Servia, they appear in great flocks, at certain seasons of the year, and are shot in large numbers by the sportsmen and peasants of these countries.

Multitudes of wild pigeons visit us in the winter, from their more northerly summer retreats; appearing about November, and again retiring (except a few that breed with us) in the spring. While the beech woods were suffered to cover large tracts of ground, these birds used to haunt them in myriads, frequently extending above a mile in length, as they went out in the morning to feed. In a state of domestication, these pigeons are rendered of very material service. They frequently breed eight or nine times in a year; and though only two eggs are laid at a time, their increase is so rapid and prodigious, that, at the expiration of four years, the produce and descendants of a single pair may amount to the immense number of nearly fifteen thousand.
The usual way of enticing pigeons to remain at a required spot, is to place what is called a salt-cut near them. This is composed of loam, old rubbish, and salt, and will so effectually answer the purpose as to decoy even those belonging to other places; it is on this account held illegal. There are a great many varieties of the domestic pigeon; and of these the carriers are the most justly celebrated. They obtain their name from the circumstance of their conveying letters and small packets from one place to another. It is through attachment to their native place, and particularly to the spot where they have brought up their young, that they are thus rendered useful to mankind. The bird is conveyed from its home to the place whence the information is intended to be sent, and the letter is tied under its wing, when it is let loose. From the instant of its liberation, its flight is directed through the clouds, at an amazing height, to its home. By an instinct altogether inconceivable, it darts onward in a straight line to the very spot whence it was taken; but how it can direct its flight so exactly, will probably for ever remain unknown to us. The carrier-pigeon is easily distinguished from the other varieties, by a broad circle of naked white skin round the eyes, and by its dark-blue or blackish colour.

The Ring-Dove.

This is the largest of all the British pigeons, generally weighing about twenty ounces; and may at once be distinguished by its size from all the rest. It builds on the branches of trees, generally preferring those of the pine; the nest is large and open, formed principally of dried sticks; and the eggs, which may be frequently seen through the bottom of the nest, are larger than those of the domestic pigeon. Attempts have frequently been made to domesticate this bird, by hatching its eggs in dove-houses under the common pigeon; but as soon as the young ones were able to fly, they always escaped to their proper haunts.

Some writers think the wood-pigeon (for it often goes by this name) has considerably decreased within late years; but this is, at least, doubtful. When Mr. White, of Selborne, wrote his admirable History, we believe the birds were pretty numerous; and our belief is that they are as numerous now (if not more so) as at any previous period. It is impossible to travel in any direction in Great Britain and not see vast flocks of them, at least on those tracts of country which abound with a fair portion of wood, and are in a state of tolerable cultivation. Mr. White says, on this point, that "he had often killed near twenty in a day; and that on some occasions, with a long fowling-piece, he has even shot seven or eight at a time on the wing; as they came wheeling over his head; and that there were often, among them, little parties of small blue doves, which are called rockiers."

In shooting the wild pigeon, it requires rather a heavy blow to knock it down. Its feathers are close, and resist shot like those of water-fowl. When these birds collect in considerable numbers about turnip-fields in winter, they invariably set pickets to watch over a surprise. These sit on two or three of the highest trees in the neighbourhood; and when they give the alarm, the entire body immediately take flight. We have been often struck, and sometimes a little mortified into the bargain, to see how adroitly and cleverly these sentinels perform their duty. Yet in spite of their instinctive and systematic vigilance, the sportsman may often succeed in getting within range of the flock, and do considerable execution, by having a reliable gun, and using rather large-sized shot. In the months of July and August, this bird visits old pasture-fields, and feeds rather keenly on the seeds of a species of grass which is then abundant. We give this hint to the sportsman that he may profit by it, if it suit his inclination.

About the beginning of winter, ring-doves assemble in great flocks, and leave off cooing. The multitude thus collected during that season, is so disproportional to those which continue here the whole year, as to render it certain that by far the greater part of them quit the country in the spring. It is most probable that these pass into Sweden and the adjoining countries, to breed; and return thus far southwards in autumn, from being unable to sustain the rigours of that climate in the winter months. They again begin to coo in March; soon after which, those that are left among us, commence their preparations for breeding.
THE PASSENGER PIGEON

Is about the size of the common pigeon, and its bill is black. Round the eyes there is a crimson mark; and the head, throat, and upper part of the body are ash-coloured. The sides of the neck are of a glossy, variable purple. The fore part of the neck and breast are vinaceous; and the under parts are the same, but paler. The tail is tolerably long. The legs are red, and the claws black. The passenger pigeons visit the different parts of North America, in enormous flocks. We ourselves have seen them there in countless thousands. In the southern provinces their numbers depend greatly on the mildness or severity of the season; for, in very mild weather, few or none of them are to be seen. Actuated by necessity, they change their situations in search of acorns, mast, and berries, which the warmer provinces yield in vast abundance. When they alight, the ground is quickly cleared of all esculent fruits, to the great injury of the hog, and other mast-eating animals. After having devoured everything that has fallen on the surface, they form themselves into a great perpendicular column, and fly round the boughs of trees, from top to bottom, beating down the acorns with their wings; and then they alight, in succession, on the earth, and again begin to eat.

THE TURTLE-DOVE.

This is the Columba Tutur of Linnaeus, and is famed, from the earliest times, for its plaintive and tender note. The length of this bird is nearly twelve inches. The bill is brown; the eyes yellow, and surrounded with a crimson circle; whilst the top of the head is ash colour, mixed with olive. On each side of the neck there is a spot of black feathers, tipped with white. The back is an ash colour, with each feather fringed with a reddish brown; and the wing-coverts and scapulars are likewise of a reddish hue, slightly spotted with black. The quill-feathers are dusky, with pale edges. The fore part of the neck and breast is of a light-purplish red; and the belly, thighs, and vent are white. The two middle feathers of the tail are brown; the others dusky, and tipped with white. The two outermost are also edged with the same, and the legs are of a reddish hue.

In addressing his note, the male turtle-dove makes use of a variety of winning attitudes, cooing at the same time in the most gentle and soothing strains. This has given rise to his emblematical representation of committal attachment and happiness. These birds arrive in this country late in the spring, and depart about the latter end of August. They frequent the thickest and best-sheltered localities of woods and plantations, where they build their nests on the highest parts of the loftiest trees. The female lays two eggs, and, in our island, has only one brood; but in warmer climates she is supposed to breed several times in the course of the year. Turtle-doves are pretty common in Kent, where they are sometimes seen in flocks from twenty to thirty, frequenting the pea-fields, where, it is said, they do great damage. Their stay seldom exceeds four or five months, during which time they pair, build their nests, and rear their young, until they are strong enough to follow them in their retreat.

A variety of the common turtle has been described by the name of the "spotted-necked turtle-dove." The difference consists in the whole side of the neck being black; and instead of those feathers being tipped with white, there is a round spot of white on each, very near the end. Dr. Latham says this bird was shot in Buckinghamshire, and that he observed one of these amongst some birds that came from the last expedition to the South Seas; but as it was in a parcel wherein were some which belonged to the Cape of Good Hope, it is possible that this single bird might come from that place. The bastard produce of the common turtle with the turtle of the aviary, has been proved by frequent experiments to be barren, although the two species whence it originates appear to be closely allied, and a mixed breed is easily produced.

Pigeon-shooting is, in this country, both a sporting and a gambling amusement. We have already observed that the varieties of the pigeon family are very numerous, and naturalists and ornithological writers have differed considerably on the subject of their classification. Linnaeus places them among sparrows, upon the ground that both species pair in the season of love; both work jointly in forming the nest, and take their turns in sitting on
Ist, so which 3rd, for, 599 and, there, of necessary. lowed, sport, tires, sport, lines.

Pigeon-match shooting.

When pigeon-match shooting first commenced in England, it is difficult to say. It is noticed at length, and as an established sport, in the Sporting Magazine, before the close of the last century. The account given of it there, shows that the sport, as it was then followed, was pretty much the same as it is at the present day. Pigeons require to be bred for shooting-matches; and, for this purpose, a commodious place to rear and protect them is necessary. This, of course, will be varied according to the circumstances and position of the pigeon-breeder. But whatever be the size or shape of the dove-cote, it must have two holes or rooms for the birds to nest in. Without this arrangement there will be constant confusion, and the eggs will get broken continually. A dove-cote, entirely isolated, will prove more secure than any other, as vermin will then find it difficult, and in some cases impossible, to shelter themselves in it. When pigeons are kept in a room, and have to lay their eggs on the floor, they are liable to be destroyed by rats.

Every dove-cote should, if possible, have a south-west aspect; and if a room be fixed upon for that purpose, a hole may be made in the roof of the building for the passage of the birds, and a platform constructed at the entrance for the pigeons to alight upon, and with some defence against cats, which will often destroy a whole dove-cote in a single night. If cats can be reared to be familiar with pigeons, then they may become guardians instead of destroyers of them, and prevent the cote from being invaded by rats or mice. This platform should be painted white, which is a favourite colour with the birds, and it is likewise conspicuous as a mark to enable them to find their way home. The boxes should also be coloured, and renewed whenever necessary; for which purpose lime and water will be sufficient.

Cleanliness is of great importance in a dovecote, to prevent the birds from becoming infested with vermin, and also to keep them otherwise healthy. All dove-cotes should, therefore, be cleaned at least once a week, and the pigeons ought to be kept well supplied with water to drink. When confined in a room, they should be allowed a wide pan of water; and this should often be renewed, as acid, which cools, refreshes, and assists them to keep their bodies clear of vermin. In attending to pigeons, care should be taken that they do not fight, as, when this occurs, both the eggs and young are endangered.

The common barrel dove-cote is very common, and, no doubt, found very suitable for a pigeon-house. It is to be seen in almost every situation where pigeons are kept.

Pigeon-breeding.

In pairing pigeons for breeding, a considerable degree of care is necessary. It may be done according to the fancy of the keepers, for the purpose of varying the colours, or with any other view. Old pigeons are difficult to retain securely, as they are apt to fly away on every opportunity of gaining their freedom. It is better to have what are called squakers, or such as have not yet flown: these, being confined, will fed, and gradually accustomed to the surrounding scenery before they have acquired sufficient strength of wing to fly from their cotes, will, in a short time, become perfectly domesticated.

In a room or loft appropriated to the rearing of pigeons, the shelves should be placed sufficiently high to secure them against the attacks of vermin. It is recommended that the usual breadth of the shelves should be about twenty inches, with the allowance of eighteen between shelf and shelf, which will be quite enough not to inconvenience the tallest birds. Partitions between the shelves should be fixed at the distance of about three feet, making a blind, by a board nailed against the front of each partition, where there will be two nests in the space of every three feet; so that the pigeons will sit in privacy, and not be liable to be disturbed. Or, a partition may be fixed between each nest; which will prevent the young from running to the hen, sitting over fresh eggs, and perhaps occasion her to cool and addle them; for, when the young are about a fortnight or three weeks old, a good hen will leave them to the care of the cock, and lay again.
The food and water given to pigeons should be so disposed as not to allow them to soil themselves in any way. Earthen pans may be used for this; but there are neat meat-boxes and water-bottles made for the purpose; which are excellent things, and preserve great cleanliness in feeding. The meat-box is formed in the shape of a hopper, covered at the top to preserve the grain from dirt, which descends into a square hollow box. Some fence this off with rails or holes on each side, to keep the grain from being scattered over; others again leave it quite open, that the young birds may the more readily get at their food. The water-bottle is made of glass, with a long neck, holding from one to five gallons; it is shaped like an egg, so that the pigeons may not alight upon and soil it. It is placed upon a stand, or three-footed stool, made hollow above to receive the belly of the bottle, and let the mouth into a small pan beneath. The water gradually descends out of the mouth of the bottle as the pigeons drink, and is thus kept sweet and clean. It always stops when the surface reaches the mouth of the bottle.

Pigeon-match shooting is still practised in many parts of England, and in the metropolis and suburban localities. The terms of these matches vary. Sometimes they are arranged for single, sometimes for double guns; occasionally for one weight of shot, and sometimes for another. Within the last few years, however, these matches have been on the decline, and are not now considered so fashionable as they were some years ago; more especially in the vicinity of the metropolis.

CHAPTER XV.

SMALL BIRDS.

Of late years there has, both in England and France, been considerable speculation among naturalists and farmers, in reference to the wanton destruction of small birds, which, by some, are supposed to do great damage to the crops of the agriculturist, robbing him of much of his grain, and thereby greatly reducing the value of his crops. On the other hand, it is argued that these birds are rather the guardians than the thieves of granivorous property; that, if they do take a little grain, it is as nothing, when compared with the quantity that they save by devouring innumerable insects, which, without their activity and voracity, would soon overspread the land. Whichever of these opinions may be right, we will not stay to inquire; but, if admiration, as well as inclination, be permitted to have any weight in the matter, we should cry, “Spare the little birds!” There is, however, much wantonness and thoughtlessness exhibited, now-a-days, in the destruction of many of the “beauties of Nature,” whether belonging to active or still-life. We would not in any degree discourage any fair use of God’s creatures, either in the way of investigation or even sport; but a habit greatly prevails of useless destruction, whenever either rare beast, bird, or plant is met with in our rambles. Who that has wandered over the wilds of Snowdonia, has not mourned over the disappearance of many a rare plant, which might well have rewarded the toils of climbing, had it been left for the examination of him who loves to see Nature’s rarest productions flourishing in their native wildness! Yet, the hand of the spoiler must root it up, and selfishly appropriate, perhaps, the last specimen. If a rare bird appears in any locality, numberless guns are at once levelled at it; when surely a moment’s reflection would check such selfishness, and induce us to think that the more rare the bird or plant, the more we should be careful not to destroy it. Had a different and more rational spirit prevailed, we might still have had a sight of the bustard on Salisbury Plain, and the bittern in the marshes of Wales;
but these noble and beautiful works of Nature are now sought for in vain. Next to this ignorant mischief is the wanton destruction of harmless and useful birds. The wretched and wicked habit of almost all children seeking after and taking birds’-nests, with no other object than mere wilful destruction, is, we believe, conducive to many a wicked propensity in after-life. It is in itself not only a cruel, but a purloining act, and tends as much to blunt the natural sensibilities as it does to degrade the moral sentiments. Not to follow up this moral strain too deeply, we would notice one or two birds which, we think, are often destroyed more in a spirit of wantonness than of sport. These are the lapwing, peewit, or common plover, which, is, perhaps, one of the most elegant inhabitants of the air, the white owl, and the starling. The first, in its elegant flight, with plaintive pipe, gamboling, and wheeling, and dipping over and around its mate, must have delighted every real lover of rural rambling. One would have supposed that the thousands of slugs that it lives upon, would have made it a peculiar pet of the farmer; and its vigilance of giving the alarm, if either weasel, crow, magpie, dog, or poacher cross its resting-place, ought to make it sacred to the gamekeeper; and yet how constantly is it destroyed through sheer thoughtlessness! So, likewise, the beautiful white owl, that best of mousers, how rare has it become! Its usefulness is without a drawback, and yet how wilfully is it persecuted! We know of hardly any sight so beautiful as to see this spirit of the early night, silently glide along the dim hedge-row, and then, light as the foam of the wave, perch upon the picturesque stump of some old tree. And so the starling, that endless mocker and imitator, that croaks and whistles, and screams and warbles in mockery of all its feathered songsters. Whether we see this bird among the countless myriads of his winter companions, winging his wonderful flight, without confusion, in that cloud of birds which darkens the wintry sky, or, at other times, when faithful to his native roof, separating himself and mate from that companionship, to chatter and flutter on the old-accustomed chimney or parapet; if we consider the countless worms and insects, their only food, which these never-tiring searchers must consume, no reflective mind would ever think of raising a gun against them. This same strain of sentiment might, we think, most usefully be carried out in reference to all the tribes of harmless birds. Let each man have his pet, and do his best to encourage its preservation.

If there is to be an exterminating war carried on against these little creatures, what is to become of the “music of our groves,” and the multitude of poetical associations with which our small birds are linked in every mind? Our ornithological works will be read, by future generations, with the same sort of interest that we read of animals that lived before the flood; that had an existence, but that, long ago, became extinct, and are now only to be met with in a fossil state, imbedded in strata, or buried in long-concealed caverns.

THE COMMON STARLING.

Handsome in appearance, social in disposition, lively in manners, and harmless in its habits, the *Sturnus vulgaris*, or starling, is one of the best known and least molested birds which inhabit our green fields, lawns, parks, and pleasure grounds. It loves society, and, consequently, at almost all periods of the year, considerable flocks are met with, which range, feed, and roost together.

Starlings commence nest-building early in the year, occasionally during the third week in February, but more usually in March or April. They select a hole for a nest in an old weather-worn tree, a church-steeple, or the roof of a house; and having fixed upon one, they maintain possession of it with remarkable perseverance. A pair once fixing upon a hole beneath the rafter of a cottage, were found very troublesome, and the cock-bird was shot: the hen found another mate. Next time the hen was shot: the cock-bird paired again. Afterwards both were shot: another pair came and built. The hole was then plugged up with straw; they pulled it out piecemeal: it was next plastered over with mortar; they made a hole through it. They were afterwards allowed to tenant the spot, because it was so difficult to effect their ejection.

Starlings are particularly fond of parks which abound with ancient and venerable trees. As the nesting season comes in, these old domains present a busy and bustling aspect; for the
birds have nests in the cavities of the oaks, and are continually winging their way to and from them. The nest consists of a mass of stick, bents, shreds of cotton and feathers, and contains eggs about the end of April. It is occasionally composed of clean white straw; and, when this is the case, the eggs, which are of a delicate transparent blue, contrast very pleasingly with the light colour of the straw. Some eggs are dotted over with a few well-defined black spots, like those of the song-thrush. The young are hatched about the third week in May, and are principally fed with worms, both male and female assisting in the operation.

About September, the birds which have been reared in a particular district, collect in flocks, which, being augmented in number from other districts, grow gradually larger, until they consist sometimes of thousands; and when the whole body settles in a pasture, the ground (owing to the sable plumage of the birds) seems overspread with a wide, spacious pall. When alighted, they all generally rise in a body, and, after wheeling through the air for some time, alight upon the top of a broad oak or elm tree, which seems nearly bowed down with the weight of its burden; when in such a situation, it is anything but pleasant to listen to their chattering voices. If attacked by hawks or other predatory birds, the flock rises on the wing, closes in, very compactly together, and presents a mass which, being constantly in motion, is not easily to be broken by their swift-winged enemies.

A naturalist writes—"On the 2nd of October, 1844, I noticed the most amazing flock of birds which it was ever my lot to witness—they were starlings. At a distance they resembled some gigantic mass of cloud slowly traversing the heavens, occasionally changing its form, and breaking into smaller masses. It was evening, and the birds had probably collected to roost for the night in a large wood, over the top of which they were enjoying the few moments before retiring to rest. The ease and elegance of their flight, as they wheeled to and fro—the firm and compact manner with which they kept together when moving in a mass—the peculiar facility with which the main army was broken into numberless smaller ones, and yet instantaneously united again, was perfectly astonishing, and excelled anything which I ever witnessed amongst the feathered tribes."

At particular seasons of the year, starlings frequently visit dove-cotes; and many people imagine that they do so to take the eggs and young pigeons. This idea, however, is erroneous. At Walton Hall, in Yorkshire, these birds were allowed to haunt the pigeon-cote for years, yet they were never seen to molest either the eggs or the young. The seasons in which they frequent dove-cotes, are spring and winter. At the former, their object, in repairing thither, is to build their nests in the pigeon-holes; at the latter, it is to roost, more especially in the cold nights. In districts where woods and trees are scarce, this is a frequent occurrence. Near East Isley, in Berkshire, as many as twelve dozen have been caught in a single evening, whilst roosting in a dove-cote.

**THE REDWING.**

The *Turdus Iliacus* of Linnaeus is about five ounces in weight, and eight inches in length, with a dark-brown bill, deep hazel eyes, and the plumage, in general, similar to that of the thrush. A white streak runs over the eye, which distinguishes it from that bird. The belly is not quite so much spotted; and the sides of the body, and the general mass of feathers under the wings, are tinged with a lively red, which constitutes its peculiar characteristic, and which confers upon it its name. These birds arrive in this country a little earlier than the fieldfares, with which they fraternise, frequent the same localities, live upon the same kind of food, and to which they are very similar in their leading features. The redwing leaves in the spring, therefore its song is not known to us; but travellers tell us it is very harmonious and sweet. The female builds her nest in low bushes or hedges, and lays six eggs of a greenish-blue colour, dotted with small black spots.

The Romans held the flesh of the redwing in the highest estimation; and they kept thousands of them together in aviaries, and fed them with a species of paste, chiefly composed of bruised figs and flour, and on various other kinds of food. These receptacles were so constructed as to admit very little light; and every object which could remind the birds of
their former liberty, was sedulously kept out of sight, such as fields, woods, birds, or whatever might disturb or break in upon their memories, or impair their improvement. Under this treatment, the redwing fattened to a great extent, sold for a good price, and held a high place at the tables of this luxurious people.

Bewick tells us that a redwing was taken up, November 7th, 1785, at six o'clock in the morning, which, on its approach to land, had flown against the lighthouse at Tynemouth, and was so stunned, that it fell to the ground, and died soon after. The light, it is conjectured, had attracted its attention. The same writer observes, that when redwings appear on the eastern coast, they as commonly announce the approach of the woodcock, as does the arrival of the wryneck that of the cuckoo in the south. The best time for shooting this bird is in hard frosty weather; it is then more bold in keeping to its feeding-grounds, and is in greater numbers. The sportsman should, however, conceal himself as much as possible, as these birds set scouts to watch the approach of danger; and, on this account, it requires considerable art to get within range of them.

THE FIELDFARE.
This is the Turdus Pilarus of Linnaeus, and is a very pretty bird. It is about ten inches long. The bill is yellow, and each corner of the mouth is furnished with a few black and bristly hairs. The eye is light brown, and the head and back part of the neck are of a light ashen hue; the former spotted with black. The coverts of the wings are of a deep hoary brown, the rump ash-coloured, and the throat and breast yellow, with regular spots of black. The belly and thighs are of a yellowish brown, and, in the young birds, more decidedly yellow.

There are some varieties of fieldfares which display a somewhat different plumage; but the differences are not very important. They are mostly confined to the comparative faintness of the black spots on the breast, or the greater predominance of white in various sections of the body.

This bird is migratory, and arrives in this country commonly in the first week in October; subject, however, to some variation on account of the weather. The character of the coming winter is supposed to be prognosticated by their appearance. If they arrive early, it is said that we shall have a hard season; if late, a mild one. They generally arrive in large flocks, and disappear about the latter end of February, or the beginning of March, and retire to Russia, Sweden, Norway, and as far as Siberia and Kamtschatka. Buffon tells us, they do not arrive in France till December, when they assemble in flocks of two and three thousand. Their food is haws and other berries, with worms, snails, and slugs.

The fieldfare being a shy bird, is difficult of approach with a gun. When they are in any considerable numbers, they appoint regular scouts to give the alarm of danger. They can, therefore, seldom be shot, except by stratagem; but they are easily killed, their feathers being loose, and their frames delicate.

Bewick says that fieldfares seem of a more social disposition than the thrush or the missels. They are sometimes seen singly; but, in general, form very numerous flocks, and fly in a body; and though they often spread themselves over the fields in search of food, they seldom lose sight of each other, but, when alarmed, fly off, and collect together upon the same tree.

THE THRUSH, OR THROSTLE.
This bird is often, in country districts, an object of the sportsman's attention, more especially if he be a young one. It is the Turdus Mucius of Linnaeus, and is larger than the red-wing, but less than the missel-thrush, to which, in other respects, it bears a great resemblance, both in form and colour. A small note is found at its bill, which is characteristic of all the thrush species. The throat is white, and the spots on the breast are very regularly formed, and of a conical shape. The inside of the wings and the mouth are yellow; so likewise are the legs. The claws are strong and black.

The thrush is distinguished by its clear and harmonious notes, and is one of the principal songsters of the groves, taking the lead among the feathered tribes; which ought to preserve it from wanton destruction.

It is not properly migratory; but, in this country, is more numerous in particular places at some part of the year than at others; and this circumstance has given rise to the idea
that it goes, to a certain extent, from one country to another. The female builds her nest generally in bushes—the hazel, the thorn, and sometimes on the branches of trees. It is composed of dried grass, cemented together by clayey matter. Buffon maintains that these birds are migratory in France, and appear, in the southern section of the kingdom, about the end of September, and before either the red-wing or fieldfare are seen. The female has not such a brilliant plumage as the male—the colours and spots being more blended and faint in the former than in the latter.

THE MISSEL THRUSH.
This bird is about eleven inches long, and is the Turdus Visceorius of Linnaeus. The bill is of a dusky hue, and the base of it yellow. The eyes are hazel. The head, back, and lesser coverts of the wings are of a deep olive colour, and the latter tipped with white, which, in some instances, is much more brilliant than in others. The lower portion of the back or rump is tinged with yellow; and the cheeks are of a yellowish white, spotted with brown; and so likewise are the belly and breast. The quills are brown, fringed with pale edges, and the tail-feathers are the same, the three outermost being tipped with white. The legs are yellow, and the claws are black.

The female builds her nest in bushes or low trees, and lays four or five eggs, of a greenish colour, irregularly marked with red spots. The nest is made of moss, leaves, and small fibres of twigs, and lined with dry grass. The bird commences early in the year to sing, even when the weather is stormy and ungenial; and this circumstance has induced country people, in many districts in England, to call it the storm-rook. It feeds on various kinds of berries, particularly those of the mistletoe. It likewise feeds on caterpillars, and different kinds of insects, on which it chiefly rears its young.

It is a native of almost every country in Europe, and, in some sections of the continent, is said to be migratory. It remains in England the entire year, and has frequently two broods in the season.

THE LARK.
This is the Alauda Arvensis of Linnaeus, and is so common in this country, that it hardly requires a description here.

“Tha daisy ted he loves, where turfs of grass
Lushant delight the riddle; there, with his mate,
He founds his lowly house of withered herbs
And coarsest spear-grass; next, the inner work
With finer and still finer fibres lays,
Rounding it curious with his speckled breast.”

This “herald of the morn,” often made an object of sport by the thoughtless tyro, builds its nest upon the ground, where it is exposed to the depredations of many of the smaller animals of prey, as the weasel and the stoat. Mr. Mudie says—“The lark selects her ground with care, avoiding clayey places, unless she can find two clods so placed as that no part of a nest between them would be below the surface. In more friable soils she scrapes till she has not only formed a little cavity, but loosened the bottom of it to some depth. Over this the first layers are placed very loosely, so that if any rain should get in at the top, it may sink to the bottom, and there be absorbed by the soil. The edges of the nest are also raised a little above the surface; have a slope outwards, and are, as it were, thatched. The position in which the bird sits is a further security; and as the head is always turned to the weather, the feathers of the breast and throat completely prevent the rain from entering the nest at the side; while the wings and tail act as pent-houses in the other parts; and, if the weather be violent, and the rain fall at a small angle with the horizon, the fore part of the bird, upon which the plumage is thickest, receives the whole of it.”

What is called the twirling for larks, is followed as an amusement in France, and is thus described:—These birds are attracted to a given spot, in considerable numbers, by a singular contrivance called a mirror. This is a small mahogany machine, shaped like a chapeau-bras, and highly polished; or else it is made up of common wood, inlaid with small bits of looking-glass, so as to reflect, upwards, the rays of the sun. It is fixed on the top of a thin iron rod, on an upright spindle, dropped through an iron hoop or ring, attached to a piece of wood to drive into the ground. By pulling a string fastened to the spindle, the mirror twirls round, and the reflected light unaccountably attracts the larks, which hover over it, and become a mark for the sportsman. There is often what the French call capital
sport in this way. Sometimes six dozen of these birds are shot before breakfast: sometimes the sportsman sits on the ground, and pulls the twirler himself, and sometimes a boy or servant is employed to do it. Ladies often participate in the amusement on a cold, dry morning, not by shooting, but by watching the sport. Occasionally there are ten or a dozen parties out together, firing at a distance of five or six hundred yards; and by this device the larks are kept constantly on the wing. The most favourable mornings are, when there is a gentle light frost, with little or no wind, and the sky clear. When cloudy the birds will not appear. To a bystander it would almost suggest the thought, that the larks themselves enjoyed their own destruction; for the fascination of the twirler is so strong, as to rob them of the usual fruits of experience. After being fired at several times, they return to the twirler, and form again into groups above it—some of them even flying down, and sitting upon the ground, within a yard or two of the astonishing instrument, looking at it this way and that way, and all ways together, as if nothing had happened. In some parts of Germany, larks are taken in great quantities; and we are informed by Dr. Latham, that the duty paid at Leipsic for these birds, amounts to twelve thousand crowns per annum, at two-pence-halfpenny for every sixty larks.

In this country, some lark shooters, in winter—when there is a certain portion of snow on the ground, with hard frost—sweep a part of the snow from the surface, and strew it with a little chaff or grain. This area need not be more than twenty yards square. The birds will eagerly frequent it; and, by means of a natural hedge embankment, or an artificial screen, numbers of them are taken.

Speaking for ourselves, however, in this matter, we regret the destruction of every bird of song. Amongst all the enjoyments of this world, not the least is the music of birds, which, when combined with the elegance of their forms, the loveliness of their plumage, and the liveliness of their actions, are capable of affording pleasure to every ear or eye. As a study in natural history, that of birds is by far the most beautiful and interesting; yet how comparatively few are those who are acquainted with the habits of even those that are most common amongst us! It would really appear that many think that birds were created only to be shot, and for no other purpose whatever. "In natural history," says Mudie, "and more especially in the natural history of birds, which, from the elegance of their aerial motions, carry the mind more readily and directly over the general map of the earth than any other class of the earth's productions, this inversion of the order of nature—this substitution of the end for the beginning—is peculiarly hurtful, and must be the cause why people, even well informed, otherwise, know so very little about the nature and habits of those species which are before their eyes every day, and which appear to come for the express purpose of being observed and studied. Take, as a familiar instance, the common redbreast, and ask your next neighbour when and where it builds its nest?—what are the number and colour of its eggs?—how long the incubation lasts?—how the young are fed, and on what?—and the chances are many to one that you do not get direct answers; and, if you do, they are the second-hand answers of someone who has written a description of the bird, which, if original at all, has most probably been obtained from observations made in a climate differing from yours, and, therefore, is not quite so accurate as the description of your redbreast. Carry your interrogations a little further. Ask what is the geographical distribution of the bird?—what are its uses in the general economy of nature?—and you will find the answers still more difficult to be obtained, and more unsatisfactory where you can obtain them." This is at least the case with those who dwell in cities.
CHAPTER XVI.

RABBITS.

There are four kinds of rabbits known among dealers and fanciers. They are called warreners, parkers, hedgehogs, and sweethearts. The warreners are widely distributed, and are to be found in almost every section of the British coast, where there are sand-banks, or mounds of any kind. Though all of one species, they vary considerably in size; those in the English warrens being greatly superior to those found in Scotland, both in bulk and flavour. The warren rabbits of the Irish coast are very much like those of Scotland; though, on the whole, a shade larger in bulk. The richest and finest are located in the warrens along the eastern coast of England, extending from Lincolnshire to Berwick-upon-Tweed. It is a curious fact, but, nevertheless, one well ascertained, that all the rabbits on the warrens in the west side of the island, are of a comparatively diminutive size, and, in many places, have a strong fishy taste.

Those who rent warrens with a view to commercial objects, seldom or ever allow shooting upon them. The reason is, that when a rabbit is wounded it will make for some hole or burrow; and it is known to regular shooters of them in such places, that so strong and powerful is this desire to get back to their holes, that, in the very struggles of death, rabbits will often succeed in getting into a sand-burrow. Now, we are informed by warreners, that if a wounded or dying rabbit get into a burrow, none of the living ones will ever pass it. They will die in their holes first; so that a single wounded or dead animal will cause the death of perhaps a score of its own kind in the same locality. This, as a matter of course, becomes a serious loss to the proprietor of a warren. As much as a couple of guineas have been offered for two or three shots in a warren, and refused, solely upon this ground.

The obstinacy of the rabbit is curious; and it is equally, if not more singular, in reference to the ferret. This little animal is often used by sportsmen to make the rabbits spring out of their holes; they are also very extensively used by warreners to make them spring, and fall into small poke-nets, as they are called, placed at the mouths of the holes. These ferrets are sometimes long in coming forth from the warren-holes; when the warreners have to dig for them, and will perhaps find them lying, though muzzled, beside a dead rabbit, whose very brains have been scratched out, or its back-bone laid bare, rather than budge an inch for the ferret. This is a circumstance of daily occurrence in all the great rabbit warrens that lie on the eastern side of the island in the north of England. Nothing injures the productive remuneration of a regular warren so much as shooting over it, even though it be but for a week or two in a season.

The parker and the hedgehog rabbits are very much alike. They both frequent plantations, and high inland rocky ground, and are nearly of the same length and weight as the general run of Scotch and Irish rabbits. In many parts of England, and even in Scotland, it has, of late years, been a custom among gentlemen of landed estates, who are much attached to fox-hunting, to introduce these parker and hedgehog rabbits into certain localities of their grounds, with a view of supporting the foxes. But we believe that, in numerous cases, the rabbits are found to breed in such prodigious numbers, that they become a regular nuisance, and very difficult indeed to root out again. Besides, the practice has given rise to serious disputes and bickerings among farmers and their landlords, about the destruction of the crops of grain by the rabbits in such places. A person of considerable experience, writing on the wild rabbit, says—"It would be no easy matter to say what weight a wild rabbit would attain if taken and fed like any of those prize animals, such as sheep, cattle, &c.; for in the case of sheep, the difference of feeding, against the natural food which the animal seeks for itself, is almost incredible, at least to those who have
not seen the effects, or paid any attention to the matter. But I am afraid I am getting out of my way. I had a good opportunity, one season, of seeing the size, and trying the weight of rabbits, as I have been in at the death of very few short of 500; and I must say, I never have killed any above 5 lbs., most of them being from 3½ lbs. to 4 lbs.; in fact, I do not remember of more than one being above 4½ lbs., and very few of the latter weight; but I did not weigh them all—only the very large ones attracted my curiosity; and it is rather singular that the largest rabbits were always killed by means of the ferret, and, in many cases, lay in the hole till killed by this blood-thirsty enemy. But I once witnessed a rabbit that was shot on a neighbouring estate, which weighed over 6 lbs. This was assuredly the common grey rabbit, in all but the ears and head, which were somewhat larger than the common, being nearly as large as those of a hare; but, at the same time, the head seemed to be quite in proportion to the body. The ears, however, were something the shape of the long-eared, domestic rabbit, but differed from it in being erect, in place of hanging down. The flesh of it was dressed, and was found to be that of the rabbit, thereby settling the notion that it was a cross with the hare. It has been stuffed as a curiosity; was shot in a high country; was quite wild; and is the greatest weight I have known a wild rabbit to attain."

With respect to the shooting of these animals in such localities, every degree of caution is requisite. It is indispensable that they should be approached in a straight line, even to obtain a glance at them; and this must be done by stealth. If you have a dog, he must be kept close to your heels. Stoop down, and prevent the animal from seeing you, if you can. This, and such like stratagems, are the only means to get a shot at this kind of rabbit.

"More difficult than hares to hit,
They frequently appear to sit
Like shadows past one—good, indeed,
Is then the aim that bids them bleed.
If you would see them nicely stopped
In the thick wood, you must adopt.
Shot-shooting, for you'll seldom there
Have time to take them full and fair;
E'en lost to view, advance your gun
Quickly to where you think they ran;
Regard not grass, nor brush, nor brair;
Through each and all that instant fire.
Bang! 'tis well—you saw him not,
And yet you've killed him on the spot."

In taking our leave of the rabbit, we may briefly allude to hare shooting, though this animal is more an object of the chase than of the gun. Yet, throughout the shooting season, there are a vast number of hares shot. Few sportsmen allow her to make her escape, when a chance offers. Some fowlers are remarkably clever at finding and shooting hares; and, with some, it becomes quite a passion, to the entire exclusion of every other kind of sporting. We have often seen an individual in a stubble-field, on a fine evening, crawling upon his knees, and sometimes on his side or his belly; and, without any dog, gaining upon poor puss so slowly but surely, that her death became certain. This shooter would never, however, fire at a hare in her seat in a hedge, or cover of any kind. She is not difficult to kill, and her mode of running is more favourable to the sportsman than the bouncing and stotting movements of the rabbit, which are apt to mar the young sportsman's aim.

CHAPTER XVII.
DEER-STALKING.

Deer-stalking is comparatively a modern sport, and is confined principally to the higher classes of English sportsmen. The deer, it is well known, has been an interesting object of the chase from the earliest records of the human family. Stag-hunting is treated of by
Xenophon; and it forms a conspicuous item in Anglo-Saxon history. During the middle ages, we find that it was pursued in most of the countries of Europe. As practised in those parts of the Highlands of Scotland, and in other mountainous countries, deer-stalking is by no means a drawing-room amusement. It keeps the powers of both mind and body upon the full stretch, and takes us into scenes of the most magnificent and sublime description.

In the *Penniless Pilgrim*, of Taylor, the water-poet, who flourished about a couple of centuries ago, we find the following description of deer-stalking as it was pursued at that time:—"I thank my good Lord Erskine; he commanded that I should always be lodged in his lodging, the kitchen being always on the side of a bank, many kettles and pots boiling, and many spits turning and winding, with great variety of cheer, as pigeons, hens, capons, chickens, partridge, moorcocks, heathcocks, capercailles, and ptarmigans; good ale, sack, white and claret, and most potent *aqua vitae*. All these birds, &c., and more, we had continually in superfluous abundance, caught by our falconers, fowlers, fishers, and brought by my Lord Marr's tenants and purveyors to vicitual our camp, which consisted of fourteen or fifteen hundred men and horses. The manner of hunting is this: five or six hundred men do rise early in the morning, and they do disperse themselves divers ways, and seven, eight, or ten miles' compass, they do bring or chase in the deer in many herds (two, three, or four hundred in a herd), to such or such a place, as the noblemen shall appoint them; then, when the day is come, the lords and gentlemen of their companies do ride and go to the said places, sometimes wading up to the middle through burns and rivers; and then they, being come to the place, do lie down on the ground till their foresaid scouts, which are called the tineckell, do bring down the deer; but as the proverb says of a bad cook, so these tineckell men do lick their own fingers; for besides their bows and arrows, which they carry with them, we can hear now and then an arquebuss or musket-shot go off, which they do seldom discharge in vain; then, after we had stayed three hours, or thereabouts, we might perceive the deer appear on the hills round about; which, being followed close, are chased down into the valley where we lay; then, all the valley on each side being waylaid with a hundred couple of strong Irish greyhounds, they are let loose, as occasion serves, upon the herd of deer, that with dogs, guns, arrows, darts, in the space of two hours, fourscore fat deer were slain."

At the great hunting gatherings which took place in Scotland, under the auspices of the chief nobility, during the sixteenth and seventeenth centuries, fire-arms were occasionally used to kill the red deer. These hunting *forays* were conducted upon a most gigantic scale of magnificence, and were attended by many thousands of the clansmen, who encompassed extensive tracts of country, and drove the game to where their respective chiefs were located. In an entertainment of this kind given by the Earl of Athol to James V., the queen, his mother, the pope's ambassador, and many hundreds of the most distinguished ladies and gentlemen of the court, there was a kind of palace constructed, of green timber, interwoven with boughs, provided with turrets, and moated completely round. The hunting continued three days; and we are told that many of the animals were shot with the gun, through the apertures of the rough building; and that even some of the ladies were bold enough to fire off some of those field-pieces, which were then of considerable size.

The natural shyness or wariness of the deer, suggests many devices to overreach them. Almost every sportsman has some general method of his own to get fairly within range of them, some of which have been immortalised by Sir E. Landseer upon the canvas. The sportsman must always approach them up-wind, to prevent his being scented, for they possess the faculty of smell in high perfection. Sometimes a circuit of several miles has to be taken before they can be approached so as to give a fair chance of sport. Weather, as in every other sport, has much to do with success in deer-stalking. When this is of such a kind as to oblige the deer to frequent the well-heads, or pools of water, and more especially if these be in a locality where there is any portion of brushwood or shelter for the gunner, then his chances of success are considerably increased. If otherwise, the labour, of course, is considerably more severe, and the chances of good sport less likely to be so plentiful.
In order the more certainly to bring down the deer, the sportsman always, if possible, takes his aim behind the shoulder of the animal; and if effective in this direction, death follows instantly. When, however, the deer is only wounded, it is then left to itself by the herd, when the deer-hounds are set to work to follow and capture it. These animals display singular sagacity and earnestness in hunting the stricken captive: they will confine their hunting solely to the wounded deer; and when they have overtaken him, either seize, or hold him at bay till the sportsmen arrive, when another shot, in some vital quarter, puts an end to the scene. The dogs are rewarded by the blood of the noble quarry.

Shooting the roebuck in the Highlands of Scotland, is held to be a most animating sport. This animal is considerably smaller than the red-deer; and dogs of the harrier breed are used to drive it into certain favourite localities, where the deadly rifle does great execution. Shooting it, and all the sporting incidents and circumstances attending this, are much of the same description as those mentioned in reference to the red-deer: but it is impossible to describe the irresistible pleasure which the pursuit of such a noble quarry gives to the thorough-bred highlander. Day after day he will range the bare hills, and traverse the haunts of these animals, or sit, with Job-like patience, enveloped in his plaid, behind a grey rock, which, whilst it conceals him, enables him to command an extensive view of the country spread out before him. Should he then be fortunate enough to get a sight of a stag, he will think nothing of creeping for miles, like a worm, on his belly, in order to get within shot of him without being discovered. Time and the weather are to the highlander of no consequence. Wet, cold, and hunger he will willingly bear to circumvent his prey; and if he is successful in this, how does he rejoice! but if not, he will renew his efforts until his perseverance and toil are rewarded with success. When a deer is killed, an operation called “breaking” takes place, and which consists of cutting the throat and disembowelling it. Whilst this is going on, the highlander frequently apostrophises the dead animal in Gaelic. He calls him every evil name he can think of at first, for perhaps having frequently escaped his deadly aim, and for having often led him many a weary journey over hill and dale before he had at last succumbed. After this, he may change his note, and pronounce him the “bonniest,” or most beautiful beast that it was ever his lot to behold. Whilst upon this strain, the very perfection of gratification and delight irradiates every feature of his usually hard and rugged countenance.

In bidding adieu to this portion of our work, we must be permitted to say a few words upon natural history, and the great additional enjoyment its study must give to the sportsman who associates it with his pursuits. In itself it is delightful; and animals are so diversified in form, so curious in structure, and so interesting in their habits and manners, that they furnish a wide range for observation to every inquiring mind. They are, moreover, so liberally distributed over the earth’s surface, that, let the naturalist wander where he will, he is almost sure to meet with one species or other of the object of his pursuit. The daisied meadow has its lark; the wood its nightingale; the heath-clad hill its red-deer or its roebuck; the stream its grayling or its trout; the rocky dell its ouzel, flitting from bush to bush, or crag to crag. Nay, even the ocean-wave has its inhabitants its algae, or its birds, as the snow-capped mountain has its parmigan. What life, what interest, what spirit do these various beings infuse into the elements which they people! The field may look beautiful, clad in its spring-tide robe, with the sun glancing brightly upon its thousand flowers; but if the thrush plays its flute from a neighbouring tree, or the lark rains down music from a summer cloud, how greatly are its charms enhanced by their dulcet notes! Enchanting may seem the river, as it winds gracefully through some pastoral vale, an evening sun perchance turning to gold the liquid silver of its currents; but, should the osprey pounce down upon its waves, or the otter move stealthily along its margin in search of prey, what interest, what animation do they give to the lovely scene!

One is almost led to believe that the love of nature is inherent in the heart of man. It is visible in earliest life, when children evince a

SHOOTING. [DEER-STALKING.

desire to ramble amidst pleasant fields, to gambol on banks of daisies, to call buttercups, or to weave, for their hair, coronets of green rushes. In the breasts of many, this love "grows with the growth, and strengthens with the strength;" in some, it is well nigh extinguished; in others, it peeps out in a diminished form. In different ranks, it is exhibited under different aspects. What induced the elder Wortle's "to build a lone lodge on Wharncliffe?" Was it their love of solitude or retirement? Not exactly. We are told, "that they might resort unto it to hear the wild bucks bell." And what induces the magnates of modern times to pitch their tents periodically in the Highlands? Osten-sibly to shoot the grouse, leister the salmon, or stalk the red-deer. Is this their only motive? Do they not exhibit a partiality for field sport because it brings them more immediately into contact with nature? They derive pleasure from hearing the whir and cry of moorland fowls, from noting the habits of animals, or from observing the heath-covered hills under their ever-varying character of light and shade. And what pleasure do sportsmen take in detailing their experiences of these things, or describing the instinct and sagacity which their dogs have exhibited under various circumstances! Certainly such men are naturalists. The love of nature discloses itself perhaps more modestly in other ranks of life.

Is it not manifested at the village parsonage, with its embowering creepers mantling the walls, and the carefully trained shrubs which decorate the garden? Does the six days' pent-up mechanic take up his Sunday stroll merely to inhale the fresh air, or to exercise his limbs? The songs of skyward birds, and the incense of delicate flowers, must, we think, give a zest to his walk. The same principle is visible in the tradesman, who loves his villa, with its grassy slopes and beds of flowers; in the husbandman, who has a longing to till fields and tend cattle, or to employ himself in those never-ending processes of agriculture, which are the natural employment of man. Nay, the love of nature exists even in the hearts of crowded cities. The intercourse of man with man, the strife of trade with trade, may have subdued, but not destroyed it. The rose, the lily, the mignonette, exhibited in the windows of the rich, and the half-starved, smoke-dried wretch of a geranium in the windows of the poor, alike attest that, although their possessors are cut off by barricades of brick and stone, from intercourse with nature in her woods and fields, their love for her is not entirely extinguished. May it increase, and with it all those enjoyments which generally follow in the train of innocent and edifying pursuits!
DIVISION IV.

CATTLE.

CHAPTER I.

WILD AND TAME CATTLE OF DIFFERENT COUNTRIES.

THE URUS AND THE AUROCHS OF THE ANCEINTS.

It requires no great amount of discernment to perceive how much man is indebted to the herds of the field, for supplying him with those necessaries of life by which his comfort is increased, and his happiness enlarged. The ox, in many parts of the globe, takes the place of the horse, in assisting him to cultivate the soil; and the cow supplies him with the most nutritious of all beverages. Milk, cream, cheese, and butter, enter largely into his dietary, and form a species of food and drink at once nourishing and agreeable. Even after death these useful animals are made subservient to his wants. Portions of their cooked carcasses become converted into the “roast beef of old England;” and their hides furnish the material for shoes; their horns are made into combs, and other articles of ornamentation; while their hoofs supply him with glue, and various gelatinous substances; their bones are fashioned into knife-handles, and applied to numerous other purposes; whilst their refuse, in the shape of dust, is restored to the earth whence they came, to help to multiply its productive power, and increase its vegetation, by which other animals may be raised, and their species perpetuated. Such is the important part which these patient animals perform in the grand scheme of creation! How much, then, does man owe to them for the many comforts, and even luxuries, they are the means of bringing within his reach? In natural history, these animals are designated as the genus Bos (oxen), and their characters are defined, as both sexes having horns; but they have neither suborbital sinuses, interdigital fossae, nor inguinal pores. The teats in the females are four. The animals of this genus are, with some few exceptions, the largest and most massive of the hollow-horned Ruminants. Their limbs are low and strong; their bodies heavy, with wide haunches, and thick, and often elevated shoulders; their heads are large; and the progressive increase of their horns is marked by annuli at the base. They sheathe a hollow or cancellous bony core, continued from the sides of a bold frontal ridge. The forehead, or chafiron, is expanded; the muzzle, except in the sub-genus Ovibos, is broad, naked, and moist; the neck is thick, deep, compressed laterally, carried horizontally, and furnished with a pendent dewlap. The spinous processes of the anterior dorsal vertebrae, at the withers, are very long and stout. All the Ox group are gregarious in their habits; and no quarter of the globe is destitute of its indigenous species, existing in a state of freedom, tenanted the deep glades of the forest, or roaming over hills or plains. The genus may be subdivided into the following minor groups, or sub-genera:—Bos, Auroch, Bubalus, Bison, and Ovibos; descriptions of which we will give in their proper places, as they rise before us, in this division.

The Ox (Bos Taurus) is now only known as a domesticated animal, widely diffused over almost every region of the globe, and everywhere contributing, by its services and products, to the well-being of man. Although referred to as a domestic animal in the earliest ages, by the author of the Mosaic record, impenetrable darkness hangs over its primeval history; nor is its wild origin known, or whether that origin is in existence. Temperature, soil, food, a thousand circumstances, operating through the revolutions of years, have
combined to effect a series of modifications in the ox. Every country possesses its peculiar races; and these races, by their intermixture, are perpetually producing others; so that it is impossible to say to what extent these changes may be carried, and how far the original type may have already become modified. Certain it is, that we are acquainted with no animal in a state of original independence, to which the primitive type of the ox can be referred. It is true, however, that within the period of authentic history, certain wild oxen existed in Europe; but it is not to Europe that we must look as the cradle of the domestic ox; nor, indeed, are the accounts left us of these oxen reconcilable with any of them having been specifically identical with our domestic race, which, when we look at the Zebu breed, seems to claim more than one source. One of these wild animals was termed by the ancients Urus (*latius cornirus*), and another, *Bison (jubatus, or villowus).* We have also an animal described under the name of Bonasus—the *Bównasog,* or *Bównasog,* of Aristotle.

The Urus, which existed in the Hercynian forest, is thus described by Caesar:—"These uri are little inferior to elephants in size, but are bulls in their nature, colour, and figure. Great is their strength, and great their swiftness; nor do they spare man or beast when they have caught sight of either. These, when trapped in pitfalls, the hunters unsparingly kill. The youths, exercising themselves by this sort of hunting, are hardened by the toil; and those among them who have killed most, bringing with them the horns as testimonials, acquire great praise. But these uri cannot be habituated to man, or made tractable, not even when young. The great size of the horns, as well as the form and quality of them, differs much from the horns of our oxen. These, when carefully selected, the people ring round the edge with silver, and use to drink with at their ample feasts." Perhaps the wild bulls, with horns of extraordinary size, which Herodotus assures us inhabited Macedonia, were uri.

The Bison (*jubatus* of Pliny).—This species, regarded by Cuvier and most naturalists as identical with the Bonasus of Aristotle, is considered, and perhaps with reason, as referable to the Aurochs or Zrub (*Bos urus* of modern naturalists, not Urus of Cesar), still existing in the wild forests of Lithuania. In Europe and Siberia, the fossil crania of aurochs are not uncommon; and these skulls, though they scarcely differ in anything from the Lithuanian animal, Cuvier inclines to think may be of a different, though closely-allied species. He gives the figures of a skull in the Paris museum, so like, as he observes, to the living aurochs, that the most practised eye can scarcely distinguish it; and also so fresh, that he is in doubt whether it be really a fossil relic, or, on the contrary, recent, owing its fossil appearance to having been much weathered. Mr. Lyell states, that the bones of the auroch or bison have been found in the North Cliff, in the county of York, in a lacustrine formation, in which all the land and fresh-water shells, thirteen in number, can be identified with species and varieties now existing in that county. The Urus of Cesar and the ancients was characterised by the immensity of its horns, and its vast stature; in the former of which it differs materially from the ancient full-maned bison, or Lithuanian auroch. This urus no longer, as it would appear, exists; but fossil skulls, of a species far exceeding the largest domestic ox in magnitude, with the core of massive horns, are abundant in the superficial strata of Europe. This species is termed, by Cuvier, *Bos primigenius;* and he carefully distinguishes the skull from that of the fossil auroch. In a specimen found at Melksham, and described by Mr. Woods, the cores of the horns measured, at their widest expansion, upwards of four feet. We may easily conceive what must have been the expansion of the horns themselves: the skull, destitute of the lower jaw, and not perfect otherwise, weighed sixty-three pounds. Larger specimens, however, have been discovered.

This extinct species Cuvier regards as the type of the domestic ox; in which opinion Mr. Bell and most naturalists coincide, at the same time that they consider the "celebrated white, wild oxen of Craven, of Chillingham Park, and Scotland, as specifically the same with the common ox. Contrary to this, however, Colonel Hamilton Smith and Mr. Swainson regard the white ox of Chillingham Park (*Bos Scoticus* of some authors) as distinct from the common ox. The former regards the Chillingham ox
as a white variety of the fossil species *Bos primigenius*; while Mr. Swainson believes it to be the descendant of a smaller species belonging to the same genus as the *Bos primigenius,* or ancient urus, of which "the skulls exhibit the type of a form essentially different from that of the domestic ox."

"All these skulls," he continues, "are nearly one-third larger than those of the *Bos Taurus:* they are square from the orbits to the occipital crest, and somewhat hollow at the forehead. The horns, placed at the side of the above crest, show a peculiar rise from their roots upwards; then bending outwards, and then forwards and inwards. No domestic races show this turn; but numerous specimens of inferior sizes, found fossil in the Cornish mines, have this shape; and the wild bull of Scotland, the only example of this type now known to exist, retains it. The domestic oxen, on the contrary, of whatsoever country or breed they may be, have the square concave forehead, with the horns rising from the ends of the frontal ridge.

* * * * It appears, then, that the ancient urus, or wild bull, was a perfectly wild, savage, and untameable animal: not only does every account handed down from remote antiquity assure us of this, but it is even verified by the only living example of this form we possess—the *Bos Scoticus,* still preserved in one or two of the northern parks. Although domesticated so far as to live within such precincts without absolute unprovoked violence to its keepers, it retains essentially all the savage characters ascribed to the more powerful species mentioned by the ancients. As to the specific identity of the white oxen of Chillingham with our ordinary breed, some have no doubt on the subject. In size, form, and aspect they resemble the finer breeds of black cattle; and the query is, not—are they distinct? but—are they the descendants of a wild breed, or, on the contrary, the descendants of domesticated individuals, which have resumed their wild character, "from having ceased to feel, through many generations, the effects of human domination?" The latter is suspected. With regard to Cuvier's *Bos primigenius,* granting it to be the urus of Caesar, it is not so easy to determine whether it was the wild type of the domestic ox. Its vast size, and the extraordinary magnitude of the horns, to say nothing of its ferocity, and the probability that it is to Central Asia, rather than to the wild forests of Central Europe, that we ought to look for the type of the domestic race (or races?), are sufficient to beget a doubt.

The term urus is evidently identical with the terms auro, ur, aurochs, ur-ox, the root also of the word taurus; and we agree with Mr. Woods, in the belief that the aurochs, or ur-ox, of the ancient Germans, was the urus of Caesar; but that the word, on the extinction of that animal, became transferred to the bison of the ancients, now known as the aurochs; and also under names derived from a different root, as *zubr* (Lithuanian), *zimbr* (Moldavian), bison, visont, wisont, and wisant; whence bonus, monnsus, &c.

Besides the *Bos primigenius,* the following fossil species of ox have been named:—*Bos trechoerus* (Hermann von Neyer), subapinge beds; *Bos* (Bison) *priscus* (Bonjusus), *Buffle fossile de Siberie* (Cuv.), *Bos latifrons* (Harlan), Broad-headed fossil Bison and *Bison fossilis,* "diluvium" of Europe and North America; bone-caves and bone breccias; *Bos* (Bison) ? *bombifrons* (Harlan), Big-bone-buck, North America; *Bos Pallasi* (Dekay), *Bos moschatus* fossiles? *Bos canaliculatus* (Fischer)? Siberia and North America, *Bos veluanus* (Robert), Cussae, Hauto Loire.

Abundant remains of the ox were found by Captain Cautley in the Sewakil Mountains, at the southern foot of the Himalayas, between the Satlej and the Ganges, partly lying on the slopes among the ruins of fallen cliffs, and partly in situ in the sandstone, in company with the bones of the mastodon, elephant, rhinoceros, hippopotamus, hog, horse (comparatively scarce), elk, deer, several varieties; carnivora, canine and feline (comparatively scarce); crocodile, gavial, enys, trionyx, and fishes. There were also portions of undescribed mammalia.

**CATTLE IN THE PATRIARCHAL AGES.**

To Asia and its border-lands let us turn our attention—regions in which the ox, from the earliest epoch, has been in a state of domestication, and where this animal, with sheep and goats, constituted the riches of patriarchs, and chiefs, or princes, who, deemed it not beneath them to take an active interest in the management of their flocks and herds. In that age of
patriarchal simplicity, such scenes as we have seen delineated by the pencil of Berghem were not imaginary; and the pastoral poetry of classical antiquity has not only rendered them familiar, but thrown an air of grace, and even dignity over them.

In the fourth chapter of the Book of Genesis (ver. 20) we read of Jabal, that “he was the father of such as dwelt in tents, and of such as have cattle.” In the thirteenth chapter of the same book, cattle are enumerated as forming part of the riches of Abraham, and also of Lot; and in the previous chapter we read, that oxen were presented by the Pharaoh of Egypt, together with sheep, asses, and camels, to Abram, during his sojourn in that land. In the eighteenth chapter, veal, or the flesh of the calf, and butter and milk, are mentioned as articles of food. Subsequently, abundant mention is made of all these domestic animals; while, at the same time, we glean that a wild race of oxen long continued to exist in Syria and the adjacent regions. For instance, in the Mosaic injunctions regarding animals to be used as food (Deut. xiv. 5), the wild ox is expressly noticed; and Isaiah alludes also to the wild bull, “as a wild bull in a net.” Hence it would appear, that though a domestic breed, established at a period antecedent to historical record, the Scripture outline excepted, formed part of the wealth of man in the primeval ages of his history, that a wild race still tenanted their aboriginal pasture-lands. Wild oxen are exhibited in the Egyptian sculptures, and they are frequently represented as objects of the chase. They were sometimes hunted with dogs, the huntsmen bearing bows and arrows; and sometimes they were caught with the noose or lasso.

The utility of the ox was highly appreciated in remote ages, insomuch, that it became an emblematic object of worship among most of the nations of antiquity. The traditions of every Celtic nation place the cow on the list of the earliest of animals, and represent it as a kind of divinity. Among the Egyptians, the god Apis was worshipped in the form of a bull; and Herodotus describes the ceremonies performed at the choosing of this bovine deity, to whose honour other bulls, chosen by the priests, were sacrificed. The goddess Isis was represented, by the same people, by the figure of a woman with the horns of a cow, as the Grecians represented Io; and the sacrificial offering was a bullock. The cow was never sacrificed, being sacred to Isis. The veneration of the cow was equally prevalent in Lybia. The people of that country, says Herodotus, from Egypt to the Lake Tritonis, are breeders of cattle, eat flesh, and drink milk, but abstain from the flesh of cows, as do also the Egyptians; and they will not keep swine. Nay, among the women of Syria, to strike a cow is accounted a crime, because they celebrate the feasts and festivals of the Egyptian Isis. Neither will the Barccean women taste the flesh of a hog or of a cow.

In India, where, in many points, the practice and worship of the ancient nations were the same as those of the Egyptians, the ox was held sacred, and still is so by the Brahmins. One of the causes of the Sepoy rebellion of 1857, is ascribed to some imaginary greased cartridges having been served out to the native soldiery. The religious writings of India say that the cow was the first animal created by the three gods, who were directed by the supreme lord to furnish the earth with animated beings. In the sculptures of the cave-temples of Ellora, the sacred bull is represented with great truth and spirit. In the Transactions of the Royal Asiatic Society, vol. ii., page 560, Colonel Tod says—“In Hindu mythology, the bull Nanda is at once the guardian of one of the two gates of heaven, of Iswaro or Bal-Siva, and his steed. The astronomic allusion thus blended with mythology is evident—viz., the entrance of the sun into the sign Taurus, the equinoxial festival of remote antiquity, and regarded as a jubilee by the Indo-Scythic nations hemming the shores of the Mediterranean to the Indian Ocean.” We need not say how the idolatry of the Egyptians affected the Israelites, and mingled itself with the religious ceremonies of other nations, whose worship required the ox as a sacrifice to imaginary deities.

The estimation in which the ox was held, and which led to its consecration, did not arise from the circumstance alone of the cow yielding milk, or from the value of the flesh of the animal as food, but from its services in agricultural labour. It was employed as a beast of burden, for the cart, for the plough, and for treading out the grain from the ear. The Mosaic ritual lays down several rules
respecting the treatment of the ox: one forbids the yoking together of the ass and the ox in the same plough, perhaps from the inequality of their size and strength, which would render the draught irregular, and oppress both animals. Another injunction is, "Thou shalt not muzzle the ox when he treadeth out the corn." The first idea suggested by this passage is, that the operation of threshing was effected simply by the feet of the cattle passing over the sheaves; and such, indeed, was the case in the times of patriarchal simplicity. Afterwards, as other passages show, rollers and wheels of wood, and threshing instruments with teeth, were used. These were drawn over the sheaves by oxen, and greatly facilitated the process. With respect to the primitive mode of threshing by means of the feet of oxen, there is express allusion made to it by Homer, leading us to the belief that the practice was common in his country at the period in which he flourished:—

"As with autumnal harvests covered o'er,
And thick bestrewns, lies Ceres' sacred floor,
Where round and round, with never-wearied pain,
The trampling steers break out the unnumber'd grain."

The ancient Arabs, Egyptians, and Romans, as well as the ancient Greeks, threshed their corn in this manner. Virgil, in the first book of his Georgics, describes the manner in which the threshing-floor is to be laid down, showing that nothing like our modern mode of threshing could have been practised. In Syria, Egypt, and Nubia, at the present day, the grain is, as formerly, either trodden out by the feet of oxen or mules, or partly trodden out, and partly crushed out, by means of a roller, or other machine, which the oxen drag after them, and which, more or less, destroys the straw, and even injures the grain. There were two modes of threshing; viz., by the drag, and by the sledge upon rollers, which are still practised in Egypt, Syria, and Western Asia.

In these remote ages, and in these countries, oxen were used for drawing the plough, as they are in Egypt at the present day. This implement, however, was of very simple construction, as it still continues to be in the East, and is rather formed for superficially turning up a light soil, than for making deep furrows in heavy land. It appears that the ploughman, to work it effectively, was under the necessity of guiding it with great care, bending over it, and leading it, as much as possible, with his own weight, otherwise the share would only glide the surface, without making a furrow; and the slightest inattention, or cessation of his labour, would be followed by the dragging out of the share from the earth, or by irregularity in the depth and direction of the furrow; hence the expression of Pliny, "arator, nisi incurvus pravaricatur."

THE ZEBU BREED.

The Zebu breed of oxen claims a few observations. Whether this breed be derived, as some contend, from a distinct origin from that of the ordinary ox, it is not easy to determine; let it suffice that it presents marked peculiarities which clearly characterise it. Narrow, high withers, surmounted by a large fatty hump; an arched back rising at the hanches, and suddenly falling to the tail; slender limbs; a large pendulous dewlap falling in folds; long pendent ears, and a peculiarly mild expression of the eye, are the characters which define the zebu race—a race varying in size from that of our largest cattle to that of a young calf. This breed is spread over India, China, and the Indian Islands. It is also found in Madagascar, and on the eastern coast of Africa, in the interior regions, and parts of the western coast, and is used for the ordinary purposes of draught and burden. India appears to be its parent country; and we may readily believe that, in remote ages, when an extensive commerce existed between that country and Egypt, it was introduced into the land of the Pharaohs. In Upper Egypt, Abyssinia, and Ethiopia, it is now almost exclusively prevalent; but in Lower Egypt, as we learn from Burekhardt, the zebu, or humped race, is unknown. In the ancient Egyptian representations of animals, both the humped race, and the ordinary ox, with long horns, are clearly depicted. It is the zebu ox which is sculptured in the cave-temples of Ellora, and the seven pagodas, as they are commonly called, at Mahâmalipuram, on the Coromandel coast. These are proofs of the extreme antiquity of this breed, and of its distinctness, at a remote era, from the ordinary ox.

Buffon observes, that the ox without a dorsal
hump, which he erroneously terms the Auroch race, occupies the cold and temperate zones, and is thinly distributed towards the regions of the south. The contrary, however, is the fact. The ox with the hump, which he terms also erroneously the Bison race, exclusively occupies all the southern regions—namely, the entire continent of the Indian empire, the islands of the Eastern and Southern seas, and the whole of Africa, from Mount Atlas to the Cape of Good Hope, including Madagascar, and the island of St. Juan, on the channel of Mosambique. With respect to the Cape of Good Hope, it is certain that the zebu race does not prevail there, at least in the present day; but F. Leguat, in the narration of his Voyages, says, that "the oxen are of three sorts at the Cape of Good Hope, all of a large size, and very active. Some have a hump on the back; others have the horns long and pendent; while others have them turned up, and well shaped, as in English cattle."

With respect to the ox represented on the Greek and Roman sculptures—which is not of the true zebu race—it must be confessed that, in many points, and more particularly in the pendulous, folded dewlap, it resembled the zebu, and may probably have been the ultimate product of a mixture of the zebu race, introduced at an early date from India, with the ordinary cattle of Greece and Italy. This, however, is a mere supposition. In the Greek sculptures the ox is represented without any hump, but the withers are high, and the crupper rounded. "To the classical antiquary," says a talented writer, "we beg to suggest that the dewlap of the Brahmin bull offers an object of much attention and interest, by reason of its sharp and decided outline, and perpendicular creases or folds, wonderfully verifying the correctness of those Greek sculptures on bronze and marble, in medals and statuary, in which we see representations of Victory sacrificing a bull, of the oxen of Ceres, &c. These representations will no longer be considered out of drawing by those who may have an opportunity of examining the sacred bull of India, nor exaggerated in their fore quarters; although critics of the last century, less fortunate in this respect than the visitors of the Zoological Society's gardens, have determined them, without hesitation, to be altogether incorrect." Several beautiful specimens of the zebu ox, both of the large-sized variety, and also of the dwarf caste, are in the Zoological Gardens. They are remarkable for their docility and quiet temper.

Mr. Youatt informs us, that a beautiful zebu bull and cow, of the Nagore breed, were, on one occasion, exhibited at the Christmas Cattle-show; and adds, that they were bred by Lieu.-tenant-colonel Skinner, on his farm at Danah, near Pokah, on the borders of the Bichanneer desert, a hundred miles to the westward of Delhi. They were of the finest breed of Indian cattle, used by the higher orders to draw their state carriages, and much valued for size, speed, and endurance. The specimens in question "arrived at Calcutta, a distance of 1,400 miles, when under six months old. They were sent as a present to Mr. Wood, who was then residing at Calcutta, and by whom they were forwarded to Mr. Perkins. Colonel Skinner had a large stock of them; and six or seven beasts were always kept saddled, to carry the military despatches. They remained saddled three or four hours; and, if not wanted in that time, fresh ones were brought out to relieve their companions. They would travel, with a soldier on their back, fifteen or sixteen hours in the day, at the rate of six miles an hour. The action of the Nagore cattle is particularly fine—nothing like the English cattle, with the sideways circular action of their hind legs. They bring their hind legs under them in as straight a line as the horse. They are very active, and can clear a five-barred gate with the greatest ease. Mr. Perkins had a calf which leaped over an iron fence higher than any five-barred gate, and the bull frequently jumped over the same fence in order to get at the water; and when he had drunk his fill, leaped back again. * * * Mr. Perkins observes, that the chief advantage of these Brahmin bulls would probably consist in their speed and strength, in both of which they surpass any of our breeds."

Of the extensive use and consequent value of the Brahmin or large zebu breed, in their native climate, we can scarcely form an adequate idea. In some parts of India the dwarf races are unknown, and the large is bred exclusively. According to an observation of Colonel Sykes, in the Proceedings of the Zoological Society, the Brinjarees, a singularly
erratic people, possess vast herds, and breed the Brahmin cattle on an extensive scale: "and an army rarely moves in the field without 15,000 or 20,000 bullocks to carry its grain. Dwarf cattle are not met in Dukhan." The buffalo, however, divides the palm of usefulness with the zebu in the agricultural labours of India, and is preferred for many purposes, on account of his more robust constitution. In the Mawals, or hilly tracts among the Ghauts, this animal surpasses the zebu. "In those tracts," says Colonel Sykes, "much rice is planted; and the male buffalo, from his superior hardihood, is much better suited to resist the effects of the heavy rains, and the splashy cultivation of rice, than the bullock. The female is also infinitely more valuable than the cow, from the very much greater quantity of milk she yields." In point of beauty and docility, there is no comparison between the heavy savage buffalo and the "Sacred bull of Bramah." Nor is the former ever devoted to Bal-Siva as a meritorious offering. On the contrary, it is common to meet with Brahmin bulls thus devoted, which wander at their pleasure, exempt from the servitude of the yoke, and which are regarded as endowed with a sacred character. The beautiful form and sleek appearance of these fortunate creatures, particularly engaged the notice of Bishop Heber. The first which the bishop met, in his journey, was grazing in a green paddy-field, and was branded on the haunches with the emblem of Siva. He crossed their path, and found them both tame and fearless; and seeing some grass in one of the European's hands, they coolly walked up and smelt it. These privileged bulls are turned out, when calves, on certain solemn occasions, by wealthy Hindus, as acceptable offerings to the divinity Siva. To strike, or in any way to injure or molest one of them, is held a mortal sin. "They feed," he observes, "where they choose, and devout persons take great delight in pampering them. They are exceeding pests in the villages near Calcutta; breaking into gardens, thrusting their noses into the stalls of fruiters' and pastry-cooks' shops, and helping themselves without ceremony. Like other petted animals, they are sometimes mischievous; and are said to resent, with a push of their horns, any delay in gratifying their appetites or wishes."

Between this absurd reverence for consecrated bulls, and the ordinary treatment of the working ox, there is a vast distinction; the latter is harshly, and often severely treated. The cow, however, has more forbearance exercised towards her than, from the treatment of the ox, might be expected. Bishop Heber, speaking of the mode of treading out the corn still practised in India, relates the following:

"One of the Hindu farmers was threshing out a small kind of millet by driving oxen over it, round and round in a circle. They were just leaving off work as I came up; and a hind was bringing a large bundle of green Indian corn, weeded from the thick crop, for their provender. I observed, however, that the animals, during their previous employment, were not muzzled, according to the Scriptural rule; at the same time, they were kept so constantly moving, that a few mouthfuls were all they could get. While I was examining this heap of grain, and asking the old man some questions, his cows came for the evening; and I pleased him exceedingly, when the cowman ran forward to beat them from my path, by forbidding him to strike them. 'Good! good!' he said, with an air of much satisfaction; 'one must not beat cows.' It seems to me that the tender mercies of the Hindus towards animals, are exhausted on cows and Brahmin bulls only; for oxen they have no pity—they are treated with much severity." That the ox should be severely treated or employed in hard work by the Brahmins, seems a sort of contradiction to the principles by which these people profess to be guided; but such inconsistencies are too common to be surprising. Thévenot, who describes the zebu oxen of India as excellent both for the saddle and draft, adds, that some gallop as fast as a good horse; and goes on to state that they are equally used for the plough, and for coaches and chariots. They are harnessed by means of a long yoke at the end of the pole, which is placed on the neck of the two oxen, and the driver holds in his hand the cord which is attached to a small double cord passed through the gristle of the nose, instead of a bit in the mouth, as in the case of the horse.

It would appear that white oxen are highly esteemed in India, as they have also been in other parts of the world. Olearius notices the procession of an Indian prince, who was drawn
in a carriage by two white oxen, which had the neck short, and a hump between the shoulders, but which were as lively and active as horses. Bishop Heber observes, that the Thakooos, generally travel in covered waggons drawn by white oxen, the horns of which they gild. Tavernier observes—

‘The two oxen which were harnessed to my carriage cost me nearly six hundred rupees. The render need not be astonished at this price; for these are oxen of great strength, and can travel journeys of twelve to fifteen leagues a day for sixty days, and always on the trot. When they have done half their day’s work, they have two or three balls, the size of a penny loaf, of wheaten flour kneaded with butter and coarse sugar; and, in the evening, their ordinary fare consists of chick-peas bruised and steeped half-an-hour in water.’ Of the docility, activity, and services of the zebu ox in India, much more need not be said. Numerous travellers, both in the past and present century, have borne the same testimony, and record observations bearing upon the same point.

**PERSSIAN OXEN.**

Receding westward from India to Persia, we gradually lose the zebu race, or at least find it intermingled with that of another type. Chardin observes, that the oxen of Persia are like ours, excepting towards the frontiers of India, where they have the hunch on the back. Throughout the whole country, the ox is seldom eaten as food; it is only reared as a beast of burden or for tillage. Such as are used for burdens are shod with iron, in consequence of the stony mountains over which they have to travel. The shoeing of oxen, where the country is rugged and the roads hard or stony, is also practised in India, as Thévenot relates, but is not a general custom. The shoes are light, and two are placed on each foot, as the cloven character of the hoof necessarily requires, so that the natural freedom of each part is not impeded. In Persia, the bull is often made to fight with the lion, and sometimes comes off victorious, though dreadfully lacerated.

Thus much respecting the distinction between the zebu race of cattle and the ordinary breeds of Europe, and their apparently natural distribution. Whichever race or breed we contemplate, we shall find it adapted to the service and necessities of man, its value being in proportion. It will readily be admitted, however, that the interest which attaches to the ox does not arise from its intelligence, but from its absolute utility. The pleasure which the mind experiences when we gaze on peaceful herds, feeding in tranquil security, is of a complex origin—the result of an association of ideas, more or less remotely connected with the presence of these creatures; which, from time immemorial, have formed the wealth of man, and which have, therefore, engaged alike the attention of the statesman, the poet, and the philosopher.

**THE GAYAL.**

*(Bos Gavæus).* Gavaya, Sansc.; Gavâi, or Gayâl, Hind.; Gobaygoru, Beng.; Gaujangulî, Pers.; Methanâ, Mountainers (Cúcis, &c.), east of Silhet; Shâlâl, Mountainers (Cúcis), east of Chatgaon; J’hônguwa, Mugs; Núnece, Burmas; Gauvera, Ceylon.

India presents us with several species of wild oxen, independent of such as belong to the buffalo tribe, some of which are domesticated in certain districts, beyond which they are not dispersed; and such is the Gayâl. According to Mr. Maerae, the gayâl is found wild in the range of mountains which form the eastern boundary of the provinces of Arracan, Chittagong (Chatgaon), Tipura, and Silhet. The Cúcis, or Lunetas, a people inhabiting the hills immediately to the eastward of Chatgaon, have herds of them in a domesticated state. The animal is called Gabay in the Hindu Sástra; but, as it would appear, is little known beyond the limits of its native mountains, except to the inhabitants of the provinces above mentioned. We learn from the same author, that the gayâl is of a dull heavy appearance, but that its form, like that of the wild buffalo, indicates great strength and activity. Its disposition is gentle; and, in a wild state, on its native hills, it is not considered dangerous, never waiting the approach of man, much less standing and sustaining his attack. The Cúcis hunt the wild animals for the sake of their flesh. The gayâl is a tenant of the forest, and prefers the tender shoots and leaves of shrubs to grass. It never walls in the mud like the buffalo. In a state of domestication among the Cúcis, it does not undergo any labour; nor is the
milk of the female (which, though small in quantity, is extremely rich) held in any request; the animals are bred and reared solely for the sake of their flesh and hides, of which latter the Cúcís make strong shields. These domesticated herds roam, at large, in their forests during the day, and return home to their villages in the evening, being taught to do this very early, by being fed, when young, every night with salt, which, to these animals, is extremely palatable. Though the Cúcís slaughter the domestic gayál, the Hindus, in the province of Chattaon, will not kill this animal (their gabay), which they hold in equal veneration with the cow; but they hunt and kill another gayál (as l'gayal, or Selot), as they do the wild buffalo. The cry of the gayál is a kind of lowing; shriller, but not so loud as that of the European ox, without any resemblance to the grunt of the buffalo. In size and shape it resembles the English bull; has short horns, which are distant at their bases, and rise in a gentle curve upwards and outwards, their transverse section near the base being ovate. The forehead is broad, and crowned with a tuft of lighter-coloured, long-curléd hair; the dewlap is deep and pendent; there is no mane or hump as in the zebu, but the withers rise to a considerable elevation. The tail is short; the body covered with a tolerable coat of straight dark-brown hair; on the belly it is lighter coloured; and the legs and face are sometimes white. From various experiments, it is proved that the domestic gayál will breed with the ordinary zebu cattle of India; but whether the offspring will interbreed with each other is as yet to be ascertained.

THE GYALL.
(Bos frontalis, Lambert). In the seventh volume of the Linnaean Transactions, will be found the figure and description of a Gyall, which died in London, in 1842, by A. B. Lambert, Esq., who quotes the following letter from George Harris, Esq., who was well acquainted with the domestic gyall in its native country. Referring to a communication from Mr. Lambert, he writes—"I have before me your note, with the drawing, which appears to me to be the figure of the animal I mentioned to have in my possession. Some parts of the drawing seem to be rather too much enlarged, as the base of the horns and the rising between the fore shoulders. The animal I described to you, and which I have kept and reared these last seven years, and know by the name of the gyall, is a native of the hills to the north-east and east of the Company's province of Chittagong, in Bengal, inhabiting that range of hills which separates it from the country of Arracan. The male gyall is like our bull in shape and appearance, but I conceive not quite so tall, and of a blackish-brown colour; the horns short, but thick and strong towards the base, round which, and across the horns (chaffon), the hair is bushy, and of a dirty-white colour. The chest and forehead are broad and thick. He is naturally very bold, and will defend himself against any of the beasts of prey. The female differs little in appearance: her horns are not quite so large, and her make is somewhat more slender; she is very quiet, and used for all the purposes of the dairy, as also (I have been informed by the natives) for tilling the ground, and is more tractable than the buffalo. The milk which these cows give has a peculiar richness in it, arising, I should conceive, from their mode of feeding, which is always on the young shoots and branches of trees, in preference to grass. I constantly made it a practice to allow them to range abroad amongst the hills and jungles at Chittagong during the day to browse, a keeper attending to prevent their straying so far as to endanger losing them. They do not thrive in any part of Bengal so well as in the aforementioned province, and in the adjoining one, Tipporeh, where, I believe, the animal is also to be found. I have heard of one instance of a female gyall breeding with a common bull."

Lesson, and the author of the article Ox, in the Penny Cyclopedia, seem to regard the gyall and the gyal as distinct: from the descriptions, however, which are given, it is quite evident that they relate to one and the same species, as Fischer, in his Synopsis Mammalium, considers them to be. The title frontalis, therefore, must be retained by right of priority over gyallus.

Duvauclc, who hunted this animal at the foot of the Silhet Mountains, describes it as very wild, but easily domesticated. He says, that until he had opportunities of seeing it in a natural state, he entertained the opinion that
it did not differ essentially from our domestic ox, his impression having been received from an inspection of specimens living tame in the menagerie at Barrackpore. Subsequently, he regarded it as distinct.

THE GOUR.

According to Captain Rogers, the Dus gour is found in several of the mountain districts of Central India, but chiefly in Myn Pat, or Mine Paut, a high insulated mountain, with a tabular summit, in the province of Sergojah, in South Bahar. "This table-land is about thirty-six miles in length, by twenty-four or twenty-five miles in breadth, and rises above the neighbouring plains, probably, two thousand feet. The sides of the mountain slope with considerable steepness, and are furrowed by streams that water narrow valleys, the verdant banks of which are the favourite haunts of gours. On being disturbed, they retreat into the thick jungles of saul-trees, which cover the sides of the whole range. The south-east side of the mountain presents an extensive mural precipice, from twenty to forty feet high. The rugged slopes, at its foot, are covered by impenetrable green jungle, and abound with dens formed of fallen blocks of rocks, the suitable retreat of tigers, bears, and hyænas. The western slopes are less rugged, but the soil is parched, and the forest seems withered by excess of heat. The summit of the mountain presents a mixture of opens, lawns, and woods. There were once twenty-five villages on Myn Pat, but these have been long deserted on account of the number and ferocity of the beasts of prey. On this mountain, however, the gour maintains his seat. The Indians assert that even the tiger has no chance in combat with a full-grown gour, though he may occasionally succeed in carrying off an unprotected calf. The wild buffalo abounds in the plains below the mountains; but he so much dreads the gour, according to the natives, that he rarely attempts to invade his haunts, and the hunting-party only met three or four urnas (arnees) on the mountain. The forests which shield the gour, abound, however, with hog-deer (Sambur-deer), samners, and porcupines." In these wild and romantic retreats, Capt. Rogers and his party hunted the gour, which, when wounded, turns round upon its adversary, ready to do battle. A short bellow, imitated by the syllables UGH-UGH, was the only cry which the animal was heard to utter, and that not until it had been struck by the bullet. The gour is gregarious, herding together in parties varying from ten to twenty; browsing on the leaves and shoots of tender trees and shrubs, and also grazing on the banks of the streams. In cold weather the saul-forests are their places of concealment, and the heats bring them out to feed on the green lawns and valleys. They do not, it seems, wallow in swamp and mire like the buffalo. If the natives are to be credited, this animal will not brook captivity; and, even when captured at an early age, the mountain-calf droops and dies. The period of gestation is stated to be twelve months; the females produce their young in August. The native name of the bull-calf, for the first year, is Purórah; of the cow-calf, Paréeh. The full-grown cow is termed Gouirin.

The gour attains to a very large size. Dr. Traill gives the dimensions of one not fully grown, which measured, from the nose to the end of the tail, nearly twelve feet, and stood nearly six feet high at the withers. The limbs are vigorous, clean-made, and more deer-like than bovine. The back is strongly arched; and, when the animal stands still, the line from the nose to the base of the tail, along the spine, presents a nearly uniform curve. This appearance is partly owing to the curved form of the chaffron, and, still more, to a remarkable ridge of no great thickness, which rises six or seven inches above the general line of the back, from the last of the cervical to the middle of the dorsal vertebra, where it gradually declines and becomes lost. This elevation is very conspicuous in gours of all ages, although they may be loaded with fat, and has no resemblance to the hunch found on the withers of the zebu breed. There is not a trace of the dewlap, which is well marked in the gayál. The hair of the skin generally is short and sleek, having somewhat the oily appearance of a fresh sealskin. The colour is deep brownish black, almost approaching to bluish black. Between the horns is a tuft of curling, dirty-white hair; and over each hoof is a ring of the same colour. The animal, altogether, has a striking appearance.
THE YAK OF TARTARY.

We may here briefly notice a species of the bovine race, the Yak of Tartary (Bos grunniens), too remarkable to be altogether omitted in our sketch of the ox tribe. Whether the yak belongs to the restricted genus Bos is very doubtful. In some points it certainly is related to the musk ox (Ovibos), at least if we are to judge from the skins, more or less imperfect, which we have had opportunities of examining. The following is the description of a skin wanting the horns and limbs, in the Zoological Museum:—The nostrils are narrow, converging below, with a small nude space between them, and a thin naked border round them, so that there is no true broad naked muzzle, as in the common ox. The ears are small and pointed, and the forehead is covered with black, curling locks; but its degree of convexity cannot be accurately determined, owing to the absence of the skull. The back is clothed with smooth hair, of a deep chocolate brown, a white stripe occupying the ridge of the withers, and another the centre of the croup. From the shoulders, sides, and under surface of the body, and also from the inside of the thighs, hangs a pendent mane of long hair, falling in huge masses, so as to cover the limbs, and almost touch the ground. This mane is grizzled black, except a central line along the belly, of pure white. The tail is tufted with a huge mass of glossy white and rather coarse hairs, from eighteen to twenty inches in length. In size, the animal could not have exceeded the small Scotch breed of cattle. On the authority of Gmelin and Turner, the horns are round, small, pointed, and bent in a semicircle forwards. The withers are elevated, and the colour is said to vary. We have known an instance in which the tail was black.

The yak is a native of the mountains of Tibet, and, when wild, is said to be savage and dangerous. It is, however, reigned, and a domestic breed is kept by the natives of the range tenanted by the animal in its wild condition. It is, perhaps, the Poephagus described by Ælian. From an early period, its tail was used as a standard by the Mongols and Tartars, being one of the distinguished insignia of superior officers. In India these tails are mounted on ivory or silver handles, and, under the name of chowries, are used to brush away the flies. Elephants of state are taught to carry a splendidly mounted chowrie in their proboscis, and wave it backwards and forwards.

Of the habits of the yak, in a state of freedom, little or nothing is known. As regards the domestic yak, Turner, in his Account of an Embassy to China, after giving a description of it, observes, that "these cattle, though not large-horned, seem, from the profuse quantity of hair with which they are provided, to be of great bulk. They have a downcast, heavy look, and appear, what indeed they are, sullen and suspicious, discovering much impatience at the near approach of strangers. They do not low loud, like the cattle of England, any more than those of Hindostan, but make a low grunting noise, scarcely audible; and this but seldom, when under some impression of uneasiness. These cattle are pastured in the coldest parts of Tibet, upon the short herbage peculiar to the mountains and bleak plains. The chain of mountains, situated between the latitudes 27° and 28°, which divides Tibet from Bootan, and the summits of which are mostly clothed with snow, is their favourite haunt. In this vicinity the southern glens afford them food and shelter during the severity of the winter. In milder seasons the northern aspect is more congenial to their nature, and admits a wider range. They are a very valuable property to the tribes of itinerant Tartars called Duckka, who live in tents, and tend them from place to place, and to whom they afford an easy mode of conveyance, a good covering, and wholesome subsistence. They are never employed in agriculture, but are extremely useful as animals of burden, for they are strong, sure-footed, and carry a great weight. Tents and ropes are manufactured of their hair; and, amongst the humbler class of herdsmen, I have seen caps and jackets made of their skins. The best requital with which the care of their keepers is at length rewarded, for selecting them good pastures, is in the abundant quantity of rich milk which they yield, and in the butter produced from it, which is most excellent. It is the custom of the Tartars to preserve this in skins or bladders, and, the air being thus excluded from it, it will keep in this cold climate throughout the year; so that, after some time tending their herds, when a sufficient
store is accumulated, it remains only to load their cattle, and drive them to a proper market with their own produce, which constitutes, to the utmost verge of Tartary, a most material article of commerce."

THE ANOA.

Genus Anoa.—This rare animal has been considered by some naturalists as belonging to the antelopes; and, by others, to the Ox tribe. The uncertainty here arises from the circumstance, that though the animal has been noticed for many years, only a few fragments of skulls and horns have hitherto been brought to Europe. The horns are erect, perfectly straight, and in the plane of the forehead. They are about the same length as the head that is, about nine or ten inches; strongly depressed or flattened in front; of nearly the same breadth till within three inches of the extremities, whence they are rather attenuated to the tips, which are bluntly pointed, and irregularly wrinkled, or rather crumbled, through out the greater part of their length. The head is long and narrow, terminating in a broad muzzle.

Mr. Pennant is the first naturalist who has mentioned the anoa, but he has given no account of its characters, and merely relates, that it is about the size of a muddling sheep, is wild and fierce, and resides in large herds among the rocky mountains of the island of Celebes. He considers it as a small species of wild buffalo, and adds, that it is captured only with great difficulty; and is so fierce in confinement, that some of them, belonging to Governor Loten, in one night, ripped up the bellies of fourteen stags which were kept in the same paddock with them. The next author who mentions the anoa, from original documents or personal observation, is Colonel Hamilton Smith, who, in the fourth volume of Griffith's translation of the Regne Animal, describes the head and horns, and considers the animal as a species of antelope. Colonel Smith's fragment was brought from Celebes by the late Dr. Clarke Abel, who obtained it on his return from China, in the suite of Lord Amherst; but, since that period, various other heads have been brought to Europe, some of which are deposited in the British Museum, and in the rooms of the Zoological Society.

THE ARNEE, OR URNA.

Genus bubalus.—This is the Bos arni of Shaw and other naturalists; and is, by some, regarded as nothing more than the wild ordinary buffalo. It may, however, be found to be a distinct species, if a judgment were to be formed by the characters of the horns, which are not uncommon in museums, though no specimen of the animal itself exists in Europe. It tenants the high lands of Hindostan; and is known in Bengal, and the neighbouring provinces, by the name of Arna. It is described as a large and formidable beast, conspicuous for strength, courage, and ferocity. The horns are remarkable for their enormous size, often measuring from four to six feet in length. They rise upwards, first inclining outwards and backwards, and then, arching gradually towards each other, as they proceed to the points, form together a bold crescent. They are compressed on their anterior and posterior surfaces, and rough, with numerous transverse furrows and ridges. The chaffon is narrow and convex.

THE COMMON BUFFALO.

The Bos bubalis (Buffalo) has long been domesticated in India, where its services, as a beast of draught and burden, render it extremely valuable. From India it has spread into Egypt, Greece, Italy, and Spain. In its form and general aspect, it differs materially from the ox, being a heavier and more clumsy, as well as a more powerful animal. Though lower in stature than the bull, it is more massive in the body, which is supported on short, thick, solid limbs. The hide is coarse and dense, covered rather sparingly with black wiry hair. The head is large, and carried with the muzzle projecting. The forehead is convex, and the muzzle wide. The horns are compressed, and lie back, turning up laterally, and often attaining to a great size; but the direction seldom allows the points to be used for going. The ears are large and pendulous, and the dewlap is small. The eyes are wild, savage, and malicious in expression; whilst the tail is long and slender.

In its native regions, the buffalo is a formidable animal, and capable of contending with the tiger, which is often foiled in the deadly
When excited, it rushes desperately on its foe; strikes him down with the horns or forehead, kneels upon him, crushing-in his chest, and then tramples on the lifeless body, as if to satiate its vindictive fury. Its natural temper, indeed, renders it difficult to tame, and difficult to manage; while its prodigious strength and adaptation for certain localities, render it a valuable acquisition. The hot morass, teeming with pestilence, is the genial abode of this animal; and its delight is to wallow in the stagnant water, where it will luxuriate for hours during the heat of the day, with its black muzzle just elevated above the surface. Its flesh is hard and unsavoury; but the milk of the buffalo-cow is of peculiar richness; and, in the East, a considerable quantity of butter is procured from it. The hide is greatly esteemed for its solidity and toughness. Colonel Sykes states that the long-horned variety of the buffalo is bred in great numbers in the Mawals, or hilly tracts along the Gahnts. In these tracts much rice is planted; and the male buffalo, from his superior hardihood, is much better suited to resist the effects of the heavy rains, and the splashy cultivation of the crops, than the bullock. The female is also infinitely more valuable than the common cow, from the very much greater quantity of milk she yields.

Dillon states that the buffalo at Malabar is larger than the ox, with white eyes, flat horns, often two feet long, and thick and short legs. "It is an ugly animal, almost destitute of hair; goes slowly, but carries very heavy burdens. Herds may be seen, as of common cows; and they afford milk, which serves to make butter and cheese; their flesh is good, though less delicate than that of the ox: the animal swims perfectly well, and traverses the broadest rivers. Besides the tame ones, there are wild buffaloes, which are extremely dangerous, tearing men to pieces, or crushing them with a single blow of the head. They are less to be dreaded in the woods than elsewhere, because their horns often catch in the branches, and give time to the persons pursued to escape by flight. The skin of these animals serves for an infinity of purposes; and even cruces are made of them for holding water or liquors: the animals on the coast of Malabar are almost all wild, and strangers are not prevented from hunting them for their flesh." In Ceylon, as in Malabar, the buffalo exists both in a wild and domesticated state; and the tame herds are not unfrequently joined by wild individuals, which the inhabitants sometimes entrap, and at other times shoot. It would appear that the animal is more common in Bombay than in Bengal. At Boitpoor, Bishop Heber was shown a white buffalo, probably an albino, which was pointed out by the Indians as a rare curiosity. From India the buffalo is distributed throughout Siam, Cochinchina, Malacca, and the adjacent islands, as Sumatra, Java, Borneo, &c., together with the Philippines. It is also common in China, where it is used in the various labours of agriculture. In Africa it is abundant along the Nile, and in other districts, existing in a wild or emancipated state, as well as in a state of domestication. In Abyssinia, more particularly in the forests of Ras el Fil, the buffalo is very common. Its skin is chiefly employed in that country for the making of shields, in which considerable art is displayed. In the middle ages the buffalo was introduced into Spain and Italy, where, in course of time, the animal became naturalised; and, in some districts, may be regarded as in a state of nature.

In the worst parts of the pestilential tract, known as the Maremma in Italy, the savage buffalo may be seen, roaming at will, under the care of wild keepers (buffalari), whose lives are passed in this dangerous employment. Wherever large herds of buffaloes occur, it may be taken as the sure index of malaria. In the wild provinces of the Calabrias, where most of the plains and valleys are always partially swamped by the Laino, the Chratis, the Amato, and numerous other rivers and torrents, they are very common. They range, almost the only occupants, over the plains of Pustum, and the still wilder and more extensive flats of Apulia. The Pontine Marshes offer them a favourite retreat; and in the pestilential Maremma, both of Rome and Tuscany, scarcely any other animals, except wild boars, are ever seen. In Northern Italy, where there is infinitely less malaria than in the south, they occur in greater numbers, as there the causes of that pest exist, and there its effects are often felt, in the inundated rice-grounds of Lombardy, in the marshes formed by the overflowing
of the Po, the Tanaro, the Ticino, or of some other rivers or lakes. In every part of Italy, but especially in the south, buffaloes are used as beasts of burden, and their strength and perseverance render them available in many emergencies when oxen or horses would fail. In some of the marshy plains of Calabria, communication would be almost impracticable were it not for the buffalo. There are not only morasses, swamps, and bogs in every direction, but rivers, suddenly swollen to torrents in rainy weather, and unprovided with bridges of any sort, frequently occur. Here horses, mules, or oxen are useless; but a pair of good buffaloes, working chest-deep in the mud, will, slowly indeed, but surely, drag a large carro, with its goods or passengers, through them. Yoked to a high cart, with wheels of prodigious diameter, they will fearlessly take to the swollen torrent, and, provided the water does not entirely cover them, drag it safely to the opposite bank. On the great plain of Apulia the buffalo is the ordinary beast of draught; and, at the annual fair, held at Foggia at the end of May, immense droves of almost wild buffaloes are brought to the town for sale. Fearful accidents occasionally happen, enraged animals breaking from the dense mass in spite of all the exertions of the buffalari, and rushing upon some object of their vengeance, whom they strike down and trample to death. It is dangerous to over-work or irritate the buffalo; and instances are known in which, when released by the brutal driver from the cart, they have turned instantly upon him, and killed him before any assistance could be rendered.

The buffalo, as well as the bull, is baited in the amphitheatres of Italy. One kind of sport with the buffalo is called La Botta. A large tube, made of wicker-work or other flexible materials, well wadded without and within, and open at both ends—looking, in short, like a cask or butt (whence its name)—with the ends stove in, is rolled across the arena. Presently a man creeps into this cask, and then, lifting it up on end, rises on his feet and begins to move, with his head peeping above the cask towards the buffalo; which, at first, stares, bewildered at the sight, and then runs and upsets the novel object. In this game the man must be careful, when the charge is made, to draw in his head and legs, and keep himself entirely covered, like a tortoise in its shell. The buffalo, seeing that the cask no longer moves, kicks it, butts at it for a while, causing it to roll along, and then leaves it; but presently the cask is again raised on end, and moved by the man towards the beast. This trick could not be played with the Toro Vaccino, the sharp and strong horns of which, being better placed for attack than the buffalo's, would pierce the cask through and through. The attack of the buffalo in the arena is more dangerous than that of the bull; and, in his rage, when he has missed his tormentor, he often strikes the wall furiously with his head and horns, making fragments of stone fly in all directions, apparently without suffering any injury from the violence of the shock.

THE CAPE BUFFALO.

This ferocious animal (Bos Caffer) is a native of Southern Africa, associating generally in troops, and frequenting the watered glens and ravines among the hills. Like the common buffalo, it delights to wallow in pools or swamps, where it sometimes passes the greater part of the day. Its temper is depicted in its lowering eye, and the malevolent expression of the countenance, to which the position of the horns overshadowing its fiery optics, not a little contributes. These weapons form at their base a solid rugged mass, covering the forehead, from which they bend downwards, and somewhat outwards, gradually diminishing to the points, which suddenly take an upward curve. The distance between the points of the horns is frequently five feet; but the rugose, massive base of each is in contact, forming an impenetrable helmet. Their colour is black. The ears are a foot in length, pendant, and, in a great measure, defended by the horns; yet it is observed that they are always torn and jagged, either from the wounds received in their combats with each other, or from the laceration of thorns and spines, the animals continually forcing their way through the dense thickets. Though not taller than an ordinary ox, the Cape buffalo is a far stouter, heavier, and more powerful beast. Its limbs are short and thick; its body bulky, and its head ponderous. The hide is thick and tough, and sparingly covered with harsh blackish hairs; those on the under lip, and about the corners of the mouth, being
CATTLE, AND THEIR VARIETIES.

The genus *Bison, Bison Europaeus* (*Bos urus* of Gmelin), is a noble species, existing in the great forest of Bialowieza (pronounced Bralaweza in Poland), in Lithuania, where it is protected by stringent laws. In proportions, the auroch is robust, and its withers are massive and elevated. The largest males stand about six feet high at the shoulders. The hair is of two sorts: one is soft, woolly, and short, covering the whole trunk and limbs; the other is long and rough, covering the upper part and sides of the head, the neck, and shoulders, where it forms a mane; under the lower jaw, and along the throat to the chest, it is lengthened into a sort of beard. In old bulls the mane is often a foot in length, and is thickest in November. The eyes are small, but fierce and sparkling when the animal is irritated. The tongue, lips, and palate are blue. The tail, which is short, is furnished with a tuft of stiff hairs at its extremity. An odour, described as between that of musk and violets, is exhaled from the skin; especially from that part of the skin covering the convexity of the forehead. It is stronger in the male than the female, and may be perceived at the distance of a hundred yards from the herd. The flesh of this animal is highly esteemed; but, when roasted, is said to have a bluish tinge. Its voice is a deep, short grunt, which can be heard at a considerable distance.

Thickets, near the swampy banks of rivers, are the favourite resorts of the aurochs; but in summer, and during the warmer portion of autumn, according to Dr. Weissenborn, the herds select sandy spots. In winter, they keep quiet by day in the thickest part of the fir-wood, only browsing by night, and finding sustenance in the bark of young trees. In spring, they visit spots where the herbaceous plants they relish begin to sprout. They are fond of tree lichens. "The strength," says Dr. Weissenborn, "of the zubr is enormous, and trees of five or six inches in diameter cannot withstand the thrusts of old bulls. It is neither afraid of the wolf nor bear, and assails its enemies both with its horns and hoofs. An old zubr is a match for four wolves. Packs of the latter animal, however, sometimes hunt down even old bulls when alone; but a herd of zubras has nothing to fear from any rapacious animal. Notwithstanding the great bulk of its body, it can run very swiftly. In galloping, its hoofs are raised above its head, which it carries very low. It has, however, but little bottom, and seldom runs farther than one or two English miles. It swims with great agility, and is very fond of bathing. In its habits it is exceedingly shy, and avoids the sight of man. It can only be approached from the leeward, as its sense of smell is extremely acute. But when accidentally and
suddenly fallen in with, it will passionately assail the intruder. In such fits of passion, the animal thrusts out its tongue repeatedly; lashes its sides with its tail; and its reddened and sparkling eyes project from their sockets, and roll furiously. Such is its innate wildness, that none of the species has ever been completely tamed. When taken young, it becomes, it is true, acenstomied to its keepers; but the approach of other persons renders it furious; and even its keepers must be careful always to wear the same sort of dress, when going near it. Its great antipathy to the *Bos Taurus*, which it either avoids or kills, would render its domestication, if it were practicable, but little desirable. The experiments made with a view of obtaining a mixed breed from the zubr and *Bos Taurus*, have all failed, and are now strictly prohibited.

**THE AMERICAN BISON.**

The *Bison Americanus*, or American Bison, was formerly more extensively diffused than at present; still it exists in vast numbers in Louisiana, roaming over the prairies, which are watered by the Arkansas, Platte, Missouri, and upper branches of the Saskatchewan and Peace rivers. Like its congeners, the auroch, the American bison is of powerful frame, and exceeds, in bulk, the ordinary race of cattle; its height at the fore quarters being upwards of six feet, and its weight from twelve to fifteen hundredweight, and sometimes much more. The head is huge, ponderous, and carried low; the withers are massive and elevated; the eyes are small, and their expression is ferocious; and the horns are small and black. The neck, withers, and chest are covered with a profusion of long shaggy hair, contributing to render the appearance of the animal wild and terrific. The hind quarters are clothed with shorter wool. The general colour is umbra brown, acquiring a rusty tint in winter. Endowed with the sense of smell in great perfection, wary, and fierce, the bison associates in large herds, conducted by one or two old bulls, whose motions the rest appear to follow; but herds of bulls also live separately. Their food consists of grass and rank herbage; to obtain which, in winter, they scrape away the snow with their feet. On the approach of an enemy, the herd immediately takes to flight; but if one be wounded, the life of the hunter is placed in great jeopardy; for, turning in a moment, it rushes on its assailant with headlong impetuosity, and with determined resolution. Several fatal instances might be cited in which the hunter has perished from want of caution in attacking this formidable beast, and many hairbreadth escapes are on record. In defending itself from a dog, the bison strikes violently with its fore feet, and easily keeps its annoying foe at bay. Its flesh is accounted excellent; the tongue and hump, or flesh on the top of the withers, being especial delicacies. The chase of the bison is, therefore, assiduously pursued, both by natives and Europeans. It swims well; and during the heats of summer, vast herds make their way to shady rivulets, streams, and pools, in which they delight to plunge and bathe. Herds of twenty thousand, crossing rivers upwards of a mile in breadth, have been seen, as Lewis and Clarke inform us; or darkening the plains on their passage to fresh feeding-grounds.

Salt-springs, or saline morasses, or salt-lakes, are great attractions to this animal, and, at all seasons, are visited by numerous herds. These, however, are incessantly thinned by the hunters; and the time is probably not far distant, when the American bison will be as rare and as limited in its extent of range as the aurochs of Lithuania. At certain seasons of the year, the bulls engage in terrible conflicts, and rush furiously upon man, or any other animal which ventures near them. With the exception of man, the most formidable enemy against which the bison has to contend, is the huge grisly bear; and before this dreaded monster the strongest bull goes down. The bison will breed with the ordinary race of domestic cattle, against which the auroch displays the greatest antipathy; though, in one respect, the latter approaches nearer to the common ox than does the bison. We allude to the number of ribs, which are thirteen in the ox on each side, fourteen in the aurochs, and fifteen in the bison.

**THE MUSK OX.**

*Genus Ovibos*—the *Ovibos Moschatus*. The characters of the genus *Ovibos*, as exhibited by the only known species, are defined by the horns being expanded at their base, forming a helmet-like mass, covering the forehead, where
their edges are in contact with each other. From this mass they emerge, round and tapering, first bending down between the eye and ear, and then sweeping suddenly upwards. The ears and tail are short; the eyes moderate; the nostrils oblong, and inclined each other from above downwards. There is no true naked muzzle; but a very narrow nude line surrounds each nostril, the rest being covered with hair. There is no furrow in the upper lip.

The musk ox is a native of the high latitudes of North America, ranging from the sixty-first to the seventy-fifth degree of latitude. In size it scarcely equals the smallest of the Highland breed of cattle; but appears larger than it really is, from the profusion of long, matted, woolly hair with which it is covered, and which hangs on each side almost to the ground, nearly concealing the limbs to the pasterns. The tail is entirely hidden. Beneath the lower jaw, throat, and chest, the hair flows full, long, and mane-like. The general colour is dull, grizzledumber brown, darker on the sides and under surface. On the centre of the back is a brownish-white mark or saddle. The districts inhabited by the musk ox, says Dr. Richardson, are the proper lands of the Esquimaux; and their name for it is Oomingmak. It frequents wild and rocky situations, mostly destitute of wood; feeding on grass during one season of the year, and on lichens during the other. When fat, its flesh is tolerable; but, at certain times, both that of the bulls and cows smell strongly of musk.

Though the limbs of the musk ox are short, they are very vigorous, and the animal is fleet and active. Dr. Richardson mentions one pursued on the banks of the Coppermine, which scaled a lofty sand-cliff, so steep, that the party were obliged to descend to their hands and knees, in order to crawl up the declivity.

In September, these animals assemble in herds, and are then much harassed by the hunters. The sport, however, is not free from danger, for the bulls are very irascible, and, when wounded, will dart furiously upon the hunter, who requires both practice and presence of mind in order to escape. If, however, the hunters remain concealed when they fire upon a herd of musk oxen, the poor animals mistake the noise for taunter, and forming themselves into a group, crowd nearer and nearer together as their companions fall around them; but should they discover their enemies by sight, or by their sense of smell, which is very acute, the whole herd seek for safety by instant flight. Their wool is very fine; and some stockings which were made from it in France, are said to have been equal to those made from silk. If it could be obtained in sufficient quantity, it might doubtless be employed advantageously as an article for manufacture.

**BRITISH WILD CATTLE**

The wild cattle of this country are kept in their native purity in the park of Lord Tankerville, at Chillingham, in Northumberland. A few are also kept in Scotland, in a park of the Duke of Hamilton's, at Chatelherault, in Lanarkshire; but the latter have a less certain pedigree. The former nobleman, in a communication to the Society of Arts, gives a very interesting account of their characteristics and habits, and assigns them the palm of being the aboriginal cattle of the island. That the original breed in this country, or at least some early breed of cattle, have been very large in size, is evident from the fossil bones found in bogs; yet a smaller kind has been discovered in Cornwall, with a species of horn more resembling the cattle of the Duke of Hamilton. Fitzstephen, who flourished in the twelfth century, alludes to the wild bull of the woods as having its haunts in the large forests near London. Guy, Earl of Warwick, whose contest with the Wild Dun Cow is commemorated by the animal's skull being still preserved in Warwick Castle, doubtless had an encounter with a monstrous animal of the wild breed. Hollinshead also speaks of Bruce being, in the fourteenth century, nearly killed by a bull in the forest of Caledon; and from his attendant having rescued him, the well-known name of "Tunibull" originated. So recently as the sixteenth century, it seems, these wild cattle were common in the Callender or Calder woods. Conrad Gesner describes them, in the quaint legend-language of the day, as "white oxen, maned about the neck like a lion." * * * * This beast is so hateful and fearful of mankind, that it will not feed of that grasse, or those hearbes whereof he savoureth.
a man hath touched — no, not for many days together; and if, by art or policy, they happen to be taken alive, they will die with very sudden grief. If they meet a man, presently they make force at him, fearing neither dogs, spears, nor other weapons."

CATTLE OF THE MAREMMA.

We have already alluded to the Maremma of Italy; to which we must return, to notice an uncouth, savage, wild breed of cattle, which inhabit its marshes. This piece of country consists of a flat strip, except in a few places where hills intervene, extending from the mountains of Genoa to the extremity of Calabria, a length of about seven hundred miles. Its breadth is from the base of the lower range of the Apennine chain to the shore of the Mediterranean. This sweep of country is pastoral in the extreme in summer; and though it yields the most luxuriant harvests, is only partially cultivated, the greater portion being left for pasture. Here, besides the cattle used as beasts of burden, or draught, and employed in the work of the farms, large herds roam unmolested under the care of keepers, which, together with the buffalo-keepers, before alluded to, and forest-rangers, are the only stationary population in the wild Maremma. The former, as wild and savage as the animals under their charge, are always mounted on fleet horses, and armed with a long lance, which they use in driving the cattle, and in defending themselves against the fierce bulls, which, as well as the buffaloes, are extremely dangerous. These men are often criminals, who have fled from justice into the Maremma, where they are obliged to sojourn, and where they are often employed by the proprietors of the farms and cattle, as rangers or drivers. Those who are not fugitives adopt their occupation from choice, which, dangerous and laborious as it is, is one of independence and freedom. They are the analogues of the Arab of the desert, or the Gauchos of the Pampas. Besides being paid for their services, they rear cattle of their own. In the summer months they retire to the shady forests along the sea-shore, where the air is not so unwholesome as in the open plains. The cattle are collected at various times, and driven by these men, called Vaccari, to the fairs held in the towns, for sale.

Both the bull and the buffalo are baited in Italy by men and dogs, for the entertainment of the Roman people, who seem to be as fond of such scenes as were their great predecessors. The scene of the sport, which is called La Giostra, is, like many other buildings in Rome, a curious compound of the modern and the ancient. The Amphitheatro Correa, as the place is designated, is situated in a massive cluster of buildings raised upon the site, and partly with the materials, of the mausoleum of the Emperor Augustus, in the Campus Martius. The walls of this amphitheatre, and the seats, are all of modern structure. The arena occupies the platform of the ancient mausoleum, which, in other times, was cultivated with flowers and rare shrubs; while the pyramid, that bore the statue of Octavius, rose in the midst. The vaults beneath, which once held the ashes of the Caesars, are now in part used as dens for the wild cattle that are brought in from the Campagna, and other places, to be baited. Twice every week, during the summer, do these exhibitions take place; commencing at five in the evening, and lasting till dusk. The men who are to encounter the bulls and buffaloes are called Giostratori. They are dressed in white, with a red sash round the waist. Each bears a short staff, with a red pennon at the end of it; and they muster in the arena, make their bows to the assembled spectators, and wait the onset of the mighty animal. Among them are generally two or three of great reputation for skill; these are usually vaccari (herdsmen), or buffalieri (buffalo-keepers)—men brought up from their childhood among the cattle they respectively manage, and familiarised with their habits. The Giostratori, from Viterbo, have the reputation of excelling all others; and hence the term il Tiberese (the Viterbonian) is used metonymically to designate any celebrated bull-fighter. In the centre of the arena is a strong post firmly fixed, by dodging round which a man may, for a considerable time, evade the assaults of a bull or buffalo. At a given signal, the door of a den is opened, and the bull rushes forth, wildly gazing around him, till, observing the Giostratori, with their scarlet sashes and pennons, he singles out one, and roaring and lashing his tail, drives furiously towards him. The man nimbly avoids the charge; others
come to the rescue, drawing off the bull's attention from him, and inviting its attack; till the enraged animal, distracted by the number, quickness, and manoeuvres of his antagonists, and wearied with vain efforts, ceases the pursuit. The den is then thrown open, and he generally retires of his own accord, as if glad to escape. When the bull, as is sometimes the case, perseveringly follows a man, and presses him hard, he catches hold of one of the iron rings, placed at certain distances round the wall enclosing the arena; and, by a rapid movement, springs to the top, which, like a terrace, runs round the foot of the lower seats of the amphitheatre. The height of this parapet is six or seven feet; and it requires great agility, strength, and presence of mind, as well as precision, to avoid being pinned to the wall in the act of taking the leap. Such accidents sometimes happen; but when the Giostratori see one of their number thus endangered, they use every means to divert the bull's attention. The bull (and also the buffalo) is, on some occasions, baited with fierce dogs of the Corsican breed, resembling our bull-dog, and distinguished by the same "tenacity of tooth" and indomitable courage. These dogs usually pin the bull by the nose or lip; but are very frequently tossed in the air, or ripped up by the sharp horns of the maddened animal. At these exhibitions, strange to say, females are among the spectators, and not less interested than the rougher sex. Some of the bulls procured in the Campagna of Rome are very noble and spirited animals, of fine figure and great strength.

CATTLE OF SPAIN AND PORTUGAL.

In Spain and Portugal, where extensive wilds and forest lands afford ample pasturage, large herds of oxen, born in freedom, wander uncontrolled and untroubled, excepting by man, from whom they flee with precipitation, till roused to fury by his assaults, when they attack in turn, and bear upon him with resistless impetuosity. It is from these herds that the Spaniards and Portuguese select the fiercest and boldest for the revolting contests of the arena; while others are tamed, and broken-in for the ordinary purposes of husbandry. It is easy to imagine the excitement produced by the chase and capture of a herd of these fierce brutes, and the danger to man and horse. Such sport frequently takes place in the great forest of Alentejo, where an eye-witness of one thus describes it:—"I had received," he says, "intimation that the village of Aloxete, on the Tagus, was to be the scene of a bull-fight, and that the villagers, for many miles, were invited to join in the hunt, which was to take place the following day. I accordingly crossed the river in the company of about twenty persons, each being provided with a long pole, having a small spike fixed in one end, and mounted as inclination or ability suited. When we arrived at the opposite bank, a little before daybreak, we found about 250 or 300 persons assembled, some mounted on different sorts of quadrupeds—from the noble Andalusian horse to the humble donkey; and many were on foot. All were armed in a similar manner to ourselves. We divided into two parties—one stretching in a long line to the right, the other to the left. We had not advanced far, in this manner, when we fell in with a herd of cattle, having twelve bulls with it; which no sooner desired us, than they bounded off with the speed of lightning. The sport had now begun. We put our horses to the utmost speed, threading our way among the tall pine-trees as well as we could, and endeavoursing by wild cries to drive the bulls towards the other party. At length, after about an hour's chase, some half-dozen of us, who were better mounted than the rest, came up with them, and commenced the attack with our long poles. The manner was this:—One person, riding at full speed, gave the bull nearest him a sharp prick with the goad, which it no sooner felt, than it turned upon its assailant and gave chase; another horseman then coming up, attacked it on the other side, when, leaving the first assailant, it turned upon the second; he, in like manner, was rescued by a third, and so on. The attention of the infuriated animal was thus so distracted as to prevent his escape, and give time for the other hunters to come up. The bulls were thus at length separated from the herd; and a sufficient number of persons having arrived to form a circle round them, we commenced operations for the purpose of driving them towards the town. All the skill of the riders was now necessary, and all the activity possessed by both man and
horse, to keep clear from the pointed horns which were presented against him, as well as to prevent the herd from breaking through the living net with which it was surrounded. This was, perhaps, the most difficult part, and was attained by keeping each bull separately engaged, and thus preventing united action; for what line was sufficient to resist the simultaneous rush of these powerful animals? The continued exertion had knocked up many of the horses which had started in the morning, and the circle became smaller and smaller as the day advanced; several persons, indeed, had been carried off, severely wounded by the horns and feet of the bulls. Redoubling our efforts, however, we at length, about four o'clock in the afternoon, succeeded in driving them into an inclosure, where a number of oxen (all at one time wild) were quietly grazing. Here they were kept till required for the next day's sport." These bulls were baited in the square of Alcozete, converted into a temporary arena; and afterwards reduced to a complete state of servitude. The picadores, or men who encountered them, were on foot, and only armed with short darts, and displayed the most surprising courage and address; and when at last they were to be thrown, a man, leaping between the horns, there supported himself till the cords were lashed round the animal's limbs.

The bull-fights, as conducted in the amphitheatre of Spain and Portugal—the lingering relics of those contests in which Rome so much delighted, and which prevailed more or less throughout the Roman empire—have been often described. These sanguinary spectacles are the delight of the Spanish people, and are not only tolerated, but encouraged by the higher classes of both sexes, who find a morbid gratification in the torments which the bull endures from the lance of the cavalier, or the horse from the horns of the bull. The most graphic and spirited description of this "ungentle sport," is that by Lord Byron, in Childe Harold's Pilgrimage, canto i.; attached to which there is a note by Sir J. C. Hobhouse, which further describes the scene:—"The magistrate presides; and after the horsemen and picadores have fought the bull, the matal- dore steps forward and bows to him for permission to kill the animal. If the bull has done his duty by killing two or three horses, or a man (which last is rare), the people interfere with shouts, the ladies wave their handkerchiefs, and the animal is saved. The wounds and death of the horses are accompanied with the loudest acclamations, and many gestures of delight, especially from the female portion of the audience, including those of the gentlest blood." Of the effects of such exhibitions on the character of the people, nothing need be said; whatever atrocities may be committed by men, "nurtured in blood betimes," cannot surprise us.

**CATTLE OF RUSSIA.**

Within the Arctic Circle the ox gives place to the reindeer; but in Iceland, cattle are reared in great numbers, and are valuable. In size and appearance, excepting that they are seldom horned, they resemble the breeds of the Scottish islands. It would appear that the Icelandic farmers conduct the breeding of their stock on no principles; consequently, there is great room for improvement: nevertheless, the cattle, on the whole, are handsome, and the cows yield a considerable quantity of milk. In Norway and Sweden, cattle are numerous, and also in Russia. From this last country, the main exports to England consist of tallow and hides. In that extensive empire vast numbers are reared, principally in the southern provinces; and the markets of St. Petersburg, and other towns, are supplied with cattle sent from distant parts of the country. The herdsmen live in a state of barbaric simplicity, and are nomadic in their habits. They travel with their herds to Moscow, St. Petersburg, and other places, which depend more upon them for a supply than upon the farmers of the adjacent districts. The following passage, in Johnston's Russia, conveys a just idea of the Russian cattle-keeper and his herd:—"Along the road," he says, "we passed one or two large droves of horned cattle proceeding to St. Petersburg. We learned that they were brought from the provinces south of Moscow. These cattle are all of a whitish colour, well made, and of about seven hundredweight. Their journey to St. Petersburg occupies three months; they travel from eight to sixteen miles through the night, and are allowed to pasture and rest, during the
day, on the sides of the road. The herds are attended by one or two men, who convey their cooking utensils, baggage, &c., in a waggon drawn by two oxen; and while their numerous herds repose undisturbed under the shade of the delicate birch, they stretch themselves on the ground, and pass their time in a true Scythian state. Here are also seen a few sheep, but of an inferior breed, covered with hair somewhat like that of a goat. This country is not favourable for the pasture of sheep, owing to the coarseness of the grass, and the abundance of wood. Little or no attention seems to be paid to the rearing of any other animal besides the horse. To him alone the Russian devotes his whole attention, and from him he derives his livelihood."

CATTLE OF MOLDAVIA AND WALLACHIA.

In Moldavia and Wallachia cattle are abundant; in the former district, indeed, the people continue, in a great measure, their ancient nomadic habits, making use of the services of the ox as a beast of draught or burden. United in immense caravans, they roam over a vast extent of territory, transporting, in tall vehicles of singular construction, various articles of produce, provisions, and other things, to the towns scattered at long distances about the wide plains of Moldavia. Day by day they move cheerfully on, to the slow and measured sound of the footsteps of their oxen, and are often an entire month without seeing a single human habitation. At the approach of evening the caravan halts; the numerous waggons are disposed in the form of a square, and the oxen are turned out to graze at large, under the watchful care of intrepid dogs which accompany the caravan. In the middle of the square a fire is now lighted, at which the conductor prepares his simple repast, and afterwards disposes himself to sleep, sheltered by a warm and heavy coverlid, which completely wraps him. These indefatigable walkers are no less excellent riders. They possess a fine race of horses, which are employed for drawing lighter vehicles; while the heavier waggons are drawn by the slow oxen. There are no high roads in Moldavia; the plain is open, and each traveller chooses his own track; and it is often with difficulty that the oxen can drag their way through heavy ground. Storms of wind, rain, or snow make the matter worse, so that a passage can only be achieved by great patience, labour, and resolution. A bullock-caravan of Moldavia, wending its weary way over the vast plains of that province, while lighter vehicles, drawn by swift horses, are seen in the distance, furnishes an interesting scene for the artist of rural life. It is by these caravans that the trade and commerce of Moldavia are carried on, and the town supplied with grain.

CATTLE OF SWITZERLAND.

In Switzerland there is an excellent breed of cattle; and in no country are these animals more carefully attended to, or held in greater esteem for their utility, as far as the dairy is concerned. Travellers have frequently noticed their docility and intelligence, which they have, at the same time, not a little exaggerated. It is customary to hang bells round the necks of the cattle, sheep, and goats, in order that, if they stray among the hills and mountains, the herdsmen may be directed by the sound in his pursuit of them, the slightest tinkle being heard at a great distance in those lofty and quiet regions. The cows selected to bear the bell become accustomed to it from habit, and often, we doubt not, betray signs of uneasiness when deprived of it; but the account given by some writers, respecting their feelings, borders on the ludicrous. "The cow, whose superior beauty, sagacity, or good conduct seems to entitle her to be the leader of the herd, is always, on gala days, distinguished by the largest and finest-toned bell, and the bravest ornamental collar, and so down through all the gradations of good, to the small appendage that marks the indifferently good or clever animal, and the total absence of ornament and distinction which points out the self-willed or vicious. If any cow has been guilty of straying, of unseemly behaviour, breach of discipline, or any vicious trick, the displeasure of the Vacher is not testified by blows, but by the temporary deprivation of her bell; and this seldom fails to reduce her to order, and prevent a repetition of the offence. It is only necessary to see the cow on a gala day, with her badge of distinction strapped round her neck, and then to see her deprived of it for some reason or other, to be convinced that..."
CATTLE, AND THEIR VARIETIES.

African Cattle."

This is true. She is now gay, good-humoured and frolicsome; then sulky and gloomy."

The pastoral economy of Switzerland, which is common to Savoy and other Alpine countries, and the annual progress of the shepherds and cowherds, with their flocks and cattle to and from the mountains, are interesting. The richer proprietors and breeders in the Alps, possess tracks of pasturages, and sometimes houses, at different heights. In winter they live at the foot of the mountain, in some sheltered valley; but this they quit in the spring, and ascend gradually, as the heat brings out vegetation on the higher lands.

In autumn they descend, by the same gradations, to the valley. Those who are less rich have a resource in certain common pastures, to which they send a number of cows proportionate to their means of keeping them during the winter. Eight days after the cows have been driven up to these common pastures, all their owners assemble, and the quantity of milk each cow produces, is accurately weighed. This operation of weighing is repeated one day in the middle of summer, and again at the end of the season. The milk of all the cows has, in the meanwhile, been put together, and made into butter and cheese; and this common product is divided into shares, according to the quantity of milk each owner's cows yielded on the days of trial. In some parts, and more particularly in the retired parts of the forest cantons, the peasants make use of the Alp-born for the purpose of collecting their herds. This primitive instrument is a tube of wood about five feet in length, of very simple construction. It produces a deep, mellow, and prolonged note, resounding to a great distance, floating over the upland pastures, and echoing from crag to crag, and from rock to rock. On hearing the well-known summons, which is regularly given at sunset, the cattle bestir themselves, and wend their way to the chalet, where the peasants are waiting their arrival. The deep note of the Alp-born, heard among the mountains, and multiplied by echoes till the last tone dies away, produces a pleasing impression on the traveller, which he long remembers.

CATTLE OF SOUTH AFRICA.

The ox, in South Africa, is used as a beast of burthen and draught; and his services are of the utmost importance. Wagons drawn by oxen, often cruelly overtasked, are the ordinary travelling vehicles of this part of Africa, and are admirably adapted for the country, which is rugged and mountainous, and generally destitute of any other roads than the rude tracks originally struck across the wilderness by the first European adventurers. Each waggon, provided with a canvas tilt, to protect the traveller from sun and rain, is drawn by a team of six, eight, or even twelve oxen, fastened with wooden frames to a strong central trace, or trek-tow, formed of twisted thongs of bullock's hide. The driver, who sits in front, has a whip of enormous length, which he often uses with unsparing severity. Formerly, if the account given by Barrow is to be credited, the treatment exercised by the Dutch-African boors to their oxen was brutal in the extreme. The Dutch boors, moreover, made use of very large and clumsy wagons, and delighted in transporting tremendous loads at a time. It was a common sight to see six, eight, ten, or even a dozen pair of oxen yoked to an enormous vehicle; but even this number was inadequate to such burthens as they had to draw, and the resistance of such roads. The most disgraceful cruelties were used to force these poor creatures on their way. Their drivers cut them with knives; and when, worn out, they laid themselves down, and refused to rise, it was a common practice to light fires under their sides, and so force them to go. One of these brutal boors, whose knife had been often employed on the flesh of his cattle, boasted that he could start his team at full gallop by merely whetting that knife on the side of his waggon. Once, as he was exhibiting this experiment, the waggon was overturned, and one of the company—"unfortunately not the proprietor," says Mr. Barrow—"had his leg broken."

When the Dutch took possession of the Cape of Good Hope, they found the Hottentots a pastoral people, possessed of flocks and herds. The oxen were of large size, with horns that swept forwards and upwards to a great length; and they were not only trained for riding, but even as guardians of the flocks and cattle, and as instruments of destruction in battle. The Hottentots, says Kolben—who visited them
while they yet retained their name and independence as a nation—" have even which they use with success in battle. They call them Bake-leys. Every army is provided with a large troop of these war oxen, which permit themselves to be governed without trouble, and which their leader lets loose at the appointed moment. The instant they are set free, they throw themselves with impetuosity on the opposing army; strike with their horns, kick with their heels, overthrow, rip up, and trample beneath their feet, with frightful ferocity, all that opposes them. They plunge with fury into the midst of the ranks, and thus prepare for their masters an easy victory. The manner in which these oxen are trained and disciplined, certainly does great honour to the talent of these people."

Le Vaillant, when in South Africa, says that he saw some of these oxen, which were then only used by certain tribes of Hottentots; but he gives the same account of their mode of fighting as Kolben, who, also, describes the bake-leys as guardians of their flocks. "When out in the pasture-grounds, at the least sign of their conductors, they will hasten to bring back the cattle which are straying at a distance, and keep them herded together. They rush on strangers with fury, whence they are of great service against the Bochmänner, or robbers, who may attempt to plunder the flocks. Each kraal has, at least, half-a-dozen of these bake-leys, which are chosen from among the most spirited oxen. On the death of one, or when one, in consequence of old age, becomes unserviceable—in which case its owner kills it—another ox is selected from the herd to succeed it. The choice is referred to one of the old men of the kraal, who is thought to be most capable of discerning that which will most easily receive instruction. They associate this novicée ox with one of long experience, and he is taught to follow his companion, either by beating or some other method. During the night they are tied together by the horns; and they are, also, thus kept tied during the greater part of the day, until the learner has become a good guardian of the flock. These guardians know all the inhabitants of the kraal—men, women, and children; and testify the same respect towards them that a dog displays towards all those that live in the house of his master. There is, therefore, no inhabitant of the kraal who may not with safety approach the flocks. The bake-leys never do them the least injury; but if a stranger, and particularly a European, should offer to take the same liberty, without being accompanied by some Hottentot, he would be in great danger from these guardians of the flock, which usually feed round it, and which would come upon him full gallop. Then, unless he be within hearing of the shepherds, or have firearms or good legs, or unless a tree be near in which to climb, he is sure to be killed. It would be useless for him to have recourse to sticks or stones; a bake-ley has no fear of such feeble weapons." Sparrman was one of the last South African travellers who found the Hottentots in their original state of pastoral freedom. He mentions a woman, who was possessed of sixty milch-cows; and, on the cattle of the kraal being brought home from pasture, the evening was enlivened by singing and dancing.

The Caffres, Corannas, and other tribes, have oxen in abundance, which are employed as beasts of burden. The Corannas are a nomad race, frequently removing with their flocks and herds to fresh pasture-land, and transporting their mats, tents, and utensils strapped on the back of oxen, which also carry themselves and their wives and children:—

"Fast by his wild resounding river
The lissid Coran lingers ever;
Still drives his heifers forth to feed.
South'd by the gorrah's humming reed;
A rover still, uncheck'd, will range.
As humour calls or seasons change;
His tent of mats and leathern gear
All packed upon the patient steer."

Burchell, another South African traveller, describes the saddle-oxen as generally broken for riding when not more than a year old. The first ceremony is that of piercing the nose to receive the bridle; for which purpose they are thrown on their back, and a slit is made through the septum, or cartilage between the nostrils, large enough to admit a finger. In this hole is thrust a strong stick stripped of its bark, and having, at one end, a forked branch to prevent its passing through. To each end of it is fastened a thong of hide, of a length sufficient to reach round the neck, and form the reins;
and a sheep-skin, with the wool on, placed across the back, together with another, folded up, and bound on with a rein long enough to pass several times round the body, constitutes the saddle. To this is sometimes added a pair of stirrups, consisting only of a thong, with a loop at each end, slung across the saddle. Frequently the loops are distended by a piece of wood, to form an easier rest for the foot. While the animal’s nose is still mounted and put in training, and, in a week or two, is generally rendered sufficiently obedient to its rider. The facility and adroitness with which the Hottentots manage the ox, have often excited admiration. It is made to walk, trot, or gallop at the will of his master; and, being longer-legged, and rather more lightly made than the ox in England, travels with greater ease and expedition, walking three or four miles in an hour, trotting five, and galloping, on an emergency, seven or eight.

In some parts of Central Africa the ox is employed in like manner. Major Denham gives an account of its use in the central countries which he visited:—“The beasts of burden,” he observes, “are the bullock and the ass. A very fine breed of the latter are found in the Mandara valleys. Strangers, and chiefs in the service of the sheik, or sultan, alone possess camels. The bullock is the bearer of all the grain and other articles to and from the markets. A small saddle, of plaited rushes, is laid on him, when sacks, made of goat-skins, and filled with corn, are lashed on his broad and able back. A leather thong is passed through the cartilage of his nose, and serves as a bridle; while, on the top of the load, is mounted the owner, his wife, or his slave. Sometimes the daughter or wife of a rich Shouma will be mounted on her particular bullock, and precede the loaded animals, extravagantly adorned with amber, silver rings, corn, and all sorts of finery; her hair streaming with fat; a black rim of kohal, at least an inch wide, round each of her eyes; and, I may say, arrayed for conquest at the crowded market. Carpet and robes are then spread on her clumsy palfrey; she sits jaube de ca, jaube de là, and guides her animal by the nose. Notwithstanding the peaceableness of his nature, her vanity still enables her to torture him into something like caperings and curvetings.”

**CATTLE OF SOUTH AMERICA.**

The ox was one of the first of the domestic animals carried over to America by the early Spanish settlers; and there it has multiplied and spread, and indeed, in some degree, recovered its original independence. Herds of wild oxen roam the Pampas, where they are hunted and slain for their hides, which form an important article of commerce. These wild herds are, in some districts, exceedingly numerous, differing in no respect from their domestic relatives, and rendered tame without much difficulty. According to Azara,“Captain John de Salazar, born in the city of Poma in Aragon, transported, from Andalusia, seven cows and a bull to the coast of Brazil; thence he conducted them overland to the river Paraíba, at the place opposite to where it receives the river Mondai. He there constructed a raft; placed the cattle on it, and gave them in charge to a certain Gaété, whilst he, himself, went by land to Paraguay. Gaété descended the Paraíba, to its union with the river of Paraguay, and, steering up this, he safely arrived at the city of Assumption in 1586. He spent many months in this voyage; and as he had only one cow given him for payment, the saying has hence arisen, in allusion to the great value of anything—‘It is dearer than Gaété’s cow.’ The second founders of Buenos Ayres took, in 1580, some cows from Paraguay, which multiplied in the neighborhood; and, from want of due care, many of them became wild, and bent their course towards Rio Negro. The Indians of the Cordillern of Chili became acquainted with these animals, which had already attained their boundaries; and they commenced to carry from them herds of tamed cattle to Chili, where the presidents of this settlement purchased them from these Indians. Those Indians, who could not live in their country without some resource, established themselves in the plains which were occupied by these cattle, and some even mixed with the Pampas’ Indians. In the meantime, the Indians, who were unsubdued, destroyed the cattle to the south of Buenos Ayres. The Spaniards of those parts, however, did not neglect to take a portion, which they conducted to Cordova and Mendoza; whilst the Spaniards of Buenos Ayres made up entire cargoes of the hides of bulls and cows; for, at
that time, the animal itself was not considered of value, its skin being all that was sought after. The result of all this was, that, towards the middle of the century, wild cattle no longer existed in the Pampas; and the unsubdued Indians saw themselves under the necessity of stealing the domestic animals, or of making incursions into the estancias of the Pampas. This was the commencement and cause of the bloody war which the Spaniards had with the Indians. The herds of these revolted or wild cattle, which are also called oreillards in the plains of Monte Video, do not pass to the north of the southern establishments of the Guaranis' Missions. The following is the account which I have collected of their origin:—The city authorities of Buenos Ayres, in the name of certain of its inhabitants, as is proved by its archives, made, at the commencement of the century, contracts, on the one part, with the English, for the acquisition of Negroes; and, on the other part, with certain Spaniards, who were thus authorised to procure the hides of the animals on the plains situate to the north of the Rio de la Plata, on payment to the city of a certain tax, of which the sum total was shared between these Spanish inhabitants, who, from this circumstance, were called Actionnaires. The primitive source of this right, or this proceeding, is not known; but certain it is that all the inhabitants did not participate in it, and that the produce was the exclusive share of these Actionnaires, who were the descendants of the earliest of the original settlers. Such is the origin of the horned cattle of these countries, where they prodigiously multiplied. About eight hundred thousand ox-hides are annually exported from Buenos Ayres and Monte Video to Europe." Mr. Darwin states, "that, from the latter place, the annual exportation is three hundred thousand; and the home consumption, from waste, very considerable. In order to obtain these hides, some horsemen join together, and arrange themselves in two ranks which form an angle. They then press on the two sides a small number of cattle; and one of the horsemen, who goes last in the angle, hamstrings the animals with a knife, in the shape of a crescent or half-moon, fastened at the end of a staff. While this goes on, the horsemen continue to ride forwards; and when they have thus secured a sufficient number of animals, they retrace their steps; and the person who hamstring them gives each beast thus maimed a finishing stroke with a sharp spear, and the horsemen dismount to strip the carcass, sometimes of the fat and suet, but always of the skin: this they do with such dexterity, that some men, without assistance, will strip twenty-six cattle at a day's work. When a single head of cattle is to be killed for the sake of its flesh, a horseman throws a lasso over its horns or neck, and another does the same over one of its feet; then straining in opposite directions, they prevent it from struggling free, and so strangle it. Admirable is the dexterity with which, when the animals pass as they rush forwards, the lasso is thrown, so that, directed backwards under its feet, the animal, at the pleasure of the horseman, is entangled either by one foot or by two together." It is a singular feature in the history of the New World, that so many of our domestic animals there imported, should have returned to their primitive independence: the ox, the horse, the hog, the ass, the rabbit, the cat, and the dog, have thus estranged themselves from the control of man. Individuals have, at different times, escaped from confinement, or been neglected; a vast region lay before them, presenting abundance of food; they multiplied, and their offspring in turn; and thus, within a brief period, have the plains of the New World been peopled by alien races of animals, which claim Asia or Europe as their starting-point.

CATTLE IN THE ISLANDS OF THE SOUTH PACIFIC OCEAN

America is not the only portion of the globe to which, by the agency of man, in modern times, the ox has been introduced. We allude to Australia, New Zealand, and the groups of islands which sprinkle the Pacific Ocean. "With the appearance of Vancouver," says Otho von Kotzebue, speaking of the Sandwich Islands, "arose the fortunate star of these islands. Among the innumerable benefits he conferred upon them, they are indebted to him for the possession of sheep and cattle. Tanacama (the native king) declared these animals under a tabu for ten years, which allowed time for so large an increase, that they now run wild in the forests." Of the benefits resulting from the introduction of
the ox into a country naturally destitute of it, nothing need be said; but the gift of cattle to a people who, though yet uncivilised, are still capable of appreciating their value, is to commence a revolution in their state and condition, immeasurably for the better: for the possession of property is one of the bonds of society; and the desire of acquiring it, the great stimulus to industry. With the introduction of the ox, the condition of the people of these islands has necessarily been improved. Not only has cattle been reared for home consumption, but for supplying the ships that navigate these seas (whalers, &c.), other valuables being given in exchange. Hence has the rearing of cattle been generally undertaken. This, of course, involves care and attention, and a state of peace: but agriculture and commerce follow, and prepare the way for the arts of civilised life.

CHAPTER II.

BRITISH BREEDS OF CATTLE.

THE WILD WHITE CATTLE OF CHILLINGHAM PARK.

(Bos Taurus, var. Scoticus). Having merely alluded to this beautiful breed of cattle, we will here resume the subject, and lay before the reader a few interesting details respecting its history.

Mr. Youatt, in his admirable work on cattle, in the Library of Useful Knowledge, clearly expresses his belief in the identity of this wild breed with our domestic races; and adds, that the slightest observation will convince us, that the cattle in Devon, Sussex, Wales, and Scotland, are essentially the same breed changed by soil and climate, yet little changed by the intermeddling of man. "Every one who has had opportunities of comparing the Devon cattle with the wild breed of Chatelherault Park, or Chillingham Castle, has been struck with the great resemblance in many points, notwithstanding the difference in colour." In another place, the same writer says—"To the Principality we naturally look for some trace of the native breed of cattle, for the Welsh were never entirely subdued by any of the early invaders. The Romans possessed merely a portion of the country; the Saxons scarcely penetrated into Wales, or not beyond the county of Monmouth. The Welsh long resisted the superior power of the English under the Norman king; and it was not till late in the thirteenth century that the Principality was annexed to the crown of England. We therefore expect to find more decided specimens of the native productions of our own islands; nor are we altogether disappointed. Howell Dina, or Howell the Good, describes some of the cattle in the tenth century as being white, with red ears, resembling the wild cattle of Chillingham Castle. An early record speaks of a hundred white cows, with red ears, being demanded as a compensation for certain offences against the princes both of North and South Wales. If the cattle were of a dark or black colour, a hundred and fifty were to be presented. When the Cambrian princes did homage to the king of England, the same number of cattle, and of the same description, were rendered in acknowledgment of sovereignty. Speed tells us, that Maud de Breos, in order to appease King John, whom her husband had offended, sent to his queen a present, from Brecknockshire, of four hundred cows and a bull, all white, with red ears. Whether this was the usual colour of the ancient breed of Welsh and British cattle, or a rare variety esteemed on account of its beauty, and chiefly preserved in the parks of the nobles, we are unable to determine. The latter is the most probable supposition; and the same records that describe the white cattle with red ears, speak also of the dark or black
coloured breed which now exists, and which is general throughout the Principality." As a further point, in favour of the probability of the white wild cattle being specifically the same as our domestic races, we select the following quotation from the work before referred to:—"The colours of the improved short-horns are red or white, or a mixture of the two, combining in endless variety, and producing, very frequently, a most brilliant effect. The white, it is very probable, they obtained from an early cross with the wild breed; and whenever this colour shows itself, it is accompanied, more or less, with a red tinge on the extremity of the ear—a distinctive character also of the wild cattle."

Are, then, the wild cattle of Chatelherault Park, Lanarkshire, or Chillingham Park, Limehall, Cheshire, and other places, the descendants, as Mr. Youatt seems to infer, of these white cattle of ancient race, so valued in early times? or are they descendants of the wild breed which, at an early period, tenanted the great forests of our island; and which, as the forests became cleared, and the land cultivated, were gradually thinned, till, at length, their remnant found, in the chase or park of the nobleman, that safety which, as old denizens of the soil, they might well claim; and but for which, the breed would long since have been utterly extinguished? Again, was the wild breed which roamed the Caledonian forest, and the great forest north of London, so late as the latter part of the twelfth century, and mentioned by Fitzstephen, identical with the white Cambrian breed? These are questions more easily asked than solved. One thing is certain—the wild cattle of Chillingham will breed with the domestic race; but the progeny has never been preserved, the calves having been always killed at an early age, from a pardonable desire to keep this ancient race in all its purity. We firmly believe, however, that the cross breed would be as fertile as any of our domestic varieties.

The author of the article "Bos," in the British Cyclopædia, is of opinion that the white cattle in question are domesticated oxen which have run wild; and, moreover, that they are not descended from an aboriginal stock, but that the race was originally imported by the ecclesiastics from Italy, where herds of wild cattle, much resembling them, still exist. In this, as in all other theories, authenticated facts, as our basis, are wanting. The Chillingham wild cattle are invariably of a creamy-white colour, with a black muzzle; the whole of the inside of the ears, and the tip externally, are red; the horns are white, with black tips; very fine, and bent upwards. Some of the bulls have a thin upright mane, an inch and a-half, or two inches long. The weight of the oxen is from thirty-five to forty-five stone the four quarters (fourteen pounds to the stone); that of the cows, from twenty-five to thirty-five stone. The beef is finely marbled, and of excellent flavour. These cattle are fleet and active. "At the first appearance of any person they set off at full gallop; and, at the distance of about two hundred yards, make a wheel round, and come boldly up again, tossing their heads in a menacing manner; on a sudden they make a full stop, at the distance of forty or fifty yards, looking wildly at the object of their surprise; but, upon the least motion being made, they all again turn round and fly off with equal speed, but not to the same distance, forming a shorter circle; and, again returning with a bolder and more threatening aspect than before, they approach much nearer—probably within thirty yards—when they again make another stand, and then fly off. This they do several times, shortening their distance, and advancing nearer and nearer, till they come within such a short distance, that most people think it proper to leave them, not choosing to provoke them further."

The females hide their calves for a week or ten days, after birth, in some sequestered situation, and visit them two or three times a day. If any person approach the calves, they crouch close, like a hare in form, and endeavour to hide themselves; but, when roused, exhibit great fury, pawing, bellowing, and butting at the intruder. The females are resolute in the defence of their young, and attack persons discovered near their lair with impetuous ferocity. Formerly the hunting of these animals was conducted with great parade, many scores assembling on horseback, and hundreds on foot, to witness the sport; but, from the number of accidents that happened, and, perhaps, from the disturbance created among the game, this practice has been long discon-
tined. The keeper now uses a rifle, and steals upon the animal selected, until within range, and drops it at a single shot.

ENGLISH DOMESTIC CATTLE.  

(Bos Taurus). To describe the form, contour, and colour of the domestic ox is superficial; and it is generally known that, within the precincts of our fertile island, affording unequalled pasturage, the animal has ramified into many breeds, which it has been the care of the farmer to improve and modify to his own advantage. Excepting in a few districts, the ox is not employed in our country as a beast of draught, or for the labour of the plough, as it was, in ancient times, on the continent, and still is in many countries. On the contrary, it is for its flesh on the one hand, and for the milk of the cow on the other, that this animal is so valuable. Indeed, everywhere the true importance of the ox is in itself, and not its labour; though, in many parts of the world, it is used both as a beast of burden and draught. Restricting our present observations to British cattle, we may observe, that there are two parties immediately, and, we may say, professionally, interested in the culture of cattle—the grazier and the dairy farmer; and both require different, and, to a certain degree, incompatible excellences. With the grazier, roundness of form, a moderate smallness of bone, depth of chest, and an aptitude to acquire external fat upon a small consumption of food, are among the points of excellence aimed at and expected. On the contrary, the supply of a large quantity of rich milk, is the desideratum of the dairy farmer; and it very seldom happens that the qualities prized by the one party, are combined with those required by the other. Both, therefore, attend to their exclusive interests, agreeing only in the care bestowed upon the animal subservient to their respective purposes. To note every variety, and enter into minutiae—the part rather of the farmer than the naturalist—is far from being our object; a sketch, however, of some of the principal breeds will not be uninteresting, and must necessarily find a considerable space in a work of this kind.

OLD BREEDS.

Among the older breeds was a long-horned race, now greatly modified, of which Lancashire and the West Riding of Yorkshire might be considered as the central district; whence it extended—not to the exclusion of other races—through the midland counties, and even into Ireland. This breed was termed the Craven, from a district of that name in Yorkshire, bordering upon Lancashire, where it is said to have originally appeared. It was large, coarse-boned, and apt to be long in the body, which, besides, was destitute of roundness. The milk, if not abundant in quantity, was extremely rich, and suited the purpose of the dairy farmer. The horns were of enormous length; sometimes they projected horizontally on each side of the head; generally, however, they swept downwards, with an inward flexure, often reaching below the level of the muzzle, or even meeting before it, so as to interfere with the facility of grazing. Indeed, the points often press against the sides of the muzzle, rendering it necessary to shorten them. In the beginning of the eighteenth century, various agriculturists commenced a series of attempts towards the improvement of this old breed, which resulted in the establishment of the Dishley, or new Leicester long-horn. To the grazier the improvement was most immediately beneficial, but the dairyman preferred the old stock. In process of time, however, the new breed extended, improving the cattle of the middle and northern counties, and especially of Ireland. In its turn, however, this breed has almost everywhere yielded to a middle or short-horned race; and even in Leicestershire, the stronghold of the Dishley breed, few are now to be seen. In Cheshire also—which, till recently, retained a long-horned breed, derived chiefly from the old Lancashire and new Dishley stocks—the Durham or short-horned race has made decided inroads, but with doubtful advantage as respects the quality of the cheese for which that county is celebrated.

THE LEICESTERSHIRE BREED.

The old long-horned breed of this county was endeavoured to be improved by Mr. Bake-well, who here prosecuted his experiments; and, although he was successful in removing the coarseness which characterised these animals, and increased their fattening capabilities, he failed in either improving or establishing
CATTLE, AND THEIR VARIETIES.

THE CHERISHIRE BREED.

This breed is becoming rapidly extinct. The old breed of Cheshire was a long-horned variety; but the dairy system, introduced into the vicinity of large towns by the growth of their populations, has brought the short-horned cow of Yorkshire into competition with some native breeds. The quantity, rather than the quality, of the milk they produce, has been with them the great object of consideration; consequently, the character of the Cheshire cheese has been deteriorated in the markets. Another reason why the short-horned cattle have risen higher in estimation in this county than in others, is the care which is taken to prevent their exposure to atmospheric changes, and also to the enriching of exhausted grass-lands by manuring them with bone-dust. This sort of manure so improves these lands as to give great advantage to an animal requiring a good quality, as well as a fair quantity, of provender, both of which are requisite for the short-horns. Mr. Palin, in his Prize Essay on the Yoming of Cheshire, observes—"Doubts, I believe, exist in the minds of some intelligent farmers, whether any improvement has been effected in the milking properties of dairy cows, as regards quality, by the introduction of the improved short-horns amongst them. That the latter breed is much disposed to fatten, is admitted; but this class of cattle does not stand very high in public estimation as milkers. It may, therefore, be reasonably supposed that there are good grounds for thinking that it is very possible to introduce too much of the improved short-horn blood into the dairy stocks, and that great caution should be taken in crossing. However this may be, I am of opinion that an improvement may be effected by the introduction of the blood to a certain extent; care being always taken to select male animals intended to be reared from the best milkers."

THE DORSETSHIRE BREED.

It is to be expected that, in most dairy districts, a large milk-producing animal will take precedence of one which may have a more beautiful form, or be a better taker-on of fat. This is the case in Dorsetshire; and hence, an ill-formed, and somewhat coarse breed of cattle prevails throughout the county. They belong...
to the long-horned breed; are chiefly of a rufous colour; large size, with flat chests and buttocks. Crosses with the Hereford, Devon, and Ayrshire breeds, have been endeavoured to be obtained from them, but without success. One Alderney, however, has been introduced to a dairy, for every ten or twelve of the native breed; and this has been found greatly to increase the quantity of cream, as well as to improve the quality of the butter.

Crosses, or breeds more or less distinct, prevail in every dairy district of this county; but it is unnecessary to specify them here, as it would only be merely a repetition of the same thing over and over again. There are other breeds, however, of a more specific character which merit our attention.

THE SHROPSHIRE BREED.

Among the long-horned race must be reckoned the old Shropshire breed—a large-boned and hardy race, well fitted to serve the dairy. It would appear that this breed is seldom to be seen pure, having been crossed with advantage by the short-horned Holderness. In Staffordshire, the old long-horned breed has been, in most parts, superseded by short-horned cattle. It still, however, maintains its ground in the north of that county, more particularly along the banks of the Trent and the Dove, close to the borders of Derbyshire. Between the long-horned and the short-horned races of our cattle, intervenes a race termed "middle-horns," represented by the North Devonshire, Somersetshire, Herefordshire, Gloucestershire, and Sussex cattle.

THE DEVONSHIRE BREED.

This breed is of great antiquity, and has been long celebrated for beauty. Like most of our other breeds, it has become improved during the last fifty or sixty years, and has, perhaps, now attained to its perfection. The head of the Devon ox is small, but broad across the forehead, and narrow at the muzzle; the horns curve gracefully upwards; the chest is deep, and the back straight. The cow is small, compared with the bull. Thus, then, physiologically speaking, the breed is well formed, and it is of very long standing. In disposition the whole race is docile and tractable, gentle and patient; whilst they are very hardy, considering the mild and humid nature of the climate in which they subsist. They are not, however, very famous for their milk-producing qualities; nor, if early fat is the grazier's object, are they very extraordinary feeders. Still they will feed, and attain to a considerable size. At some periods of their growth they produce a class of beef of fair quality. Red, and nothing but red, is a sine qua non in a Devonshire ox. He has a moderately straight top, and a somewhat thin skin, covered with curly hair. The rump is narrower than that of the short-horns, and the crop lighter and flatter; but the brisket is large and full, the legs fine, the shoulder slanting, and the neck long and thin. He is what would be denominated, in the short-horn districts, a "shelly" animal, and cannot be pronounced a good grazer. As a draught animal, however, he stands very high. The cow is not a good milker. A short-horn breeder speaks very prejudicially of this breed. He thus describes the cattle at a fair in Devonshire:—"With the exception of one animal, I did not see a level carcase; but a want of beef in the roasting parts; low and poor loins, coarse shoulders, bad twist (thighs), and a general want of indications of inside proof." Of the beef, when killed, he says—"The meat was actually running about the stall, being nothing more than a mixture of flabby masses, deficient of fineness of texture and quality." Mr. Parkinson, in his invaluable and practical Treatise on Live Stock, mentions that a thin hide in the Devons is not quite a recommendation. He gives the weight of some specimens of six-year-old cattle, which weighed some fifty-seven stone, two pounds; but the cows much less. He says of them—"On the whole, they must be allowed to be good cattle for their soils, and particularly where oxen are worked at the plough. When slaughtered, they are a sort of beef that suits the consumption of many customers." Some have supposed that the Devonshire was the original breed of this island—a supposition which others have pronounced simply absurd.

The system of ploughing with oxen is very generally practised in Devonshire; and, where the land is not too heavy, no teams of oxen are superior, if equal, to them in this kind of work. It is, however, to the grazier, that
this breed is more especially valuable, for they will fatten, as we have said, and supply an excellent quality of flesh. Some farmers have found the North Devon to yield even a large produce of milk, so that, in this particular, much may depend on choice of pasture. In Somersetshire the Devon breed prevails; or at least the original breed has been greatly crossed by the Devon, of which it presents most of the excellences. The Somersetshire cattle are alike valuable for "the pail, the plough, and grazing." The tract of country between Bridgewater and Cross, produces cheese of well-known excellence; and the best Cheddar cheese is made either in that tract or the marshes round Glastonbury.

THE HEREFORD BREED.

The Hereford improved breed, with white faces, is valuable as fattening rapidly, and that on inferior food. The flesh is fine-grained, and highly prized in the market; but the cows yield a very scanty portion of milk. In Gloucestershire the Herefords are preferred for the teams, and by graziers for fattening; but the old Gloucester breed for milk. This old breed is of mixed origin, consisting of a race of Welsh descent, supposed to have been crossed by various other breeds; and among them the Alderney. The rich Vale of Berkeley produces the finest Gloucester cheese. The present breed is a middle-horned race, to the improvement of which much attention has been devoted. The success of short-horned breeders has caused a healthy emulation; and the difference between the Hereford cattle now exhibited, and those shown several years back, not only indicates judgment and skill in the breeds, but leads to the conclusion that the breed, in itself, has considerable fattening capabilities. The old Hereford was a deep-brown animal, sometimes with a yellow cast, free from white. An improved breed, however, now occupies the county, in which the prevailing colour is a dark red, with a white face, white belly, and not unfrequently a white back. The skin is less mellow and thicker than that of the short-horn; whilst the hair has neither the mossy softness, nor the graceful curl of the latter. The eye is full and lively; the chest deep and broad; the loins also broad; and the hips well expanded; a

level, broad rump, a round barrel, and full crop; full and deep flank, well ribbed loins; small bones, with clean and perpendicular thighs. The belly is almost parallel with the back, and the head is small. Colour and symmetry are perhaps the predominant qualifications which secure the high favour of the breeder of this race.

Whilst possessing all these excellences, however, the Hereford breed is destitute of those qualities which tend to produce early maturity and speedy fattening. It takes on flesh of a soft and mottled description on the best pastures; gets full in the siodon, rump, and crop; but it shows its beef all outside; and requires much more time to develop its proportions than the short-horned race. In milking qualities the cow is even behind the short-horn; and she must, in general, be three-and-a-half to four years old before she can be fattened with anything like decided success. The breed requires a rich pasture; and its average weight, when fat, does not exceed fifty-five to sixty-five stones. Herefordshire being more a breeding than a feeding county, the cattle are reared there, and sold off at three years old, and transported to the fatter lands of Leicestershire for the purpose of being grazed. Many of them are also sent into Northamptonshire, and other rich grass districts. But, with all their good qualities, it must be admitted that they require from ten to twelve months more to feed than the more favoured short-horn.

Much controversy has been carried on as to the merits of the two breeds—the short-horn and the Hereford. It must be admitted, however, that, while the short-horn has penetrated into the heart of Scotland and the south of England, and into the counties of Gloucester and Norfolk, the Hereford keeps its ground. A valuable breed of middle-horned cattle extends through South Wales; and of this the Glamorganshire variety is highly celebrated. The oxen are readily fattened, and the cows yield a fair quantity of milk.

THE GLOUCESTERSHIRE BREED.

This is more a mixture of the long-horn and middle-horn than any distinctive race—the old Gloucester cow being nearly extinct. The various crosses to which dairy cattle have been subjected, have obliterated all traces of the
original race; but early crosses with the long-horned breed have, to a considerable extent, prevailed. The Devons have also been used as a cross to render them more easy to fatten; and the Durham short-horns have also occasionally been tried; but the poverty of keep, allowed by the Gloucestershire dairymen to their cattle, has greatly tended to deteriorate the breed. The same fate has, in general, attended attempts to cross with the Herefords. Of the successful crosses adopted in this country, there was one made with an ordinary Gloucester bull and an Alderney cow. This obtained richness in the milk; when a Durham bull was selected, to increase the tendency to flesh and to size, and to improve the form generally. This gives a stock one-half Durham, while the other half is constituted of one part Gloucester and one-half Alderney. The average yield of an ordinary Gloucester cow may be reckoned at five hundred gallons of milk, yielding about twenty-four stones of single Gloucester cheese; the remainder of the milk being used in the family, and for fattening calves, or pig-feeding, which is largely practised in all dairy districts.

THE SUSSEX BREED.

The breed of cattle in Sussex closely resembles that of Devonshire. According to judges, it is intermediate between the Devon and Hereford; "having the activity of the first, the strength of the second, and the propensity to fatten, and the beautiful fine-grained flesh of both." Its colour is deep chestnut-red, or blood-bay; and a deviation from these colours indicates a cross. In the Weald of Sussex, oxen of this valuable stock are generally used for team-work; and so great is their strength and quickness, that many teams have been known to travel, with heavy loads, fifteen miles a day, for several successive weeks, without distress. The Sussex cow, like the Devon and the Hereford, is very inferior in size to the bull; and though the milk yielded is good, it is of indifferent quantity.

THE DURHAM, OR SHORT-HORN BREED.

The most extensively diffused breed of cattle in our island, and by far the most valuable, is that termed, by way of distinction, the Short-horned. Of this breed England may justly be proud, as it unites, as far as possible, every good quality. The form is admirable; the oxen fatten quickly, and often attain to an enormous weight, and the cows are excellent as milkers. It would appear that Durham, and some parts of Yorkshire, had long possessed a breed of short-horned cattle of large size, and celebrated for the quantity of milk yielded by the cows; but this breed, not only in figure, but in aptitude to fatten, and in the quality of the flesh, required great improvement—other races far excelling it in these points, so important to the grazier. This stock still lingers, and is certainly valuable to the dairy farmer, who might, however, substitute the improved breed for it with advantage.

It is about ninety years since the improved stock of this old, but really fine, breed began to be established on the banks of the Tees, owing to the judgment and care of the intelligent breeders of that district. It differs from the old short-horns in possessing a well-developed figure, and a more than ordinary aptitude to acquire fat. The first step of improvement, resulting from the practical knowledge of Mr. Milburn, and other coadjutors, opened the way for the successful exertions of subsequent spirited breeders, who, by pursuing a judicious plan in crossing, have brought the breed to the highest pitch of perfection. Among these crosses, it is supposed that the white wild breed has contributed a share; and to this circumstance is attributed the prevalence of white as a characteristic of the stock. In speaking of this breed, Mr. Milburn says, that these animals are supposed by some to be traced to Holderness; and, according to others, to have been imported from Holstein. From continental Europe they certainly appear to have sprung; and, being successively improved by a variety of breeders, they have ended in that distinct race of animals, extraordinary, beyond all others, for their astonishing propensities to feed. Others, again, refer their origin to a native race of cattle called the Teeswater, because they have, from time immemorial, inhabited the valley which the Tees has formed by its washings down of the mountain limestone rocks in which it has its origin. These, it is said, being crossed by the Holderness importations, gradually became a new race. The late Mr. Bates traces the short-horns to a breed in the possession of the Aslabys, of
Studley; and the Rev. H. Berry, to an improvement in the East Riding of Yorkshire, by the introduction of a breed from Holland by Sir W. St. Quintin, of Scampston. Of these originals of the short-horns, however, it is hardly necessary to say more than this—that a breed, from distant ages, inhabited the valley of the Tees, which, trained and educated to feed, for a vast succession of generations, on its fertile deposits, acquired the habit of speedy fat-forming. In these valleys, where hay alone will feed the largest ox, the production of fat would be so far an object, that breeders would always select the best and easiest feeding-animals; and thus the character of the district, through a number of centuries, might easily lay the groundwork of that improvement which the Millbanks, the Greys, the Booths, the Coates, and, above all, the Collings, effected. The description of the qualities of the modern short-horn is thus given by Mr. Dickson, an established authority. After referring to the general symmetry of the frame, and its delicate colour, either deep-red, cream-coloured, white, or delicate roan—the latter, by-the-by, the most fashionable, and, indeed, prevailing colour—he speaks of it as possessing "the mellowest touch, supported on small clean limbs, showing, like those of the greyhound and the race-horse, the union of strength with fineness, and ornamented with a small, lengthy, tapering head, neatly set on a broad, firm, deep neck; furnished with a small muzzle, wide nostrils, prominent, mild, beaming eyes; thin, large, velvety ears, set near the crown of the head, and protected in front with semicircularly-bent, white, or brownish-coloured, short, smooth, pointed horns. All these several parts combine to form a symmetrical harmony, which has never been surpassed, in beauty and sweetness, by any other species of the domesticated ox."

"Keeping in mind what has been stated to be the perfection of a fat animal, the same authority, speaking of the short-horn, says—"We have a straight level back from behind the horns to the top of the tail, full buttocks, and a projecting brisket; we have, in short, the rectangular form: we have also the level line across the hook-bones (hip), and the level top of the shoulder across the ox, and perpendicular lines down the hind and fore legs on both sides; these constituting the square form when the ox is viewed before and behind; and we have straight parallel lines from the sides of the shoulders, along the outmost parts of the ribs, and the sides of the hind quarters; and we have also these lines, connected at their ends by others of shorter and equal length, across the end of the rump and the top of the shoulder; thus constituting the rectangular form of the ox when viewed from above down the back."

The weight which many of these animals attain is surprising; whilst the prices which some of them have fetched, and still fetch, is equally astonishing. The Durham ox, a son of Charles Colling's Favourite, weighed 187 stones 2lbs. The Yorkshire ox, bred by Mr. Dunhill, of Newton, near Doncaster, weighed, when killed, 261 stones 13 lbs. These are weights of 14 lbs. to the stone, and include the wonderful capabilities to make fat and flesh possessed by this extraordinary race of animals. Though there is not, perhaps, another instance on record of any bull selling for so much money as Charles Colling's Comet, which sold for 1,000 guineas (which must be acknowledged to be a great price), yet £500, £600, and as much as £800, are still given for a first-rate short-horn bull. It is not, however, in rapid fattening qualities alone that this species excels; for it is unquestionably the most remarkable for attaining to an early maturity. The short-horns begin to develop their fat-forming powers even when calves. These powers seem to grow with their growth; and when only a year old, they have all the appearance of full-grown cows. This makes them early ready for the market; consequently their feeders, instead of keeping them to three, four, or five years of age, fatten and sell them off at from two to two-and-a-half years. They can thus turn off one-half more, at least, of beef from their farms or their stalls than could possibly be produced with any other breed. Thus they have quick returns, and large amounts of beef for the food-consumer. To accomplish this, however, care and good shelter are requisite. The cow needs nursing, and nourishing diet when young: but she repays all; for she is a cow when another is a calf. The ox is fat when the other is growing. She will purchase a horse before a Devon will buy a saddle. Hence, the short-horn stands the very first on the list of fat-producing breeds.

Among the most successful of improvers of
this breed was Mr. C. Colling, just spoken of; who bred the celebrated Durham ox, the produce of one of the ordinary short-horned cows, and a bull termed Favourite, of noble figure. At five years old, says the excellent author of the work on cattle, "the Durham ox was sold to Mr. Bulmer, of Harmley, near Bedale, for public exhibition, at the price of £110. He was at that time computed to weigh 168 stones of 14 lbs.; his live weight being 216 stones: this extraordinary weight did not arise from his superior size, but from the excessive ripeness of all his points." The Durham ox, in a short time, passed into the possession of Mr. J. Day, who travelled with him through the principal parts of England and Scotland, till at Oxford he dislocated his hip-bone, when he was obliged to be slaughtered; and, notwithstanding he must have lost considerably during eight weeks of illness, his carcass weighed—the four quarters, 165 stones 12 lbs.; tallow, 11 stones 2 lbs.; and hide, 10 stones 2 lbs. Among the most remarkable of Mr. Colling's experiments in breeding, was that of a cross between the improved short-horn and a polled Galloway cow, which, being interbred with the pure short-horned stock, gave origin to a breed called the Alloy—a term, at first, given by way of disparagement, but continued afterwards when the excellences of the breed were acknowledged. Some idea of its value may be formed from the fact, that at a sale of Mr. Colling's cattle, forty-eight animals (cows, bulls, year-old bull-calves, and heifer-calves) realised £7,115 17s. Of the Alloy breed, was the stock, or part of the stock, of the late Rev. II. Berry. The figure of the cows was excellent in every respect, and their milking quality is stated to have been by no means of inferior degree.

Among the most celebrated of the short-horned stocks of the present day, that in the possession of the late Lord Althorp, was one of the most distinguished. It was originally derived from the stock of Mr. R. Colling, and no pains were spared in bringing it to the highest excellence. A celebrated bull, belonging to this nobleman, and which is known under the cognomen of Firby, was regarded as a model of the breed. It is a peculiarity in this short-horned race, that the cows are excellent as milkers; and, moreover, that when dried, they fatten rapidly. The oxen, as it is acknowledged, are fit for the butcher at the age of two years; but this tendency to acquire fat renders them indolent workers, and more unfitted for the team than other breeds—a circumstance of little consequence, as cattle which are profitable to the breeder at two years old, and are as ready for the butcher at this age as those of any other breed at three, or even four, ought never to be submitted to the yoke. The bulls, indeed, being extremely docile, may be employed with advantage in many operations going on in every farm—a plan the more advisable as they are apt to acquire too much fat, which moderate labour would tend to diminish.

It must not be supposed that every breed of short-horned cattle is endowed with the qualities characteristic of the improved stock, which render it so valuable. There is, for example, a breed of short-horned cattle in Lincolnshire, with which the Smithfield market was wont to be abundantly supplied; but the cattle of this stock are by no means first-rate animals. The head is not finely modelled; the bone is comparatively large; the limbs high, and the hips wide. In many instances, the stock has been improved by admixture with more highly bred animals, and rendered valuable; but the flesh is not fine-grained. On the whole, these cattle are better adapted for the dairy farmer than the grazier, as the cows yield a fair quantity of milk.

THE YORKSHIRE COW.

This is a short-horned milk-producing breed, of great size, yielding milk in large quantities, and having a considerable aptitude to fatten. On this account it is chosen by the dairymen of populous towns and cities, especially those of London, for the supply of milk for a given period. Fattened on the refuse of the distillers, and such waste materials as large towns usually furnish, it doubly remunerates whatever care and attention the dairyman may bestow upon it. When fat, the Yorkshire cow will weigh from sixty to eighty stones. Her characters are thus given by Mr. Milburn:—"Her head is fine, and somewhat small; there is a serene placidity of eye, which shows a mild and gentle disposition, tending alike to produce fat and milk. The horns are small and white; the muzzle without black spots; the breast deep.
and prominent, but that and the shoulders thin; the neck somewhat narrow, but full below the shoulders, and without any loose skin; the barrel somewhat round; the belly capacious; milk-vein large; back perfectly straight; rump wide, and flat as a table; tail small, and set on so that there is almost a straight line from the tail to the head. The prevailing colour is roan, or red and white; and sometimes white, with the tips of the ears red. The thighs are thin; but the legs are straight and rather short. The udder is very large and muscular, projecting forwards, well filled-up behind, and so broad as to give the cow the appearance of a waddle in her walking. Indeed, her qualities are not inappropriately described in some doggerel lines often quoted; and two of the verses we shall venture to give, as most aptly descriptive of the Yorkshire cow:

"She's broad in her ribs, and long in her rump,
A straight and flat back without ever a hump
She's wide in her hips, and calm in her eyes;
She's fine in her shoulders, and thin in her thighs.

"She's light in her neck, and small in her tail;
She's wide in her breast, and good at the pail;
She's fine in her bone, and silky of skin;
She's a grazer's without, and a butcher's within."

The quantity of milk given by these cows by far exceeds that of any others, though less, perhaps, than that of some others in proportion to size. Mr. Milburn says that he has had instances where as much as thirty quarts per day, in summer, have been given. The distended udder has so swollen before calving—"wedged" is the local and technical term—that one was obliged to be milked several days before she calved; and, after calving, had to be milked three times a day, for fear of the consequences of an over-distended udder. Moreover, she gave a large quantity of butter as well as milk; and soon after calving she has given fifteen pounds per week. When the Yorkshire cow is purchased for the London dairies, it is generally after she has had her third calf, when the milk changes its character, and becomes less infused with butyrous qualities. This arises from her no longer having the run of her rich native pastures to graze upon. The object of the London dairymen, and those of other large towns, is not to improve the quality, but to increase the quantity, of the milk; and hence the animals are fed with brewers' grains, boiled linseed, &c., &c.; and the out-door exercise is restricted, so that their powers of secretion all converge to the production of milk alone. Considering all these things, and taking into account the carcass value of the cow after she has yielded her copious supplies of milk, it is not too much to affirm that there is no breed of the vaccine race so profitable as the Yorkshire cow.

THE ALDERNEY BREED.

Among the short-horned race must be enumerated that singular breed of cattle called Alderneys, which has gained, and deserves, a degree of celebrity from the peculiar richness of the milk afforded by the cows. These cattle were originally from Normandy and the islands on the French coast, from one of which (Alderney) they take their name. They are small in size, awkwardly shaped, with a peculiar bend in the back, and, in every point, more or less defective. The milk yielded is not great in quantity, but abounds with butter; and it is from its richness that these animals are favourites. Improbable as it might seem, from the appearance of the Alderney, its aptitude to fatten is remarkable. Even the cows, when dried, soon gain flesh, and will attain to considerable weight. It is chiefly in pleasure-gounds, and the paddocks attached to the houses of persons not engaged in farming for profit, that cows of this breed are to be seen. In Hampshire alone the Alderney breed is general, constituting the stock of the farmer. It would appear that it is more suited to the pasturage of that county than other vaccine animals which require richer grazing grounds, consume a large quantity of food, and return a disproportionate supply of milk.

The qualities of the Alderney breed being exclusively milk-producing, it cannot be expected that they will be remarkable for any great beauty of form. Indeed, until within the last thirty years, a more ill-formed animal could hardly be conceived. Its characters were large cheeks, thin, hollow neck, flat sides, hollow back, thin hams, long between hip and ribs, drooping rump, high shoulders, crooked legs, and tapering chest. Such were its characters; but, as amongst mankind, there is many a good head under an old hat, and many a white skin under a poor garb; so in the
ungainly form of the Alderney, there lurked qualities of excellence of the highest degree.

"The produce of these small animals, both in milk and butter," says Mr. Milburn, "is very great, and may be taken, in fair specimens, at twenty quarts of milk daily, and ten pounds of butter in the week, during the months of April, May, June, July, and August. Instances are recorded of cows giving twenty-six quarts of milk in the twenty-four hours, and yielding as much as fourteen pounds of butter per week! From this it is clear that the cream is of a very rich quality; the milk itself being superior to much of the town-made cream, and the cream almost resembling cream-cheese. It is considered too rich by many persons for making cheese; but instances are recorded of successful cheese-making from this milk. M. Le Fouve, of Le Hogue, succeeded in making cheese of a very superior quality from this fine milk; equal, indeed, to double Gloucester. Fourteen quarts of milk being capable of producing a pound of butter, the same quantity would give a pound and a-half of cheese; and the whey, or drainings, of twenty pounds of this cheese, would produce four pounds of butter, somewhat inferior for toast, but quite adequate for the making of pastry. Compared with the milk of any other cows celebrated for dairy purposes, that of the Alderney is very superior. An experiment was made, in the months of May, June, July, and August, between eight Alderneys and eight Kerry cows. In the first month, the Alderneys gave 25 per cent. of cream, against 10 per cent. of Kerrys; in June, 20 per cent. against 10; in July, 23 per cent. against 10; and in August, 16 per cent. against 13; giving an average of about 100 per cent. more cream than the Kerrys—a race of cows rather celebrated for dairy qualities. But this was not all. Three pints of cream from the Alderneys produced 1 lb. 8½ oz. of butter; from the Kerrys, 1 lb. 4½ oz. This, too, was taken in the month of August, when it will be seen the milk of the Alderneys was falling off. The experiment was made by Mr. White, on the farm of the Hon. R. Clive, of Oakley Park, and deserves every credit, as it seems to have been carefully made." These facts sufficiently establish the great value of the Alderneys.

SCOTTISH KYLOE BREED.

With respect to other breeds of which we have as yet said nothing, we may observe, that in the Highlands of Scotland, a race of small black cattle prevails, of which large herds are driven southwards, and departed in the grazing-lands of England. Of these, numbers are brought to the London market. Many varieties of the race exist. Among them we may particularise the Kyloes of the Western Islands and the Hebrides—small, but hardy and well-formed cattle, thriving on coarse fare, and producing fine-grained and high-flavoured meat. The different islands of the Hebrides contain, says Mr. Youatt, "about one hundred and fifty thousand of these cattle, of which it is calculated that one-fifth are annually sent to the mainland, principally through Jura, or across the ferry of the Isle of Skye. If these average about £5 per head, the amount will be £150,000, or more than the rental of the whole island, which Mr. Macdonald calculated at £106,720, but which now produces a greater sum. Cattle, therefore, constitute the staple commodity of the Hebrides. Some thousands are annually exported from the island of Islay alone."

The cattle of this breed are so called from the fact of their having crossed the Kyloes, or ferries, with which the Highlands of Scotland abound. They formed the models which Bake- well had in view when endeavouring to improve the Leicestershire breed; and had he been better acquainted with them in the early stages, they might have taken their part in the crossings which were made with the view of improving the Dishley herd. They may be esteemed the finest breed of the largest middle-horned race, being possessed of long rumps, loins, and crops, with but a moderate amount of offal. As length in these parts is generally connected or associated with thinness of chest, buttocks, and neck, it is not unlikely that improvements in this direction would enable the dairymen to obtain a rich milk-secreting animal, with considerable aptitude to fatten and form flesh on the most valuable parts, when she passed from his hands into those of the grazier.

The Kyloe cow is of a wild disposition, which is, in a great degree, counterbalanced by
her hardihood, as she can resist an atmosphere beneath the storms of which a delicate lowland animal would succumb. Her living, too, is extremely hard. It consists of the patches of short grass which she gathers among the heath, moss, and even sometimes sea-weed. In winter, when even this sort of provender is scarce, Kyloe are sometimes assisted with a few oatmeal balls, which, if they have any reflective instincts, they must consider as a sort of providential dispensation. From such kind of feeding much produce is not to be expected; consequently, the supplies of both butter and cheese are miserably small—thirty-two pounds of the former, per annum, is the produce of one Hebridian cow. Of the latter, from ninety to one hundred pounds is the average yield, and this is finely flavoured with aromatic herbs, peculiarly agreeable to the palates of many individuals.

**ARGYLESHIRE CATTLE.**

In the north of Argyleshire, the cattle are larger than those of the Hebrides, and are bred to the full size which the pasture will admit, and the good qualities of the animal bear, without deterioration. It is in this district that the most perfect Highland cattle are to be frequently seen. The animals are compactly built, short, and rather strong in the shank; straight in the back; with a fine muzzle; and small sharp horns. As they wander over a wild country, they are themselves wild, and often fierce, and their eye expresses energy and spirit. It is solely for their flesh that herds of them are reared. "Every effort," says Mr. Youatt, "to qualify them for the dairy, will not only lessen their hardihood of constitution and propensity to fatten, but will fail in rendering them valuable for the purpose at which the farmer foolishly aims."

**THE HIGHLAND SCOT.**

The Highland Scot belongs to a long-horned breed, and stands next to the Hereford as a fattening animal; and where both the Hereford and the short-horned races would die from absolute starvation, it will clothe its loins with flesh, and look as comfortable as if it were the finest-fed quadruped in the land. Like all mountain races, the Highland Scot delights in freedom. To browse on the side or the summit of the hill is, to him, like "a joy for ever;" whilst his eminently gregarious habits force him into the bovine society of his neighbours; so that, if he has any cares, he lightens their weight by the pleasures of association. Although he is extremely hardy, his size is rather small than large; and his usual colour is a light dun, or a jet-black, rarely with white on any part of the body. His horns are long, and have an upward and outward turn. His skin is covered with a sort of fleece rather than hair, being long and soft, with a strong inclination to curl. He takes on his beef principally on the back, which is therefore straight, while his body has a considerable degree of rotundity. It is not the least of his peculiarities that he obtains, from the surface of the sterile mountain, as much grass as he can fatten upon; or, at all events, preserves himself in good living condition. If he is indulged and tended with some little care, he increases in fat very rapidly, and repays his breeder by the excellence of his beef. Under such circumstances, the Highland Scot will weigh from forty-eight to fifty stones, and some have even attained to the weight of seventy. There are special exceptions, however, to this rule. The Duke of Northumberland had a very promising Argyleshire "stot," or bullock, which he kept as long as he could, to see what he would weigh. He was five and a-half years old, and weighed, exclusive of offal, 100 stones 4 lbs. Though, perhaps, one of the heaviest of the breed ever slaughtered, he was neither the fatest nor the most inactive, but seemed, in that state to display all the activity possessed by his race whilst wandering over their native hills.

The rearing of this animal was by no means remarkable for its extravagance. In the first winter he was turned out to a poor pasture, and had a little bad hay, till summer returned, when he had again poor land pasture. The next winter he was turned again to the same kind of pasture, which was, however, varied with a few turnips. During the following summer he had average pasture, and the same pasture in winter, with a more liberal allowance of turnips. The third summer he was tolerably well grazed; and in the fourth winter he had as many turnips as he could eat in the sheltered straw fold. In the summer in which he was fatted, he had all the indulgence of a feeding
animal—viz., cut clover, mangel-wurzel, hay, bean-meal, turnips, and a little oil-cake, for which he had no relish whatever. Mr. Quarl says of this animal, that his "fat was distributed in an uncommonly equable manner, of a colour resembling the finest grass butter, and as firm as wax; the lier (muscle) was in ample proportion, bright in colour, of fine texture, and beautifully marbled by admixture of his excellent fat."

THE ABERDEENSHIRE BREED.

The Aberdeen "Doddies," as this breed are called, are a polled, or hornless race; and being bad, or, at least, very indifferent milkers, they are usually passed over to the grazier, and highly fattened in their native county. They are also purchased by the Norfolk and Leicestershire grazier for the purpose of high feeding, and attain the weight of eighty, and even one hundred stones, when five or six years old. Like all the hardy Scotch cattle, they form their flesh on the back. Their colour is generally black, but sometimes red; the head is fine; the eye full and clear; the breast deep; and the back not quite straight, being somewhat depressed at the loin, and inclining to be narrow.

THE GALLOWAY BREED.

In the stewartry of Kirkcudbright, together with part of Ayrshire and Dumfries, forming the old province of Galloway, a beautiful polled or hornless breed of cattle exists, highly esteemed for many excellences. In figure they are admirable, excepting that the neck of the bull is almost too thick; but the chest is deep, the limbs clean and short, the back straight, and the body round. Black is the prevailing colour. These cattle exceed the Argyle breed in size. They fatten well and quickly, and their flesh is excellent. "Few cattle sell so high in the London market; and it is no uncommon thing to see one of these little bullocks outsell a coarse Lincolnshire bullock, although the latter is heavier by several stones." The Galloway cattle are remarkable for gentleness; and robust and muscular as the bulls are, one of mischievous habits and bad temper is seldom met with. In the *Cyclopaedia of Agriculture*, edited by Mr. Morton, we find it stated that the Galloway is some-
times called a Kyloe without horns, from the great resemblance which these animals bear to each other. The Galloways, however, have already had to yield to the short-horns in those parts of their native district where the turnip husbandry can be prosecuted to advantage; while the Ayrshires have justly supplanted them for the dairy; but, in those parts where the rearing of grazing-cattle is found the more suitable practice, they still reign unrivalled, and should be carefully preserved as a distinct breed.

THE AYRSHIRE BREED.

This valuable breed of middle-horned cattle exceeds, perhaps, any breed of dairy-fed cows in the kingdom; but they are small in size, and unsymmetrical in their forms. Their milk is extremely rich, though somewhat oily in its nature. They fatten more rapidly than many other races of cattle; for, when the butyraceous deposit is stopped by drying, the system soon accustoms itself to secrete fat, which they acquire on a pasture inferior to that required by more tender animals. They are, however, in small estimation with the grazier, although, when the cow is coupled with a short-horn bull, a valuable grazing animal is produced. Many farmers in the west of Scotland practise this successfully on a large scale.

There is no description of the race equal to that given by Mr. Aiton, whose work on *Dairy Husbandry* so far exceeds any other, that it is generally quoted, even at the present day:—"Head small, but rather long and narrow at the muzzle; the eye small, but smart and lively; the horns small, clear, crooked, and, at their roots, placed at a considerable distance from each other; neck long and slender, tapering towards the head, with no loose skin below; shoulders thin; fore quarters light; hind quarters large; back straight, broad behind; the joints rather loose and open; carcase deep, and pelvis capacious, and wide over the hips, with round fleshy buttocks; tail long and small; legs small and short, with firm joints; udder capacious, broad, and square, stretching forward, and neither fleshy, low hung, nor loose; the milk-veins large and prominent; teats short, all pointing outwards, and at a considerable distance from each other; skin thin and soft; hair soft and woolly. The
head, bones, horns, and all parts of least value, small; and the general figure compact and well proportioned." Such is Mr. Aiton's description; but, with the exception of thickness of buttock, it will be inappropriate to the present Ayrshire cow. There are two other characteristics which seem so thoroughly belonging to this breed, that they ought not to be passed over. The one is the black muzzle, and the other the yellow red, which seems to be the natural colour of the race—arranged, not in considerable quantities, but in blotches or patches. Thus the animals generally present a sort of checked aspect of golden yellow, red, and white.

The milk and butter yielded by the Ayrshire cow are very considerable. Indeed, to develop her milking qualities the greatest pains have been taken in her native county. An Ayrshire cow will give from 600 to 500 gallons of milk in the course of the year; and five gallons per day is by no means uncommon for three months after calving. This, however, falls short of Colonel Fullarton's estimate, in his Agriculture of Ayrshire, where, it is affirmed that, though the Ayrshire cow will not, when fat, weigh more than twenty to forty English stones, "it is not uncommon for these small cows to give from twenty-four to thirty-four English quarts of milk daily during the summer months, while some of them will give as much as forty quarts."

It is found that three gallons and a-half of such milk will yield a pound and a-half of butter; so that as much as 260 pounds of butter will be produced by an Ayrshire cow; and it is no uncommon thing to have eight or nine pounds given by one of these cows for some weeks after calving. About twenty-six gallons of milk will afford fourteen pounds of cheese; or a good cow will yield thirty-five stones of cheese per annum.

A question has been raised, as to whether the rich districts of Ayrshire ought to be occupied by this breed of cattle, as they are supposed to be better adapted to the means of the cotter than those of the grazier. To this it has been replied, "that while the cold rains, so prevalent in that county, would render it problematical whether the short-horns would be sufficiently hardy, it is also certain that the second-rate pasturage of much of the grassland is more suitable for the dairy cow, possessing the hardiness of the Ayrshire breed, than calculated for fattening the less enduring short-horn." Whatever attempted improvements which have been made in the Ayrshire breed, they have not succeeded in enhancing their milking qualities. To breed what would sell in England, and what would feed as steers, has been an object pretty generally pursued; and, as the larger breed of Ayrshire cattle are more profitable for the market than the smaller, which are more suitable for the dairy, the former have been more encouraged.

The difficulties which present themselves, in endeavouring to settle the origin of the different species of our domestic animals, are very great. It is hardly possible to believe that the long-horned Craven cow and the polled Angus, the gentle, quiet short-horn, and the wild and ferocious breed of Chillingham, can be of the same origin. The question is, however, one of great latitude, and takes by far too wide a range to be here discussed; but there does not seem any reasonable doubt for the fact, that, within certain limits, circumstances alone will have a great tendency to change the conformations and characteristics of a species. Thus, in cold countries, white predominates over other colours; and wool or fur is the species of covering with which nature clothes the animals. In hotter climates, brown is most prevalent, and hair takes the place of the wool and the fur. In tropical countries, the dun hue obtains, and down spreads itself over the bodies of the brute creation. "So easy is the adaptation of organised beings to the state in which they are placed," observes a writer on this subject, "and so vast is the expandibility of nature, that she can extend, or shorten, or increase, or diminish conformation, so as to render it suitable to the wants, the happiness, and the existence of the animal. Thus, though the bones of the bison and the Galloway may present but small distinction, yet the difference of skin, of mane, and of muscle, would make an ordinary observer startle at the idea of their having a common origin. The skull of a wolf and that of a wild dog of New Holland, are all but identical; and it is possible that the influence of pasture may lengthen or shorten the horns—that by breeding from long or short-horned, or from hornless animals,
the variety may be perpetuated, till they lose, in the course of ages, many of their original characteristics. It is impossible, for instance, in Essex, to grow the ox to the same size, other things being equal, as in the county of Durham; nor on the Ayrshire hills can he be produced in the same form or stature as in the Devonshire valleys. The Highland Scot is suited to the cold climate of the exposed and stormy north, and the short-horn to the sunny lowland pastures; and who shall say that the God of nature has not impressed on these created beings the capability of adapting themselves to his plastic handiwork, of developing their tendency to follow the peculiarities of the situation in which they are placed? An elephant can never degenerate into a mouse—a cat never improve into a tiger—but a wild dun cow of Warwick may be the progenitor alike of the thin, spare, feeble-looking Alderney, and the flesh-mountain ox of Durham."

On the same subject, Dr. Prichard remarks:—"In all our stocks of domesticated animals, we see profuse and infinite variety; and, in the races of wild animals, from which they originally descended, we find a uniform colour and figure, for the most part, to prevail. Domestication is to animals what cultivation is to vegetables; and the former probably differs from the natural state of the one class of beings, in the same circumstances which distinguish the latter from the natural condition of the other class. The most apparent of these is the abundant supply of the peculiar stimuli of each kind. Animals in a wild state procure a simple and unvaried food in precarious and deficient quantities, and are exposed to the inclemencies of the seasons. Their young are produced in similar circumstances to the state of seedlings, which spring uncultivated in a poor soil; but, in the improved state, all the stimuli of varied food, of warmth, &c., are afforded in abundance; and the consequence is, a luxuriant growth and evolution of varieties, and the exhibition of all the perfections to which each species is capable of being brought in a domesticated state."

We will close this chapter with a few brief remarks on some of the original breeds of France.

**FRENCH BREEDS.**

**Normandy.**—The colour of these animals is various. They are rather coarse in bone, but nevertheless are good-looking beasts, and have the reputation of giving an abundance of milk of excellent quality. They early arrive at maturity, and are, on the whole, the most useful and improvable animal of pure breed which the French possess. They are not unlike our Buckinghamshire breed in appearance, but smaller and finer. The **Flemish.**—In colour a rich brown, mostly with white faces, very good and clean-looking; but flat-sided, and stand rather too high on the leg. The **Charolaise.**—This is one of the breeds most prized in France for meat. They are very neat white beasts, kind and cheerful-looking, and good handlers. They are not unlike the Devon in everything but colour. The **Gascony** is an animal of good size, but coarse, and of either a black or grey colour. The **Garonnaise or Aquenaise.**—Good in size, and in excellent condition; but heavy and coarse about the head, hollow in the back, and with very drooping hind quarters. The colour is a light fawn. The **Bazaidaise** are very good-looking, but also fail in the hind quarters. Mouse-coloured. The **Limousine.**—Not unlike the Garonnaise breed both in colour and appearance, but smaller. The **Salers, d'Antrae, Auvergne, and Mezene,** are not worth much notice; the Salers are the best. Nor are the **Pertherais,** another fawn-coloured beast, much better. The **Brittany** is small, but very neat, hardy, and useful. The colour is black and white.—Such are considered some of the most prominent of the pure French breeds.
CHAPTER III.

AGRICULTURAL ASSOCIATIONS; THE PRINCIPLES OF CATTLE-BREEDING; FAT-ACCUMULATING BREEDS; MILK-YIELDING BREEDS.

AGRICULTURAL ASSOCIATIONS.

One of the best modes of advancing the interests of the farmer, is by that kind of agricultural association which has sprung up amongst us, and which has already been the means of effecting great improvements in those countries where it has been spiritedly adopted.

In England, almost every county has now its agricultural society, consisting mostly of practical men, who meet for the purpose of discussing those points that are more immediately interesting to themselves; and, indeed, no branch of occupation requires so much of this combination, or is literally more dependent on it for its advancement. Taking into consideration the ordinary operations by which farming is conducted—its rotations and shifts—how few are the opportunities which present themselves for any one, in the course of his life, to avail himself even of his own experience. Experiments generally are costly, and the results often too uncertain to be pursued by one who has to live by the produce of his acres. Hence it becomes of vital importance that he should derive knowledge for his own working, as it may be presented to him, through the experience of others. In this country, seed-time and harvest occur but once in the annual revolution of the earth in its orbit; and, should the husbandman fail in an experiment (unlike the manufacturer, who can immediately and incessantly repeat his trials until success reward his exertions), he cannot retrace his steps, or begin again, as the revolving year requires a different crop. The exigencies of a general system of rotation demand another course. The soil will not yield its increase without alternation; and he, therefore, compelled to wait an appointed time before he can take advantage of the experience which has enabled him to ascertain the cause of his previous failure. Science, it is true, has largely revealed the vast resources of the soil, and has modified the general laws of cropping; but the theory of to-day must be established by the practice of another day; and the success or failure requires the wholesome filtration of discussion, before any fact can be satisfactorily established.

We owe it to the enlightened agriculturists of Scotland, that such associations now exist. During the last century, a small body of Scotch landowners formed themselves into a "Society of Improvers in the Knowledge of Agriculture"; and to this humble beginning may be traced all the associations that have since sprung up, not only in Great Britain, but throughout the countries of Europe; and on the continent of America, until, at length, the importance of the subject has compelled a recognition on the part of various governments. In France and Belgium there are separate ministerial departments, under whose care and surveillance progress is made in all that belongs to agriculture; and the international exhibition which took place at Paris, has been productive of very important results, in radiating, throughout the empires and kingdoms of the European continent, the experience that was collected at that Agricultural Congress. Our own exhibitions have also done much; and if we cast a glance across the Atlantic, we find that in Canada there are provincial associations, both in the Upper and the Lower province. At Toronto, in Upper Canada, a central agricultural and horticultural society was organised some years ago. There are also a bureau and boards of agriculture; and a provision was made for imparting "a knowledge of the science and art of agriculture" in the various schools, and even in the colleges and universities. These have already been, no doubt, instrumental in placing this great colony foremost among the ranks of agricultural countries. Both in Nova Scotia and New Brunswick there are associations; and, in one of the reports of the latter, we find it stated, that "our farmers are now convinced, by experience, that they (the West Highland cattle) are the best adapted to our climate.
and pasture, crossing advantageously with our best milchers, producing profitable dairy cows, and superior working oxen, that are unequalled for reading through deep snow." In the United States such associations are also numerous.

The annual Smithfield Show in the metropolis is interesting, not only to those immediately engaged in agricultural pursuits, but to every one who reflects upon the importance of the ox in a commercial sense, independently of every other consideration. Here are to be seen the results of exertions, principally carried on during the last ninety years, to unite and bring to perfection the most desirable points in the various breeds of domestic animals which were once peculiar to different parts of Great Britain, but are now spread, in their improved form, over every part of the country. In connection with them are to be seen agricultural implements and machinery of the latest and most improved construction; roots and plants adapted to our climate, but which are as yet comparatively unknown; specimens of artificial manures, and of the soils of districts differing from each other in their geological formation. In spite of all the advances which agriculture has made during the present century, how slowly do improvements extend beyond the intelligent circle in which they are first adopted: but it is one of the great advantages of cattle exhibitions to spread them more rapidly and widely, by drawing the agriculturist from the secluded scenes in which he carries on his occupations, and bringing them before him in the manner best calculated to demonstrate their utility. A prize ox or sheep is fatter than the ordinary market requires; and hence it is often supposed that the stimulus of prizes for bringing an animal into a state of unnecessary fatness is altogether a work of supererogation. But the power of reaching an excessive size is simply a test. A piece of artillery is tried by a charge greater than is ever required in ordinary practice; and an ox is fattened for exhibition beyond a useful marketable condition, simply to show the capacity of the breed for acquiring, at the least expense of food, and at the earliest age, such a condition as the public demand really renders necessary.

If we look at the farmer of a former period, located generally in some isolated spot—his very vocation keeping him, as it were, apart and separate from others—his only opportunity of meeting with his fellow-agriculturists being, probably, confined to the weekly market at the county town—the means of travelling being limited, and communication, even by letter, restricted by the expensiveness of transmission—there was nothing left for him but to continue in the practices handed down to him. The very situation made him cling to old recollections; and hence, no doubt, has, in part, arisen the character imputed to him, of a dislike to innovation, and an obstinate adherence to the routine of a bygone age, even possibly when his judgment had been awakened by the progress he saw around him. But what a change is now presented! His means of communication have been expanded; the power of steam has opened up a speedier as well as a cheaper mode of transit; the researches of the chemist have brought about a change in agricultural operations; and, to keep up with the spirit of the age, he is, in a manner, compelled to unite with his fellows, in order that he may learn, and not be left behind in the race. Farmers' clubs are, in the most obscure districts, springing up. The principle of association has been established; and it is the farmer's own fault if he does not take advantage of what our French neighbours call "the situation." Every subject connected with agriculture is brought under discussion. The tiller of the soil begins to find that he holds an important position in the country; and he now opens his eyes to the fact, that his occupation is a science, and that he must, of necessity, raise himself to the height of his calling.

THE PRINCIPLES OF CATTLE-BREEDING.

"One of the most wonderful instances of man's supremacy over creation," observes Mr. Milburn, "is the influence he is able to exercise in directing vital processes. Here his power is perfectly talismanic. Within certain limits, he has the power of asserting his dominion so far as to make stern nature obey, and do his bidding. If he wants size or hardihood, activity or gentleness, milk or fat—nay, even wool, or mutton, or beef—he can so arrange the elements with which Divine Providence hath blessed him, as to bend, and mould, and adapt them to his will, until he has produced the kind and class of animal he requires.
This power arises more from individual skill than from science. Whatever physiological principles are involved, they are best discovered by the facts known to the breeder, and teach him little in the management of his business. The perseverance and skill, the powers of observation and discrimination possessed by some breeders, have doubtless been the cause of their success, and led to England's becoming preeminent for food-producing animals; for in no other part of the known world can it be said that there is anything like such specimens to be found, either for producing flesh, milk, butter, or cheese. To watch physiological tendencies, and avail themselves of all discoveries, was the practice of breeders long anterior to scientific research. Emulating the skill of the wily progenitor of the Jewish race, and intelligently perceiving what was required, Colling and Bakewell attempted, and attained, the art of producing cattle and sheep 'ring-straked, spotted, and speckled,' at pleasure. Seeing, also, the necessity of economising food, they set about cultivating those animals which came to maturity early, and thus produced a much larger quantity of animal food from the same amount of vegetation. Knowing that fat was an element favoured in a northern climate, they endeavoured to obtain animals with a tendency to secrete it in large quantities. In order to do this, they observed the qualities indicative of these tendencies; and, knowing that it is true in physiology, as in mathematics, that like produces like, they selected and bred from animals possessing them, until they stamped their qualities permanently and invariably on their produce. With these they managed to combine their usual concomitants, symmetry and beauty. Hence the origin of our flocks of Leicester sheep, and our herds of short-horn cattle, so intimately interwoven, even in their mortality, with the proud national boast of the 'Roast Beef of Old England.'

In all animals there are certain distinctions or differences, which, in some individuals, are so strikingly marked as to lift them far above their congeners in particular excellences. Supposing, therefore, that two of these, a male and female, were chosen for breeding purposes; it is very likely that the breeder would expect their offspring to inherit the greater number, if not all, of those remarkable qualities for which their progenitors were distinguished. This, however, would probably not be the case, and the breeder would suffer great disappointment. It is from a knowledge of this fact, that many a breeder has resigned the hope of obtaining a good breed, and has ceased to persevere in his object. But he ought to remember that the principles of breeding are now pretty well ascertained, and require only patience and perseverance to carry them out to a success. Although the animals he had selected might have apparently been perfect in themselves, yet one of them, the cow, no doubt was an accidental product of excellence, and not the offspring of a reputable ancestry. Her progeny, therefore, exhibited the characteristics of her parents rather than those of herself. This is the reason why she did not produce her own form and likeness; but the breeder should have continued to select the best that he was able to procure; he should have persevered in his path, and, sooner or later, he would have had his pains rewarded by obtaining a breed which would have fulfilled the expectations with which he set out on his breeding experiments. It ought always to be borne in mind, that the attainment of a breed of stock is not the labour of a month or a year, but of a lifetime. If it be the object of a breeder to produce a herd of cattle or a flock of sheep with some peculiar tendency, he, himself, may never so far accomplish it as to reap any real advantage from it, but his sons may, provided he has pursued his plans judiciously. Even in two or three generations, there is no certainty that the tendency which he wished to impart would be established. "There are not only limits, therefore, to the mathematical axiom that like produces like, modified by vital powers with which the breeder has to deal, but we think there is a principle deeper still—one little noticed by writers on breeding stock, yet one which all our great breeders know and practised—viz., that some one animal has much more power of transmitting his qualities than others." The remarkable results of the Collings in cattle-breeding, were really due either to the skill they had in seeking their transmissive power, or to the accident of obtaining, by chance, an animal (their bull Hubback) who possessed it in a remarkable degree. Thus, in breeding
animals which have a great resemblance to each other, though the first generation may not satisfy the expectations of the experimentalist, yet a tendency will be given to the breed to progress in the proper direction; and by pursuing a careful system of selection, leading to the desired tendency, favourable results may be expected within the compass of a few generations.

The existing breeds of Great Britain present us with sufficient variety to enable us to produce any qualities required; whilst there are, comparatively speaking, very few obstacles in the way of making a selection. Skill, however, is necessary to preserve one variety of animals at the top of the tree, especially when many excellent sorts to breed from are now so numerous. The original improvers had, perhaps, less difficulty than those of a more recent day in maintaining their position. It is true they had to work without rules or experience; but, like Adam and Eve, when they were driven from Paradise, they had the world before them, and they had fewer competitors. The race they improved was such, that every step they took was palpable and definite. There were fewer combinations of blood necessary, and, consequently, less risk of failure. The chief effort now, however, is directed to overcome a defect; and this is to be done by selecting a bull that is perfect in that part that is imperfect in the cow. On the first offspring of these there may be little or no visible improvement made; but if the same plan be continued, an impression will, by-and-by, be made, and the herd gradually assume a higher state of perfection. There will, however, still be variations. All the herd will not be alike; nor can this be expected; for even the fancy, or imagination—if we may be allowed the expression—of cows has an effect upon the conformation of the calves they produce. One trial after another, however, must be made; and, although the process may be long, still, by paying great attention to the animals selected to breed from—by weeding them, as it is called—ultimate success may be expected as a certain result. Here, however, a question, which has frequently been agitated, forces itself upon the mind; and which is—How far is this object to be accomplished by adopting a male, or making a change in the female animals? Mr. Milburn says, the "universal consent of all classes of breeders is given to the value of the male: in selecting a stallion, the greatest care is taken; whilst there is little or no attention paid to the qualities of the mare that is sent to him. The flockmaster will give from twenty to fifty pounds for the use of a ram, who would grudge to give five for a ewe: but it is, it must be confessed, somewhat different in cattle. The dairyman is very careful in selecting his cows. They are watched, as heifers, for the development of their good qualities, and are preserved, either for their succession to a maternal race of milkers, or because they are promising in themselves: but the bull to which they are sent is too often a matter of convenience rather than selection. They know he is a bull; and that is enough. The too-usual mode is, to try the heifer by her first calf. If she promises well as a milker, she is kept for a cow; if not, she is consigned as a 'druse' to the grazier, for the butcher. Reasoning from analogy, the mother would be naturally considered as more influencing the animal than the sire. The influence of the mother is long and continuous. Her blood flows through its veins; it partakes of her habits and sympathies; but still the vital force of the male animal is pre-eminent. Much as the mother may influence the constitution, the sire possesses a far greater sway over the conformation, the qualities, and the appearance. If, therefore, the object of the breeder is to perpetuate and impress the good qualities, and to remove the defects of his breed, he will be careful in the selection of both the sire and the dam of his breeding animals. A single failure—a single year's neglect—may stamp qualities on his race which it may take years to eradicate; for even to keep a breeding-stock in a high state of excellence, is by no means so easy a task as may be imagined. In connection with this part of our subject, the question of breeding in-and-in has also been much agitated, some taking one side, and some taking another. The celebrated Bakewell bred entirely from his own stock; but it is affirmed, by those who opposed his system, that his stock became comparatively diminutive and feeble, and that his plan was a failure. He, however, only put in practice one of the first axioms of breeding—namely,
to select the best you can find. He was acquainted with no stock so excellent, in his estimation, as his own. Consequently, he bred from them because they were unequalled anywhere else. He brought his animals to great perfection; imparted delicacy, uniformity, and permanency to his flock and to his herd; reared finer animals; and, if they were not so large as some others, they were less coarse, and produced much more palatable meat. All this he did; but, like many other experimentalists, he may have pursued his system to a point of refinement too far for the pains to be rewarded by an adequate degree of profit.

Breeding in-and-in, in the human subject, is said to produce various physical and mental disorders, and in every way to have a deteriorating effect upon the genus homo. To an exemplification of this, we ourselves have been a witness. At the foot of a mountain, near to the banks of the Caerlock, running in from the river Clyde, in Scotland, there lived, in a few scattered huts, about from one hundred and fifty to two hundred Highlanders, who had bred in-and-in, it was supposed, for nearly a couple of centuries, and many of them were silly, and some of them quite idiotic. They had been ordered again and again off the estate, which had fallen into the hands of a new proprietor, but would take no notice; and had, at last, we believe, to be burned out. They then took their departure to a solitary glen among the mountains, where they pitched their camp, raised their bothies, and settled down to continue to perpetuate the idiocry which their habit of inter-breeding had introduced amongst them. If a family afflicted with mania, scrofula, or consumption, intermarries with another family similarly afflicted, it is to be expected that the virulence of either of these will be increased, and that an early extinction of the race may be anticipated, provided the offspring do not ally themselves with a better, or a stronger and more healthy breed. The reason of this is, that the parents took the very plan to perpetuate, or render permanent, the evils with which they themselves were afflicted. Mr. Bates' maxim was, "Breed in-and-in from a bad stock, and you commit ruin and devastation."

In considering this part of our subject, the arguments of Mr. Milburn go to favour the system of breeding in-and-in. "The objectors to consanguineous breeding," he says, "and its deteriorating and enfeebling character, seem to forget that, in the case of the wild cattle at Chillingham Park [to which we have already alluded], no cross has been made for an immemorial number of centuries; and thus, unchanged and unchangeable, they remain, without deterioration, without feebleness—a standing objection to the indiscriminate condemnation of the system of breeding from the same stock. The answer, that these animals do not show any improved points, is an argument in favour of this system of breeding. The fact that they never had them, and possibly never will have the chance, so long as the breed is kept pure and unalloyed, is quite decisive in its favour. Like all other wild animals, a natural law prevents the feeble male from exercising any unfavourable tendency. The herd have a king, and, during the rutting season, fierce and almost deadly battles take place amongst the bulls for the favour of the females. The hardiest, strongest, and most enduring male is the victor, and he becomes the parent of the future herd. This may, and is likely to continue for some years; because, when once admitted a victor, a great change must take place before the contest will be renewed. No sooner, however, does the male animal become feeble, than another season renews the strife. The once proud patriarch is vanquished, and the youthful victor, full of vigour and virility, is, in turn, the paramour of the herd. Now, if we admit the influence of the male animal to be the greatest, we have here the most perfect adaptation for the weeding of the herd, and the best constituted bull is the parent of the whole race for two or three years of production. It is not wonderful, then, that they have no points, no superiority, no distinctiveness of breeding. There is no selection of adaptation, of symmetry—even of semblance; but there is strength of constitution in the male—the quality, above all others, best calculated for securing strength of constitution, hardness, and size in the offspring. Assuming that this tyrant strength in the patriarch of the herd will continue for three successive years—a fact extremely probable—there is a degree of consanguinity which few breeders will attempt. It may be said of Mr. Bates' herd, now that he is
dead, that their quality was unsurpassed, and that the heifers were frequently bullied by their own grandfather, or the cow by her grandson; and this was no more irregular than the wild habits of the whole herd at Chillingham, where the daughter, if not the grand-daughter, must breed with the grandsire or the sire." Mr. Colling, already alluded to, bred his animals in very close affinity. Mr. Mason, of Chilton, second only to Mr. Colling, was an in-and-in breeder; and every agriculturist is now aware of the success which crowned the persevering efforts of these gentlemen. The system of crossing is that which is quite opposite to consanguineous breeding; and when two animals entirely distinct, breed with each other, an independent variety is the result, and this is called either a mule or a hybrid. Where the zoological distinction between animals takes place beyond a given range, Nature steps in, and suffers no further admixture of the species. The mule is almost invariably non-producing; and although the union of a mule and female, of different qualities, will occasionally produce an excellent combination of the qualities of both, with, perhaps, a fair proportion of uniformity, still the union of these again amongst themselves will not be so happy. Indeed, they are likely to throw only mongrels, differing even widely from each other, and no more like their parents, than an ordinary piece of frail humanity might be considered to be to Hercules. For example, a cross was tried between the hard-working Devon and the fat-accumulating Hereford; but it was a failure. The strength and activity of the former were nowhere; whilst the fattening qualities of the latter were not obtained. A similar cross with the Albany was also a failure; as was another cross between the Hereford and the Kyloe. A cross between the short-horn bull and the Ayrshire cow, only takes the latter from the dairy, and gives her to the butcher.

The most successful cross ever made, was between the Galloway cattle and the improved short-horn, effected by Mr. Colling. He put one of his short-horn bulls to a well-selected Galloway cow; and the produce was a bull. He proceeded no further with this cross, but carried the blood to his short-horn herd. To this bull he put a short-horn heifer, with a large accession of Hubback blood. The produce of this union was another bull, the sire of his cow Lady, which, at his sale, sold for 206 guineas. From this cross, the probability is, that the straight back, the round form, and the wide hips were, in some degree, due to this Galloway cross, as well as that shortness of leg, which is the most striking defect of the Teeswater cattle, and which the Collings were so anxious to improve. This cross, notwithstanding its encroachments upon the purity of the blood, is certainly a most successful and most judicious instance; for where a large and strong-framed animal is covered with a short-horn bull, not only quality, but readiness to fatten is imparted. To proceed further is, perhaps, not wise. Attempting a system of crossing with milk-producing cows, is considered both unnatural and absurd; but there is no sort of large-framed animal intended for the grazer, which might not be improved by a cross, for one generation, with the short-horn. With the smaller West Highland cattle, even for grazing, reasonable doubts may be entertained. They live in a bleak and comparatively sterile district, to which a dash of short-horn blood, however small, could hardly ever accommodate itself; but, to the larger Scotch breeds, the same sentiment does not apply, as a single crossing would be invaluable. This is instanced in the case of a cross between a short-horn bull and a large Aberdeen-shire cow, to which was awarded a prize by the Highland and Agricultural Society of Scotland. The live weight of this cow was 224 stone, of 14 lbs. to the stone; and she weighed when killed, 173 stone 3 lbs.

In considering this subject of crossing, some very singular facts have been discovered. These have been arranged and classified; they exhibit a kind of phenomenon so extraordinary, that they cannot fail forcibly to strike the mind of every person who has given the slightest attention to this matter. It would seem that, when a pure-bred animal has been once impregnated by one of another breed, the one impregnated is thereby, for ever afterwards, a cross, and may be expected, for the future, to produce cross-bred, and no more pure-bred young. But the idea is capable of still further extension; for a female animal will always produce young that will have a strong resemblance, in character, to the animal by
which she was first impregnated, whether of a cross breed, or of the same breed as herself. Should it, therefore, be the case that a single cross will stamp its character for ever upon the animal which is the subject of it, there is the greatest necessity for the utmost vigilance and caution to be used in selecting a male animal, especially in the first impregnation of the female. Dr. Harvey, of Aberdeen, and Professor McGillicravay, hypothetically consider that the intimate connection in bovine animals, between the fetus and its mother—consisting of an absolute circulation of the blood of the fetus through the veins of the mother, and vice versa—so impregnates her with the vital functions of the sire, as to render her, for ever afterwards, incapable of transmitting her own qualities unimpaired to her offspring. This, therefore, forces upon her breeding qualities the same characters as those which marked her first young, entirely independent of either the defects or the beauties of the sire. Several well-authenticated facts will effectually establish this view. One of the Earls of Morton had a chestnut mare, which was put to a quaggar, or wild ass. The offspring gave the most unmistakable signs of the quagga in its head, its ears, its stripes on its shoulders, &c. Afterwards, in three successive seasons, the mare was put to a black Arabian horse, and in as many years the foal strictly resembled the quagga. In the Transactions of the Royal Society, it is stated that Sir Gore Ousely had a thoroughbred mare covered by a zebra. The produce was a striped animal, resembling its sire. The mare was afterwards covered by a thoroughbred horse; but a striped animal was the result: the year afterwards she was put to another horse, with the same result. Again, six black-faced, horned Scottish ewes were selected by Mr. H. Shaw, of Leochel, and were served, some with a Southdown, and others with a Leicester ram, the one white-faced, the other dun-faced, but both hornless. The lambs, as a matter of course, were crosses; and, in their second year, they were put to a horned ram of their own black-faced breed; but all the lambs were hornless, and their faces of a brownish colour. Again, they were put to a very superior ram of their own breed: on this occasion the crosses of some were less distinct; but two of the lambs were polled or hornless; one was dun-faced, with very small horns, and the other three were white-faced, with very small round horns only. The cases were considered so impure as to be thrown out from the flock; and another lamb was never obtained from them by the breeder.

A favourite setter bitch, belonging to Dr. Hugh Smith, followed him one day in the season, and she was warded by an ugly cur, which was shot, and Dido, the setter, lost her nose in the partridge season. She was put to a superior setter; but her produce were the colour and picture of the cur; and, in her many subsequent litters, no other kind of animal could be obtained from her but a cur-looking puppy. Even among the porine species there are singular instances of this kind. A person had a black-and-white sow, which became pregnant by a wild boar, of a dun colour. Of course the breed was mixed, or crossed, exhibiting symptoms of the qualities of both its parents. But the same sow was afterwards put to two different boars, and, in both instances, the dun colour pervaded the breed, though perfectly unusual before. The late Professor McGillicray tells us of an Aberdeen-shire hornless heifer being put to a short-horn bull, and had her first cross calf to that animal. She was afterwards put to a pure-bred bull of her own kind; but she again had a cross calf, a horned animal, though both its parents were polled animals. The same authority mentions another instance of a different Aberdeenshire cow which had been served by a first cross between the Aberdeenshire and short-horn, and to this animal she had a cross-bred calf. In order to have a pure-bred calf from her, she was put to a pure Aberdeen bull; but the produce was a cross calf, both in colour and appearance. The evidence of such facts as these it is difficult to resist; but facts even stronger than these can be adduced to show the influence which the first impregnating animal has upon the female for ever afterwards. In the case of Dr. Smith's Dido, it does not appear that her intercourse with the cur, if any, had been fruitful; but the following facts will show the impossibility of any connection whatever. Mr. Blaine had a pug bitch which made a companion of a small white spaniel. From this dog she was separated on account of her heat, and was warded by another of her
own breed. She threw puppies, one of which was slender and spaniel-like, and perfectly white; and, in two subsequent litters, she always produced one white puppy, though it might be less slender than the first. It is possible, however, that she might, at some period, have had unobserved intercourse with the spaniel; and if so, as a matter of course, the principle would be precisely similar to that which is involved in the preceding instances; but we have a case in which this was utterly impossible. A mare and a gelding had long been companions in the team, in the pasture, and in the stable. He was black, with white legs and face, and possessed of a singular rectangular form of hind legs. After an association of about two years, the mare was covered by a bay stallion, with black legs, which was the colour of her own. The foal exactly resembled the gelding, both in colour and shape, especially in the hind legs. Here connection was impossible.—We have already alluded to the effect of the imagination of the mother greatly influencing the colour and form of her offspring; and the following fact would seem to prove it. Mr. Boswell tells us of a hornless cow coming in season, when one of his neighbour's horned black-and-white oxen broke over the fence, and accompanied her home to the bull. Both the sire and the dam wore black and hornless, nor had the farmer any horned or spotted beast on his farm. The produce of the cow was black and white; and, in due time, its horns grew, resembling those of the ox. These facts may not, in themselves, prove much; but they raise a doubt as to whether the imagination of the mother may not, in some indescribable way or other, operate upon the offspring.

Another point in connection with this subject is, the respective influence of the parents in determining the sex of the offspring. This part of our subject is necessarily involved in no small degree of mystery. Nature seems to have decided that the sexes should be pretty evenly balanced; but the causes which lead to this decision she has refused to develop to mankind. There is a great difference of opinion among physiologists as to whether the male or the female, the sire or the mother, has the greater influence in determining the sex. Sir Everard Home thought that the ovum or germ, previous to impregnation, is of no sex, but is so formed as to be equally fitted to become male or female; and that it is the process of impregnation which marks the sex, and forms either male or female generative organs; that, previous to the fourth month, the sex cannot be said to be confirmed, but that the parts, before that period, are so blended, that either the one or the other may be formed therefrom, as the tendency towards the paternal or maternal type may preponderate. This would account for the disposition which some animals have to beget a greater number of one sex or the other. Mr. Knight, a distinguished naturalist, inclined to the opinion that the female is principally concerned in the development of the sex. "In several species of domesticated animals," he says, "particular females are found to produce a majority of offspring of the same sex; and I have proved repeatedly, that by dividing a herd of thirty cows into three equal parts, I could calculate on a large majority of females from one part, males from another, and females from the remainder. I frequently endeavoured to change the habits by changing the male, but without success." In the Philosophical Transactions, mention is made of a gentleman who was the youngest of forty sons, all produced in succession, from three different wives, by one father, in Ireland. One instance is also recorded of seven successive daughters being born to a man by his first wife, and of seven sons by his second wife. As, in this matter, both statements and opinions contradict each other, the only conclusion to be drawn is, that both the male and the female possess a certain degree of influence in determining the sex—sometimes the one operating one way, and sometimes the other. Some degree of weight, however, is to be attached to the opinion, that where the male is older than the female, the majority of the offspring is likely to be males.

The rapidly-growing population of this country has long demanded a correspondingly extended supply of animal food, which has been furnished, not by the greater productivity of the grazing districts, but by the growth of roots on arable farms; so that, in fact, a greater annual weight of meat is produced by the latter than the former. Whilst a larger
quantity of land has thus been devoted to the production of animal food, it has by no means diminished the supply of grain; but, on the contrary, has increased it by the enlarged quantity of manure which, in consequence, is supplied to the land—a fact so well established, that it has already become an adage, "No cattle, no dung; no dung, no corn." The objections that are sometimes raised against over-fed cattle, and the attempts made to disparage the "mountains of fat," as they are sometimes called, may be both sound and reasonable; there is no doubt of the practical fact, that the best butcher cannot sell anything but the best fatted beef. "Of whatever age, size, or shape a half-fatted ox may be, he is never selected by judges as fit for human food. Hence, a well-fatted animal always commands a better price per pound than one imperfectly fed; and the parts selected as the primest beef, are precisely those where there is the largest deposits of fat. The rump, the crop, and the sirloin (the very favourite cuts, which always command from twenty to twenty-five per cent. more than any other part of the ox), are precisely those parts on which the largest quantities of fat are found. Thus, instead of the taste and fashion of the age being against the excessive fattening of animals, it is, practically, exactly the reverse. Where there is the most fat there is the best lean; where there is the greatest amount of muscle without its share of fat, that part is accounted inferior, and used for a different purpose. In fact, so far from fat being a disease, it is a condition of muscle necessary to its utility as food—a source of luxury to the rich, and of comfort to the poor." The fattening capabilities possessed by various animals, are the effect of a secretive power, which enables them to reserve a store of their superfluous food for seasons of cold or of scarcity. The fat masses itself round the angular bones of the animal, and gives it that comfortable appearance of rotundity upon which the eye feels pleased to rest. Hence the tendency to secrete fat is indicated by a roundness of form, as opposed to the flatness characteristic of the milk-yielding animal. The fat lubricates the joints, gives elasticity to the skin and muscles, and obviates the effects of pressure; but, above all, it is a store of heat-producing aliment, set aside for seasons of scarcity.

The larger portion of the diet of animals may be said to consist of a saccharine, an oleaginous, and an albuminous principle. To the first belong all the starchy, saccharine, and starchy parts of the plants, which, in the digestive organs, pass through changes similar to fermentation, before they can be assimilated; through them, also, is animal heat sustained. In sluggish animals, the oily portions of plants are deposited and converted into fat; and, when strength fails, it is taken up to supply the place of the consumed saccharine matter. The albuminous or gelatinous principle of plants is chiefly required to force the accumulation of muscle; while the ashes of plants, their un consumable portions, are designed for the purpose of supplying bone, hair, and horn, as well as muscle and blood: they also replace the waste which is continually going on. Such are the several qualities which are essentially characteristic of a disposition to fatten. These marks are so definite and well understood, that they are comprehended and acted upon by every grazier. There is some difficulty, however, in endeavouring to describe, upon paper, all the indications of barrenness or fertility which a practised eye alone could detect. It is by experience and skill that the grazier acquires his knowledge, and not by theoretical rules. Observation, judgment, powerful perceptive faculties, and minute discrimination, are essential to his success.

One of his great re liances is on the touch, which may be esteemed the criterion of quality in every vaccine animal, whether to be bought for milking or grazing. The skin is a great indicator, and should neither be thick nor hard, nor should it adhere firmly to the muscles. If it does so, it may be concluded that the beast is a hard grazer, as well as a poor feeder; and as no man skilled in his calling will purchase her, she must be palmed off upon some novice, and even to him at such a price as can make her a sort of temptation to be got into his possession. On the other hand, the skin must neither hang loosely, nor exhibit that kind of flabbiness which is frequently seen upon indifferent cattle, and which discloses a delicate temperament, and a nature incapable of the retention of fat. Human physiologists give great attention to the subject of temperament; and though we do not make similar nice
distinctions in reference to brutes, yet is it of extreme importance to keep in mind those general and distinctive varieties of temperament which have a powerful operation upon the characters of various animals. Assigning, then, a broad division to the temperaments of animals, we might define them as consisting of three kinds—the nervous, the thoracic, and the abdominal. In proportion as the nervous system, the chest, or the abdomen, is strongly developed, an animal may be considered to belong to the one class or the other. In the breeding of oxen for the purposes of the butcher, the grand object has been to establish the supremacy of the belly, and to dethrone the empire of the cranium and the chest; or, in other words, to preserve and perpetuate that form of abdomen most favourable to the due performance of the digestive processes, affording the capability of extracting the utmost quantity of nourishment from the food, and, at the same time, diminishing as much as possible the development of the nervous system (which would induce too much irritability, and destroy that indolence and quietness so essential for the fattening process), as well as that of the organs of respiration, which give, at once, the capability and the disposition for muscular exertion.

In reference to the formation of the beast, in so far as it is susceptible of taking on fat, size must enter largely into the consideration where heavy weights are required. Christmas beef is not only expected to be large, but likewise to be fat. "The symbol of festivity," says Mr. Milburn, "should be capacious as well as prime," and we agree with him. A spare scrag at Christmas would certainly be enough to "chill the genial current of the soul" of any Englishman who has heard of the bountiful fare upon which his ancestors of old regaled at this season of the year; but in reference to the grazier, who is buying in order to sell, profit alone must be his guide. It may be observed, however, that in accordance with the excellence of the grazing-ground, so will be the largeness of the animal fed upon it. Small animals certainly are much more easily fed; but then they are usually the result of a poor soil. Besides size, there must be breadth of carcass, which is indicative of fattening; perhaps, above all other qualifications. If rumps are favourite joints, and produce the best price, it is best to have the animal which will grow the longest, the broadest, and the best rump. The same may be said of crop, and of sirloin; but breadth is essential to the consumption of that quantity of food which is necessary to the development of a large amount of fat. Thus a deep wide chest, favourable for the respiratory and circulating functions, enables the animal to consume a large amount of food to burn up the sugary and deposit the fatty matter, as then useless, but afterwards to be prized. A full round crop will be of the same physiological utility; while a broad and open framework at the hips will afford scope for the action of the liver and kidneys. The head must be small and fine. Not, perhaps, that it is of any special use in the fattening of the animal to be so constructed, but it is indicative of the bones being small, and the legs short. For constitutional powers, the beast should have his ribs extended well towards the thigh-bones or hips, so as to leave as little unprotected space as possible. There must be no angular or abrupt points; all must be round, broad, and parallel. Any depression in the lean animal will show a deficient deposit of flesh and fat, when sold to the butcher, and thus deteriorate its value; and hence the animal must be round and full. But either fancy, or accident, or skill (we will not pretend to say which), has associated symmetry with quality and conformation, as a point of great importance in animals calculated for fattening; and there is no doubt that, to a certain extent, this is so. The beast must be a system of mathematical lines. To the advocate of symmetry, the setting-on of a tail will be a condemning fault. The ridge of the back like a straight line, with the outline of the belly exactly parallel, when viewed from the side, and a depth and squareness when viewed from behind, like a geometrical cube, may be said to be the indications of excellence in a fat ox. As a partial résumé of what we have said, we add, that the qualities desirable to be obtained for fattening, are pretty much the same in the greater number of domestic animals—that is, in those designed for animal food. They are—the capability of converting a given quantity of food into the utmost amount of flesh and fat, and the development of this meat on those parts of the body most esteemed for food. Thus
small heads, small legs, and small bones, altogether, are essential qualifications, and early maturity is equally desirable. Connected with these points are invariably found a peculiarly quiet and indolent disposition—what physiologists would term a lymphatic temperament—which is denoted by a fineness of the skin—a certain resistance to the touch, so to speak, caused by the development of those membranes immediately under the skin, which serve for the deposition of fat in common with other objects. In cows kept for the purposes of the dairy, where butter and cheese are the sources of profit, the considerations just mentioned, though not altogether to be lost sight of, are yet secondary to others—such as the development of the lactic system, &c.

MILK-YIELDING BREEDS.

The pasture of this country having great variety, means are thereby afforded for rearing cattle of every description; consequently, the fat-accumulating, as well as the milk-yielding breeds, have each that kind of pasture best adapted to accomplish the end which their owners have in view. The scheme of creation is so admirably adjusted to the wants of those living beings which inhabit it, that every race is apparently provided for. The granivorous and the carnivorous animal has each its destined food. The elephant, that roams the region of Central Africa, has its boundless forest, its thick and long grass, with innumerable herbaceous plants, provided to satisfy its appetite, and increase and sustain the enormous bulk to which it attains. The lion, in the same region, has countless herds of the eland and the gazelle to prey upon; whilst the birds of the air are equally cared for. Animals, however, reduced to a state of domestication, have not the same resources placed within their reach. They depend upon man for what they want; and as the exigencies of a highly cultivated civilization press upon him the necessity of making provision for it, he becomes a rearer of cattle and a producer of milk, that he himself may be enabled to live by the profitable returns which such labours afford him. Flesh and milk being, to a large extent, essential to human existence, these are sought to be obtained in the greatest abundance, and in the highest state of perfection. For this reason, those animals that yield them to the largest extent are most eagerly desired; and, as nature has deemed that different races, and different individuals of those races, are better adapted than others to the secretion of the one or the other of these essential products, he selects such as he deems the most suitable for the object he has in view. There is no breed of which we are aware that is equally calculated to produce both to a profitable extent—the objects of the two secretions being quite different, and the tendencies and qualities essential for the production of both being sparingly conferred upon the same animal. As the production of milk, more or less, characteristic of all kinds of animals, it must necessarily have its degrees of proportion, as well as quality, in accordance with the size, number, and nature of the progeny which is to be nurtured by it. Some will give large quantities, but thin and poor in quality; some smaller quantities, and rich in oily matter; while others will afford a small portion, but abundant in solid matter. For profitable or commercial purposes, the first will be selected by the milkman near the populous city; the second by the dairyman, whose product is intended to be butter; and the third by the maker of cheese.

The diffusion of the milk-yielding breeds is more extensive than any other, because they are capable of being advantageously maintained on that description of herbage which is not sufficiently nutritive to sustain the fat-secreting breeds. The bulk of the grass-lands on the clay soils of this country, on the sides of the uplands, and even on the poorer sands, is sufficient to supply the means of making butter or cheese; but it will not remunerate the attempt to feed cattle on herbage so inferior. The rich alluvial feeding-pastures, which generally skirt our rivers, are far more profitably employed in raising summer beef, than in the production of milk or butter.

How far is it possible to detect, by external conformation, the capabilities of the individual animal for the secretion of milk?—is a question well worthy the consideration of all those who are engaged in dairy husbandry. There are instances in every breed, where nature has more bountifully, or more sparingly, bestowed the qualities calculated to produce the secretion
for which the race may be celebrated; and there are, doubtless, well-known marks, which, to the dairyman, rarely fail to indicate the status of the animal in the range of qualities peculiar to his race. On the European continent, this knowledge has been professed to be carried to a very minute extent. François Guénon, a Frenchman, is said to have found a mode of deciding authoritatively, not only the quantity and quality of milk which would be yielded by any particular cow, but also the period for which she would retain her milk after calving. This he professed to determine by external appearances alone; and these of a somewhat arbitrary kind. The possession of such an invaluable species of knowledge to the farmer was not readily to be lost sight of. Accordingly, the Agricultural Society of Bordeaux appointed a committee, to test Guénon’s capabilities; and they reported that, although the process by which he arrived at these conclusions was a secret, he had succeeded in satisfying them of the truth of his system. It was deemed, however, that it would be more satisfactory, if Guénon would submit it to a practical experimental test; and this was done in the following way:—Separate cows were brought from strange dairies, and he wrote down the characteristics and qualities of each. These were compared with the separate statements given by the owners of the animals; and, in cases of more than sixty head, he succeeded in stating all their peculiarities exactly, with the exception of a very slight difference in appraising the quantity of milk—a difference the committee attributed solely to the quality of food given to the animal.

At Cantal, the Central Society of Agriculture also reported upon his system with equal favour. Their description of the process of investigation pursued, is thus given:—“He accompanied the members of your committee to the farm of Veyrac, belonging to the president of the society. He examined, with scrupulous attention, the fine dairy cows of this domain, which is composed of one hundred milk cows of the best kind in the country. * * * M. Guénon gave, upon each of them separately, precise indications as to the quantity of milk each of them give per diem, and the length of time they would hold their milk after being again in calf. We must arrow to you, gentlemen, that they have, almost in every instance, agreed with the declarations of the owners of the cows.” The mode he adopted has been made known in this country; and it has for its foundation the classification of all kinds of cattle into eight families. Each of these he divides into three sections, according to size only; and each section, again, he sub-divides into eight orders. The distinguishing marks by which this division is made, are—1, the Gravure, which are those parts which commence at the udder, and extend at the bearing; 2, the Epis—a soft brush of hair on the udder of the animal; and, 3, Contrepoil, or hair growing the contrary way. These peculiarities form the distinction between the families and orders. Thus, if the gravure be large, the reservoir of milk will also be large, and the produce abundant. If it be formed of fine hair, and if the skin be of a yellowish hue, and a sort of bran-coloured powder fall from the skin, they are to be taken as the signs of a good milker. The rationale of the whole is, that the gravure is but a continuation of, and corresponds with, the lactiferous vessels under the belly of the animal. These “epis,” he states, correspond with the reservoir of milk, and are tufts of hair growing the wrong way on the right or left of the bearing. The largest indicates the most rapid loss of milk. The contrepoil, or hair growing the wrong way on the gravure, amidst that which grows upwards, indicates a deficiency in the production of milk, even if the gravure be large.—Such is a general description of a system invested with minutiae of no ordinary kind; and so precise and prolix, that it would even require numerous engravings to show the variations of family, class, and order. In speaking of this system, it has been remarked, that the observations of Guénon have been carried far beyond their legitimate objects, and are of a character rather indicative of quality; for while a wide capacity of upper udder, a fine hair, a yellow seur, are somewhat too indefinite to classify very precisely, they are just the points which may indicate a fineness of quality, and a large lactiferous capacity, that may add to the physiological signs by which a milking-cow is judged by the practical grazier.

In a good dairy cow, a beautiful form is an unimportant point in the eye of the dairyman;
CHAPTER IV.

FEEDING OF CATTLE.

In the pastoral districts of the United Kingdom, it might be imagined, that where fat is no longer regarded as a luxury at the tables of the rich, every mode which promotes its accumulation on cattle would be so generally known, that the most unsophisticated would be initiated into its mysteries. This, however, notwithstanding all that has been done, is not the case. "Everybody knows that rich alluvial pasturage, that linseed-cake and Swede turnips, that combinations of hay and bean-meal and ground corn, with a dozen kinds of roots, will feed cattle sooner or later. But the question now is simply one of economy — How can the greatest number of pounds of beef be produced at the least possible cost?"

This is the point to be ascertained; and to do this, the grazier must make his selection of such beasts as will take on fat the most rapidly. By a physiological law, there are some which will sooner attain maturity than others, and so be carrier fit for feeding. As it requires no great amount of skill in a good grazier to select an animal that is likely to thrive under his management, he will make a choice of a drove, of five, or ten, or twenty animals; and nineteen of the last number will be the best grazers for his particular farm. In doing this, his eye, as well as the signs described in the chapter on the breeds of cattle, guide him; but, more than all, he is directed by the touch. After selecting the animals, the mode of feeding them is, to turn them out into a grass field, if possible, skirted by a river, where the silt of ages has been washed into the soil so deep, that the roots of the herbage cannot find its bottom, and so firmly comminuted as to admit of the smallest filaments of the radicles of the plants easily to penetrate it. It should likewise be so porous as to allow the air to enter, and the water to filter gently through it. All its elements should be kept in a state of solution, so delicate, that they may be always ready to nourish and strengthen the plants which consume them. It should, also, have all the elements of vegetation plentifully mixed up with it. On such a soil, a lean bullock will, in a few months, become fat, because he is nourished upon all the elements congenial to his nature. A little attention, to see that he is well, is all that is required from the time of his being placed in the pasture to his being taken to the butcher. There is neither labour
CATTLE-FEEDING. CATTLE, AND THEIR VARIETIES. [CATTLE-FEEDING.

nor expense incurred. He is worth several pounds more when he is taken out of the pasture, than when he was put into it; and this is the grand point in the mind of the grazier. The requisites here laid down for feeding, are strictly conformable to experience. There is abundance of fresh and highly nutritive food; there is little or no labour in searching for and obtaining it; with water, and shelter, and warmth, and also plenty of air, and freedom from constraint. In feeding cattle in winter these should be the objects to be kept in view. They cannot feed in the open air; the cold and wet starve off the flesh as fast as the food lays it on; therefore, shelter must be provided for them.

In reference to the temperature at which the atmosphere should be kept for the feeding of animals, various opinions have been held. At the Leeds meeting of the Yorkshire Agricultural Society, this subject was partially discussed. The question was—Are we to run the risk of a wasteful expenditure of food by perspiration under excessive heat? or are we to induce them to burn it up, to keep up animal heat, by exposure to too much cold? Nay will not different classes of feeding animals be subject to different consequences, from the same degree of heat? In the same cow-house there may be some too hot, and others too cold, from their different constitutions. Oxen generally sweat at a temperature in which heifers thrive admirably. This happens, at any rate, till Christmas; after which they seem to be able to bear the same degree of heat as female animals. A gentleman tied up two sets of feeding bullocks—eight in a warmer shed than the rest, where they were allowed the same quantity and kind of food; but those in the warmer shed made more beef than those in the colder; thus showing that warm air, as well as warm food, is highly favourable to the fattening of short-horns. The temperature arrived at was about 55° to 60° of Fahrenheit.

A temperature beyond this caused them to leave their food, and lose their tone and appetite.

Perfect quiet, and proper shelter, are very necessary to insure successful feeding. This fact is well known. An animal that has to search for its food will not readily fatten, because it gives off, in waste, the very principle that is necessary to enable it to accumulate fat. Hence the turnips for cattle should always be brought to them, instead of their being driven to the turnips. Whether animals feed fastest in the dark, or not, is another questioned point. "There can be no doubt whatever," says Mr. Milburn, "that anything which distracts their attention, which excites action, or which produces nervous irritation, is opposed to fattening; and as darkness will induce sleep, and promote quietness, it is so far favourable; but it is not so easy to have darkness and sufficiency of fresh air at the same time; and therefore, the best possible state, perhaps, is to have the feeding-houses rather in a state of shady gloom than in absolute darkness. A certain amount of nervous energy is necessary to give tone to the vital powers. Beyond this, repose and quietness are easily attained by a simple gloom; while shelter from flies and heat in summer, and from blasts, wet, and extreme cold in winter, should be carefully provided."

The same gentleman adds, that abundance of good food, and regularity of feeding, are essentials in all kinds of fattening; and that it is not desirable to allow the animals to have food standing before them when they are filled; nor should they, on the other hand, ever experience a single feeling of want. The usual hours of feeding should be strictly adhered to, for the twofold purpose of inducing regular periods of sleep, and for supplying the system with food at the first call of appetite. Variety in the vegetables given them, too, is another most essential element of rapid fattening; and it may not be far from the truth to say, that all kinds of food are equally fattening, if they are given in sufficient variety. If roots, grain, and hay be changed every few days, the appetite is never closed; and the whole are devoured with a relish which develops fat in the most rapid manner.

In this country, food, to be esteemed palatable—indeed, to be consumable—must be fat. Unless it has this recommendation it is absolutely unsaleable. The tastes of the higher, and the necessities of the lower classes, demand well-fattened beef, mutton, and pork; and any meat brought to market in a lean or scraggy condition, is denounced as a sort of carrion. The younger members of the operative's family have to content themselves with
the vegetables and gravy; while the heat of
the family consumes the flesh, to enable him
to perform his labour; and thus, when the fat
is not available, one important source of the
food of his household is dried up. For this
reason the grazier must supply the whole
of his animals in a fat state to the consumer.
Be it observed, that it is not the number of
animals, nor their weight in pounds and
stones that he has to consider, but he has to
provide for them the means of fattening before
they can be brought to the consumer.

The preparation of food for the animal, or a
system of cooking it, is a very important
question; and, we believe, that all that a
feeder can wish, is attained by the cooking of
linseed. Steaming hay, potatoes, and turnips,
was tried very carefully in Scotland, and failed.
For cattle, at least, it was found useless, how-
ever valuable it might be for pigs. The fat
of animals being analogous to vegetable oil,
its elements are much of the same character
as sugar, starch, and gum; and no doubt is
entertained, by physiologists and chemists,
that the fatty matter (vegetable oil) in plants,
is assimilated into animal fat, with very little
change. The elements of those compounds,
severally, are:—

The oil contained in many seeds has been
found to be, in—

This analysis would lead to the conclusion,
that any of these seeds are, so far as they are
agreeable eating, useful; and when linseed
contains as much as seven per cent. of mucilage,
ten per cent. of sugar, and fifteen of soluble
albumen, its great value for feeding and nutritive
purposes is at once evident. There was
some difficulty in grinding it by ordinary
mills, as it clogged up the teeth; and when
given to animals, either alone or combined
with considerable quantities of corn, meal, or
other feeding matter, the effect was purgative;
and but few breeders persevered in the use of
the seed alone. The demand for the oil, how-
ever, induced the crushing of the seeds to
obtain it, and the refuse was converted into a
valuable food for animals; while the portability
of oil-cake, its cleanness, and capability of
being long kept, made it a general and desir-
able food, both for growing and feeding
stock. The oil abstracted, the cake contains—

- Water: 10:65
- Mucilage: 39:10
- Albumen and gluten: 22:14
- Oil: 11:29
- Husks: 9:53
- Saline matter and sand: 7:25

Good English-made cake has now been
thoroughly established as one of the very best
fattening products; and the extensive farmers
of Lincolnshire, and other places, expend upon
a single farm, in one year, as much as from
£100 to £500 for this article alone. It is
the opinion of some of the most intelligent
farmers, that when cake can be purchased at
the same price per ton, in pounds, that beef
and mutton can be sold at per stone in
shillings, it will be paid for in the cattle and
animals fed, without reference to the manure.
The price of cake, however, depends on no such
element of calculation. The demand for it has
become far greater than that of the oil; and,
in some seasons, it has been so great, that the
farmer became an object of commerce rather
than the latter, and realised as much as twelve
guineas per ton. To render the uncrushed
seed available by a cooking process, attempts
have occasionally been made; but it has gen-
erally been found better adapted for calves
than for store-stock or for fattening. Where
used at all for the latter purpose, it has only
been to supply a deficiency in turnips, when
the crops of these have failed, and when the
other has had to be substituted for them.

The most decisive step ever taken in the
use of cooked linseed, was by Mr. Warnes,
of Trimingham, near North Walsham, in Nor-
folk. He commenced by inquiring into the
nature of cake, which he found to be nothing
more than the refuse of linseed; and imme-
diately commenced a series of experiments
with linseed, crushed, steeped, boiled, and
cooked in various ways. He also tried the
effect of boiled barley, and other food on various animals. These ultimately led him to adopt a mode of feeding on what he termed linseed compound. This was carried out in connection with his experiments in growing, dressing, and preparing the flax, the feeding of his cattle with the prepared seed, which he put into boxes as being opposite to tying up, and to the summer grazing by soiling.

These processes excited much attention, not only in England, but also in Scotland and Ireland, and were the cause of many visits being paid to Trimingham, that agriculturists might see for themselves. On such occasions, Mr. Warnes was by no means niggardly, either in his hospitality, or in laying the whole secret of his experience before his visitors. Among these was Mr. Milburn, who describes the cooking apparatus as so simple, "that it is managed by a blind man, whose happy countenance bespeaks neither over-weening anxiety nor unmournered toil. The apparatus consists of two cast-metal boilers, fixed in brick, with a fire-place beneath them. The water is made to boil before the linseed is put in. The seed is crushed by a very powerful implement, made by Messrs. Harwood, of Ipswich, consisting of two cylinders, one of them of large diameter. They are made to press upon each other in their revolutions by two lunar springs; and two men will thoroughly grind two bushels in ten minutes. At this rate the men are able to work the whole day. The mill is, however, capable of being reduced to the capacity of one man. The crushed linseed is sprinkled upon the boiling water at the rate of one gallon of seed to eight gallons of water. Great stress is laid on sprinkling the linseed very gradually; otherwise, it is apt to adhere in lumps, and cleave to the sides or bottom of the boiler. With this precaution, however, Mr. Warnes assures us that he has had no instance for several years of this occurrence. This mixture is boiled six minutes, and for that period is slightly stirred. At the end of that time it is found to be a thick gelatinous mass. In about one minute the mass appeared more mucilaginous, and we think was improved. Nine bushels of cut pea-straw were then placed very gradually, and by one bushel at a time, in a tub twenty-eight inches high. The liquid jelly was now taken out in the scoop, and poured upon it. As each addition was made, the whole was rammed down by a kind of beater, more for the purpose of mixing the mass, and confining the heat, than for any other object. The present cost of the animals in linseed, is 3s. per head per week. In addition to this, they have about one bushel of cut Swedes per day. The animals to which Mr. Warnes at present gives the compound, are seven cattle, nine horses, and forty sheep. Occasionally he mixes his compound with corn, or rather with meal. This, when used, is also sprinkled over the boiling muckle; but when we saw the process, corn was not used. So soon as the first boiling was nearly emptied from the boiler, it was again filled with water, and was ready for another boil when required."

As a test of the value of his system, Mr. Warnes furnished the following remarks and experiments, as illustrative of the general effects:—"Linseed," he says, "has five essential properties—viz., mucilage, oil, albumen, gluten, and sugar. The shell, or external crust, is the hardest of all seeds, and the most difficult to break in pieces; but not too hard for the miller, who has every particle ground almost to powder, in order that all the oil may be expressed, which it could not be if coarsely crushed. This is demonstrated by the cake, in which the presence of linseed is scarcely apparent. To a similar state, linseed for the cattle compounds ought to be reduced; otherwise some, at least, of the properties above described, will pass off without benefit to the fattening animals. This the scientific grazier will discover by the excrements, in which he will find sufficient cause not only for grinding linseed, but also for grinding all grain or pulse, if possible, into flour. From researches like these, the profitable returns for grazing upon my premises may be dated—returns such as are represented by the following figures:—

| Deduct for 4sp. linseed, mostly grown upon the farm, £23; and 2s. 4d. for barley meal, £25 0 0 | £238 10 0

Return for 10 acres of turnips, several acres of pea straw, and about 3 months' autumnal grass for the 10 miscellaneous cattle.
FEEDING, CATTLE, AND THEIR VARIETIES.

"The linseed, with the pea-straw and turnip-tops, were formed into compound, the turnips given raw, and the barley-meal as circumstances required. Under the old system, the turnip-tops would have been mainly destroyed, and the pea-straw used for litter. But these having been employed as above described, will account for the small consumption of turnips, and show the immense importance of such auxiliaries." The expense of this copper, with the whole working apparatus for eighty or a hundred head of stock, was not more than £4. Every farmer will, we think, see, from this small outlay, the great advantage which the possession of such an apparatus gives over almost that of every other kind; whilst the labour necessary to work it in an efficient manner, is, comparatively speaking, easy and light; and, at the same time, requires very little skill.

Feeding in boxes, the growth of linseed, the manufacture of the fibre into flax, and the soiling of cattle with green food and compound in the summer, all entered into the system of Mr. Warnes, whose experiments induced trials with all kinds of modifications of linseed-cooking; but the one which obtained the greatest amount of favour, was that adopted by Mr. Marshall, late of Holme Lodge, near Thirsk. The difference between Mr. Marshall's plan and that of Mr. Warnes was, that the material cooked had not the heat applied to it directly, but to the outside of the boiler in which it was to be cooked, so that no direct application of the fire took place to burn the mucilaginous matter. Mr. Marshall insisted that, to cook the material properly, it must be boiled at least two hours. His mode was this:—One pound of linseed was boiled for two or three hours in about one gallon and a-half of water. Five pounds of straw were chopped to about the length of an inch, and very intimately mixed with two pounds and a-half of ground oat or barley-meal, which were then placed on a floor of flags or bricks, and the boiled linseed poured upon the mass and turned. It was, after this, allowed to cool for one or two hours, when it was ready to be given to the cattle. The subjoined calculations are given for one animal; though the food for a larger number may be cooked at the same time, and in the same proportions. Supposing the linseed to be six shillings per bushel, the cost for each animal, per week, will stand thus:

<table>

Another gentleman who carried out the scheme very fully, gave the following experiment with the linseed compound, as compared with oil-cake. In this the turnips were charged, as well as the compound, to make the terms equal. Sixteen polled beasts (cows) were taken up. They were divided into two lots, and each lot consisted of eight beasts, as nearly equal, in weight and condition, to the other as possible. One lot, costing 6s. 10d. per head, was fed as follows:

<table>
<thead>
<tr>
<th></th>
<th>s.</th>
<th>d.</th>
</tr>

<td>6 9½</td>
<td></td>
</tr>
</tbody>
</table>

The two lots were sold on two different dates; four being taken from one set of beasts, and four from the other set, at each sale. The cattle fed upon prepared food realised £2 6s. 6d. more than the others, and the time occupied in feeding them was eight weeks.

A Yorkshire agriculturist, of great skill, made some very important experiments on the relative value of hot and cold preparation of linseed. He took two animals, and, after ascertaining their exact weight, fed the one on hot and the other on cold food. At the expiration of six weeks they were weighed again. The animal fed on cold food weighed, when put up, 107 stones 11 lbs.; that fed on hot, 108 stones 7 pounds. At the end of the six weeks, the first had gained 2 stones 12 lbs.; while the other fed on hot food, had gained 5 stones 1 pound. To guard against the one having any special aptitude to fatten more readily.
than the other, he reversed the order; and it
turned out that the animal now fed on cold
food, and before on hot, gained 3 stones 1 lb.;
while the other, now fed on hot food, and
before on cold, gained 5 stones 11 lbs. But
this was not all. While the one fed on hot
food had only 5 stones 10 lbs. of Swedish turnips
per day, the one fed on cold food was not
satisfied till his feed was increased to 7 stones
of turnips in the same time, thus showing a
greater consumption of other food to make up
for the want of heat!

WEIGHT AND MEASUREMENT OF CATTLE.

To estimate the weight and measurement of
cattle by the senses of feeling and sight, is not
so easy an operation as some might suppose.
Indeed, it is so difficult a matter, that many
farmers, even of large experience, are unable to
perform the task with anything like accuracy.
A somewhat distant approximation is all they
can accomplish. Whilst this is the case with
the farmer who may not be moving quite in
the capacity of grazier, this latter has a still
more difficult duty to perform. He has to
purchase lean animals at a market or fair, and
to estimate their feeding qualities. He has
besides to calculate the stones they will weigh
when fat. It is all a money-calculating pro-
cess. On an average the farmer requires to
make £3 for grazing an ordinary sized animal
during the summer. Good grass will feed one
beast on an acre, and thus remunerate the
farmer. When beef is 5s. per stone, the
grazier must increase the weight by twenty
stones, in order to make his animals remunerat-
ive. Hence, if he sees a beast which, in his
estimation, has frame and capabilities to weigh
fifty stones, he ought not to give more for it
than £7 5s. But this price will not compensate
the breeder; therefore he and the grazier must
both suffer when the price is only 5s. per stone.

The various elements which enter into the
calculation of the weight of animals, are breed,
quality, age, degree of fatness, quality of food,
duration of feeding, &c. Of some of these the
buyer may be able to judge, but of others he
can form no idea. He may conceive the breed
to be good, the age to be proper, and the
quality such as he wants; he may even find
the animal well fed up, both as to quality and
food; but he may still be deficient in the re-
quisite knowledge. The offals of cattle have
also a material influence in regulating the
price. There was a time when the hide and
tallow would be an ample profit to the butcher;
but that is past, and he must now sell the best
cuts of meat at more per pound than he gives
for the whole, or he will be a loser of his fair
share of profits.

The off of ordinary beasts may be esti-
imated as follows:

<table>

Mr. Ewart, of Newcastle, who paid very
great attention to this subject, and whose
slide-rule and cattle-gauge obtained for him
a degree of merit for skill which his labours
well merited, drew up a scale of per-centages,
which may be considered as a sort of standard.
He classes animals as to their peculiar proper-
ties; and, in his first class, included the
following:

FIRST CLASS.—Short-horns, Herefords, Suffolks, and Devons. Their per-centage of fat
to live weight, he thus estimated:

<table>
<thead>
<tr>
<th>Beef</th>
<th>Live Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>Half fat</td>
<td>55 to 59</td>
</tr>
<tr>
<td>Moderately fat</td>
<td>60 to 62</td>
</tr>
<tr>
<td>Prime, to very fat</td>
<td>63 to 66</td>
</tr>
<tr>
<td>Extraordinarily fat</td>
<td>64 to 70</td>
</tr>
</tbody>
</table>

SECOND CLASS.—Craven, Lancashire and
Irish short-horns, Lincolnshire, Galloway,
Angus, Aberdeenshire, Fife, Norfolk, and
better sorts of Welsh:

<table>
<thead>
<tr>
<th>Beef</th>
<th>Live Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>Half fat</td>
<td>50 to 55</td>
</tr>
<tr>
<td>Moderately fat</td>
<td>55 to 60</td>
</tr>
<tr>
<td>Prime to very fat</td>
<td>61 to 63</td>
</tr>
<tr>
<td>Extraordinarily fat</td>
<td>64 to 66</td>
</tr>
</tbody>
</table>

THIRD CLASS.—Argyleshire, Highland, and
mountain breeds:

<table>
<thead>
<tr>
<th>Beef</th>
<th>Live Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>Half fat</td>
<td>48 to 50</td>
</tr>
<tr>
<td>Moderately fat</td>
<td>51 to 55</td>
</tr>
<tr>
<td>Prime, to very fat</td>
<td>57 to 60</td>
</tr>
<tr>
<td>Extraordinarily fat</td>
<td>61 to 66</td>
</tr>
</tbody>
</table>

These estimates may help the buyer who
has not had experience sufficient to enable
CATTLE, AND THEIR VARIETIES. [DAIRY FEEDING.

To the practical man, the influence which food exercises on the production of milk is well known. Not only is the daily quantity of milk produced by a cow dependent on the nature of the aliment consumed, but, also, the quality of the milk is greatly affected by its character. Butter and cheese may be regarded as two very important articles of dairy husbandry, and they are both the products of milk. According to the purpose for which this wholesome beverage is intended to be employed—whether for the manufacture of butter or the making of cheese—the cow should be differently fed. Chemistry has given us a knowledge of the fact, that butter contains carbon, hydrogen, and oxygen, but no nitrogen; whilst, with this last element, cheese is abundantly supplied. Food which contains a large quantity of fatty matter, or such substances as are, in the animal system, readily converted into fat, will tend to the increase of the proportion of cream in milk. On the other hand, the proportion of caseine, or cheese matter in milk, is increased by the use of highly nitrogenised food. Those, therefore, who desire much cream, or who produce milk for the manufacture of butter, direct their attention to the selection of food likely to increase the proportion of butter in the milk. In cheese countries, on the contrary, the principal object of the farmer is the production of milk rich in curd. Vetches, clover, peas, and bean-meal, abound in legumin—a nitrogenised organic compound, almost identical in composition and properties with caseine, or the substance which forms the curd in milk. The dairy farmer, consequently, feeds his cows with advantage with such and similar food as tends to add to the richness of the milk in curd or cheese. The quality, as well as the quantity, of the butter in the milk, depends on the kind of food consumed, and on the general state of health of the cow. House-fed animals, particularly if turnips is their principal food, always yield inferior butter to cows living upon the fresh and aromatic grasses of pasture-land. Succulent aliment, in which there is an abundance of water, such as the green grass of irrigated meadows, green clover, brewers' refuse, distillery refuse, &c., increase the quan-

him to judge of the carcase-weight of the animal he wishes to make his own. Let him have it weighed, and make a deduction according to the foregoing data; and if it does nothing, more, it will at least serve as some guide in the forming of his judgment. The author of The Book of the Farm, gives two rules for ascertaining the weight of cattle by admeasurement. He confesses, however, that they are not founded on any certain principle—a circumstance which must be remembered in using them.

1st. Multiply the square of the girth in inches, by the length in inches, and divide the product by 7344; and the quotient will be the weight in imperial stones. 2nd. Square the girth in feet, and multiply it by the length in feet; multiply again by the decimal .238, and the sum is the weight in imperial stones. By the length, in all admeasurement, is intended a line from the top of the shoulder to the setting-on of the tail; and the circumference round the body, just behind the shoulders, is the girth. The same author remarks, that for beasts between forty and seventy stones, the rules of admeasurement apply pretty nearly; but below or above these weights, they cannot at all be depended upon.

The following approved rule is given in the little work of Mr. Milburn:—“Measure the girth close behind the shoulder, and the length from the fore part of the shoulder-blade, along the back, to the bone at the tail, which is in a vertical line with the buttock, both in feet. Multiply the square of the girth, expressed in feet, by five times the length, and divide the product by 21: the quotient is the weight nearly of the four quarters, in imperial stones, of 11lbs. avoirdupois. For example, if the girth be 6½ feet, and the length 5½ feet, we shall have 6½ multiplied by 6½, making 42; and 5½ multiplied by 5, making 26½; then 42 multiplied by 26½, making 1,109½; and this, divided by 21, gives 52 54 stones, nearly, or 52 stones 11½. It is to be observed, however, that in very fat cattle, the four quarters will be about one-twentieth more; while in those in a very lean state, they will be about one-twentieth less than the weight obtained by this rule. The four quarters are little more than half the weight of the living animal; the skin weighing about the eighteenth part, and the tallow about the twelfth part of the whole.”
tity rather than the quality of the milk. The

town dairymen who sells his new milk to daily

customers, increases the bulk of his milk by
such succulent food, and thus renders it thin,
without afterwards diluting it with water.

In the *Cyclopedia of Agriculture*, an account
is given of the cost of producing a gallon of
milk, according to different modes; and, though
it may be a somewhat vague instance, it so
nearly approximates to the spirit of truth,
that we deem it worthy of being laid before
the reader.

The Gloucestershire system, where the cows
are fed on grass and hay, and sold lean when
unfit for dairy purposes, involves a cost, per
gallon of milk, of 6½d. The Cheshire system,
in which a few turnips are added in the winter
keep, costs 6d. The Fifeshire system, of grass
pasture in summer, and nine tons and a-half
of turnips in the winter, with oat-straw,
amounts to 9½d.; and Mr. Young's plan, in
the same county, with a more liberal allow-
ance of extra food, as bean-meal, linseed, &c.,
costs 5d. Now, though we might have ex-
pected a greater difference in the last two
cases, and in favour of the very last in pre-
currence to the former, we still see that it is the
nearest way of all to starve the cows; and that
a moderate degree of attention and care is
necessary to the most economical produce of
the milk-cow, whether it be in milk or butter.

When the pastures begin to fail, it is usual to
turn the cow upon the fog or aftermath—say
in the month of October—for nearly all cow-
keepers have, of necessity, a quantity of grass-
land producing hay; and the after-cutage of
this land affords the best possible food for the
milk-cow, whether butter or cheese be the
object sought by the dairymen. When this
runs short, a little "hand-meal"—a few turnip-
tops, or rape, or even a little bran-mash—will
be well bestowed; for if the milk does go down
at this period, it is never regained in winter
by any care which can be exercised. If town
milk is the object, a few brewers' grains would
be the most advisable addition to the catage
which could be made. If the weather should
still be open and favourable, the pasture, freed
in October, will have grown up a little, and
will afford a very useful turn-out for the cow;
for she must, usually, be housed at night, when
the fog is finished. In the house, she should
either have hay and mangel-wurzel or turnips;
or, if she have straw, she should have cooked
linseed, or oat or bean-meal mash. The chaff
of the barn, after winnowing, may be collected,
as free from dust as possible; or, if mixed
therewith, it may be sifted and laid by. A
bushel of linseed may be added to two bushels
of barley or oats, or even wheat, or any other
grain, grown in the ordinary way. This may
be boiled in a common boiler, taking care to
keep it well stirred, to prevent its "setting
on" at the bottom of the boiler. After boiling
a quarter of an hour, if this be poured upon
the chaff in the proportion of one-and-a-half
to two pounds of the meal, and a gallon of water
to one bushel of chaff, one of the most useful,
and certainly the cheapest adjuncts to milk-
cow and store-stock feeding which can be con-
ceived, will be adopted. The great objection
to turnips, at least in large quantities, is the
favour they impart to the milk and the butter.
This is a difficulty which can only be partially
removed. It is surprising, however, how few
turnips or roots will be required if a compound
system be adopted; and this quantity being
so small, it is easy to vary them, by giving
potatoes, carrots, mangel-wurzel, &c., in an
ever-changing round. It is a question whether
hay need ever be given, if this system be adopted.
If it be not, the cows must have a
liberal allowance of hay. In Norfolk, oats,
barley, or bean-meal, is mixed with chopped
hay. It is questionable, however, whether the
cow has not more gratification, and hence more
advantage, from selecting and masticating the
hay alone, than can be derived from the cutting
and mixture, which at least is a costly and
labourious process. A small quantity and a
great variety of food will, on the whole,
produce the most favourable effect on milk-
cows. In a Prize Essay of the Yorkshire
Agricultural Society, the Rev. Robert Pulleine,
of Kirby Wiske, thus describes his very
successful method of keeping dairy-cows in
winter:—"In the management of dairy-cows,
during the winter season, it is of the greatest
importance to have a dry, well-ventilated cow-
house. The side walls should not be less
than seven feet in height; and, in the two
courses immediately below the top course,
every alternate brick should be left out to
insure a sufficient ventilation. A rough board,
on a couple of bricks, may be tied to close the opening at case of very severe weather; but I have never required in. The floor on which the cows stand should be made of well-beaten soil, and behind them a kerb-stone, about three inches thick and twelve inches wide, to raise them above the channel, which should have a slight fall, to carry off the water at once. My cows are tied up in pairs; each pair having a space of eight feet by six feet six inches, which is sufficient room for any beasts under sixty stones' weight. They have a crib before them, nine inches deep by twenty inches wide, raised upon twelve inches of brickwork. The advantage of the crib being raised is, that the cows are less liable to put turnips into their throats than when they have to put their heads down to the ground for their food. A rack I consider of little moment, as the hay is all given as chop. It is a good plan to take up cows as soon as the nights become cold—say the middle of October—as the white frosts, which occur about that time, cause them to run off their milk. They are turned out during the day until the middle of November, if the weather keep fine. From that period, until May-day, they are kept entirely in the house, except being turned out a few minutes every afternoon to water. They are milked at half-past five o'clock, morning and evening. As soon as the man who feeds them comes in the morning, the dung is all removed, and each cow has a feed of 28 lbs. of roots:—

"At 7 o'clock 7 lbs. chopped hay.
9 A bail of water, with ½ lb. of beans-meal stirred into it.
10 2 lbs. of linseed cake.
2 Turned out to water, and then 2 lbs. of linseed cake.
5 28 lbs. roots.
8 7 lbs. chopped hay."

One of the first requisites, in a successful dairy cow-house, is cleanliness. Without this, a dairy is anything but what it should be. It must be kept free from smells of all descriptions; frequently washed and whitewashed; and the animals diligently rubbed, and even carried. A thriving cow, out of doors, is known by her having the marks of her tongue upon her skin. If she is not at liberty to lick her own skin, she should, at least, have it done for her. Her litter should be removed the first thing in the morning, and replaced by fresh clean straw. Above all, her pen must have a very much air, if the cold have been allowed to get off. Bad exposure is, the crowning defect in such places is considerably more. There should be ventilators at both ends, in the Laurie style; open from the north, capable of shutting up in a very or southern rain; and capacious ventilators at the bottom, by grates or ventilating bricks, are indispensable to the health of the animals. If these be neglected there can be no hope of health or success in the dairy.

Respecting the influence of the food on the character and quantity of the milk, to which, in the opening paragraph of this chapter, we have alluded, several experiments have been made. Among these, a scientific agriculturist furnished Mr. M'Ilhun with one, which showed the increase of milk, within certain limits, was almost in the power of the farmer, by an addition of beans-meal to the ordinary root food and hay. Although, as a general rule, milk may be produced by these costly and stimulative kinds of food at too great an expense, yet it is of great importance, in a particular season, or under special circumstances, to know the means of increasing the supply beyond the ordinary quantity. Two Ayrshire cows were selected by Professor Thomson, and fed with malt in various combinations, when it was found that 100 lbs. of barley, hay, and grass, produced 8·17 lbs. of milk; and that the same quantity of malt and hay, produced 7·93 lbs. of milk; the former yielding 1·93 lbs. of butter, and the latter 1·92. Although this was not at all satisfactory as to the value, or otherwise, of malt for milk cows, still, it shows how food may influence the quantity and quality of the milk. Messrs. Dumas and Buussingault also experimented upon this subject. They made a number of very careful and interesting investigations regarding the quantity of milk and its products which would be given by cows fed on different kinds of food. They tried nearly all the combinations usually given, except, perhaps, beans-meal; and the result was, that, in every case, the greatest quantity was produced when the cow had green clover; thus proving that, in each instance, this yielded the greatest quantity.
of butter; and, with one exception, the greatest produce also of cheese; and that exception was when the cow was but one day after calving, which accounted for the abundance of cheesy matter in the milk. The table is full of instruction, and justifies the quotation of some of its items.

It is found that mangel-wurzel, bean-meal, and grains, largely contribute to the increase of milk; that good hay and oat mash augment the quantity of butter; and that turnips, though they sometimes impart a disagreeable flavour, materially add to the increase of both.

The result of Mr. Pulleine’s system of management, in the production of milk, is as follows; the cows being five in number, viz.—

1. Yorkshire, 9 years old; had her last calf March, 1850.
2. Alderney, 2½ years old; calved July, 1850.
3. Yorkshire, 2½ years old; calved Nov., 1850.
4. Yorkshire, 5 years old; calved Jan., 1851.
5. Ayrshire, 6 years old; calved March, 1851.

He says—“It will be observed that Nos. 1 and 2 can hardly be called in full milk, and No. 3 is only a quey. They produced, in the seven weeks, from the 25th of March to the 10th of May, 191 rolls of butter, 24 oz. to the roll, equal to about 25½ lbs., 16 oz. to the pound. To this must be added 15½ quarts of new milk, and 42 quarts of cream, consumed in the house. The milk was not regularly measured, but averaged about sixty quarts per day.”

It is sometimes an object to keep the cow as long as possible in milk. Some cows get very early; whilst others may be milked through, though always with disadvantage to both her and her calf—both being feeble and impaired, if it be persisted in. In summer weather, however, when cows are in high condition, and good milkers, it is not only sometimes advisable, but absolutely necessary. A cow not put to the bull will hold her milk much longer than one which is regularly breeding.

The spaying of milk cows is adopted by the veterinary schools of France; and much has been said in its favour by various continental authorities. A report on this subject was furnished to the Academy of Rheims, by M. P. Charlier, which spoke almost exclusively in its favour. The practice is an old one in both Germany and England. The object is supposed to be to increase the feeding propensities of the animals, but by no means for the purpose to which we refer, and which mainly occupies the attention of the French veterinary school—viz., the prolonging of the period of lactation. The report, which is very voluminous, furnishes a variety of experiments made on cows, old and young—some as far advanced in age as eighteen years; but, in order to realise all the promised advantages, the cow is said to be best when from four to eight years old. The operation is performed on the right side, and does not, altogether, occupy more than from four to ten minutes. It is seldom fatal, unless the cow is in calf. In some instances, the cows are said to go and feed as usual, even after the operation.

“The conclusions from the above report, endorsed by the reward of the society’s medal, were—that spaying increases the supply of milk from the animal after a few days; that there is a steady return of milk of the best quality, less liability to fall off milk, and no troublesome tendency to desire the bull; that in eighteen months the milk does not diminish; that the feeding tendencies of the cow are much increased, and the quality of the beef improved. Nay, it is further said, that in one dairy (the number of the cows not being given), a difference between spayed and unspayed cows, in milk, was 850 pints per annum; no great quantity, however, if it were a considerable dairy, and where, possibly, the best cows were spayed. There is, we must confess, a barbarity about this practice—needless, we believe—which makes our kinder feelings revolt at an operation performed for so little advantage, over the gentle, patient, harmless milk cow.”

REARING CALVES.

The rearing of calves is more or less pursued on every dairy farm; and, although every cow does not annually produce young, still heifers are usually put to the bull at two years old,
and the period of gestation varies from 275 to 290 days. Therefore, the old-fashioned mode, of reckoning three months back in the almanac, is not a difficult way of knowing the date at which a cow, put to the bull, may be expected to calve. She is nearly three years old when she produces her first calf, which is very often the produce of a very indifferent sire. In about six weeks after calving, the cow will be ready to take the bull again, although she may not hold; and if the month of June be suffered to expire before she is covered, she will be likely to calve at a time when it will be unprofitable to the breeder. Sometimes only the tenth of the cows of the dairyman are in calf, when he loses both milk and produce; but whether the cows are in calf, or only in an excited state, every twenty-one days it has a very unfavourable effect on the milk. To arrest this evil, numerous remedies have been suggested; among which are confinement, bleeding, abstinence at the time of bulling, or not permitting to have the bull for one return of the season. Some drench the cows with a pailful of cold water after the cow has been served, and some change the bull. Thus, every one has his own peculiar mode of acting, and, no doubt, every one thinks his own remedy the best. Where the loins are to be served, however, it is desirable to have this done in the morning, previous to milking. But sometimes the cow will not get into season; and here also the skill and ingenuity of mankind have been sorely tried in order to force her into an excited condition. Some try one thing, and some another; but, perhaps, the best plan to adopt is, to give the animal a quart of the milk of a cow that is in season; after this, it is said that, in three weeks, she will be ready for the bull, and a second return will be productive.

After the calf is produced, as a matter of course, it requires to be fed with such aliment as nature, at the commencement of life, has provided for it. No food, therefore, is better for the sucking animal than milk. In this it finds proteine compounds, or, in other words, flesh-forming substances, to supply materials for the development of muscle; lime and phosphoric acid, from which the inorganic part of the bones is formed; alkaline salts, which enter so largely into the composition of blood and other animal juices; sugar and fatty matters to supply the waste of carbon, which is thrown off during respiration, in the form of carbonic acid. Milk thus contains, within itself, all the elements necessary to the support of life, and, from this circumstance, is justly considered a most nutritious, as it is an universal food. The sucking animal is, by nature, created to suck this beverage, and is supported by it for a length of time, which varies in the young of different animals. There can be no doubt, that if the animal is too early deprived of the milk of its mother, it will suffer in its growth. On the other hand, the addition of milk to other food, properly proportioned to the necessities of the growing animal, promotes its growth, and assists in strengthening its constitution in a more than ordinary degree. Beyond a certain period, however, milk diet alone cannot be continued with profit; for it must be remembered that herbivorous animals naturally require a bulky food to preserve them in good condition. Young animals must gradually be reared on a more solid food than milk, as it is essential to stimulate all the different parts of the alimentary canal to a healthy activity. To bring up a calf for the butcher, is by no means a difficult process. It is only necessary to allow it to suck its mother for the requisite number of weeks, until it has attained to the size and fattiness suitable to the judgment of the buyer and the taste of the consumer.

"The materials usually employed for solid food," says the author of The Cow, "are, new milk, skimmed milk, meal-porridge, linseed-tea, and hay, grass, turnips, meal, potatoes, mangel-wurzel, &c. Some breeders—whose object is the calf, and the calf alone—sacrifice every other consideration to this. The breeders of short-horns, whose early maturity require a corresponding early supply of nutritious food, generally apply nature's own provision, and allow the calves to suck either their mother, or some other dam, or in some cases more than one cow, in order that they may develop their precocious and distinctive qualities. This practice they often continue for six or twelve months. It is, however, an expensive mode of feeding for those who rear only ordinary cattle for the market. Moreover, some are so 'stingy,' that as soon as the
CATTLE, AND THEIR VARIETIES.

Cow ceases to give 'beesting,' they begin to give the calves skimmed milk. A process of this kind does irreparable injury to the young animal.

"The best mode, with ordinary calves, is to give new milk for at least fourteen days after the calving. There are two modes of doing this: either to allow them to suck the dam, or to remove them as soon as calved, but train them to drink in the first instance. For ourselves, we think that taking away the calf is both cruel and unnatural. The healthiness of the mother, we consider, depends upon it. We invariably allow the presence of the calf for at least a fortnight. We suffer the mother to lick over the whole of her offspring, because we think that a privation of this medicine of nature, is a cause of many a valuable animal being lost. After the first fourteen days, we mix one-half new, and one-half skimmed milk, for fourteen days more; this skimmed milk is scalded nearly to the boiling point, set aside to cool, and given to the animal. One great secret in the successful rearing of calves, is to give them frequently small quantities of food at a time. For the first fortnight the calf ought to be fed, at least, four times per day. About a quart at a time will be necessary; which quantity may be increased afterwards, as the animal's wants may require it. Soon after this the skim-milk time commences, when the animal, if properly trained, will begin to eat the solid food." In young and growing stock, the process of renewing, or building up the system, proceeds much more rapidly than it does in the full-grown animal. Science, therefore, has demonstrated that the food should contain a large supply of flesh-forming principles, and of phosphates, from which the bones are formed. These are plentifully supplied to the animal by the grain of barley, oats, and wheat, which also contain large proportions of gluten, albumen, and other nitrogenised organic compounds, which supply the young animal with: the materials of which the muscles consist. In peas and beans there are still larger proportions of muscle-making materials. The addition of these in a state reduced to meal, to the food of growing stock, if not otherwise detrimental to the general health, will have great influence in accelerating the growth of the fleshy parts. On the whole, then, it may be concluded that the young and growing stock require a more concentrated food than is required by animals which have arrived at maturity. The plan of Mr. Huxtable has been very freely discussed, as it is proposed to accomplish the feeding of calves at a much cheaper rate than was usually done by other breeders. We subjoin his mode, with that of Mr. Nicholson, a Scotch breeder.

In drawing this chapter to a close, we must
recommend that especial attention to cleanliness in the keeping of all animals, whether old or young, should form an essential portion of the duty of their keepers. In the earlier stages of the life of the calf, it is extremely bad policy to stint it in its food. "That calf," says the author of The Cow, "may be said to be always fed which never loses its first layer; and, as the difference is often a question in after-fattening, of some six months of keep, there can be no question that it is of the greatest importance to keep it well at first. Giving the calf that food which is easy of digestion, and suited to its feeble stomach, in early life, allowing it especially its mother's milk, the breastings and the soothing influence of its mother's tongue—weaning it from new milk gradually and cautiously, with a plentiful allowance of good sweet hay, are the real elements of success in calf breeding. This course, with a proper attention to air, warmth, exercise, and cleanliness, is all that is required in the proper management of young calves; and will generally be found sufficient for their health."

CHAPTER V.

MANAGEMENT OF THE DAIRY.—GENERAL OBSERVATIONS; BUTTER AND CHEESE; THE ART OF MILKING; PRESERVATION OF MILK; THE DAIRY.

GENERAL OBSERVATIONS.

Amongst the almost endless varieties of form in which food is used for the sustenance of animal life, there is none in which it appears to be so universal as in that of milk. In this form this liquid assumes the utmost importance. It is the first aliment with which the young of the whole class of the mammalia of natural history is nourished. The lactiferous teats are, to those, the earliest objects of their search; and the instinctive power with which nature has supplied them to seek, find, and use them, so soon after their birth, is one of the very remarkable phenomena which have excited the wonder of mankind. As the food of the rustic, as well as the citizen, it also takes a prominent place. To the young especially it is exceedingly grateful; whilst, in the shape of cream, it flavours the coffee and the tea of the poor, as well as the plough-boy. Its butter is spread over their bread, and softens and enriches their pastry. In the form of cheese it becomes the diet of the poor, and, in the same form, frequently finishes the repast of the wealthy. A beverage, therefore, so agreeable in itself, and so universally valuable in its products, has necessarily, in all ages, received a high share of consideration in the sight of mankind. In the females of the class mammalia, it is white and opaque, having a sweetish taste, and a specific gravity somewhat greater than that of water. When it is allowed to remain at rest, it separates into a thick white fluid, called cream, which collects on the surface, and the fluid beneath which is more watery. The quantity of cream obtained from milk, and the time it requires to separate, vary according to the nature of the milk, and the temperature of the atmosphere. When the milk is allowed to stand after the spontaneous separation of the cream, it first becomes accecent, and then coagulates. When the coagulum is pressed gently, a serous fluid is forced out, and the remainder is the caseous part, or pure cheese.

BUTTER AND CHEESE.

Butter and cheese are obtained artificially: the former by the operation of churning; and the milk which remains after the butter has been separated, or, as it is called, the buttermilk, has all the properties of milk from which the cream has been separated. Cheese is obtained by the addition of rennet to the milk, which is prepared by digesting the inner coat of the stomach of young sucking animals, especially that of the calf. The quality of the

075
cheese depends upon the quantity of cream remaining in the milk. The best cheese is obtained by coagulating the milk at the temperature of 100°, and expressing the whey slowly and gradually, without breaking down the curd. Whey expressed from coagulated milk, if boiled, and the whole curd precipitated, becomes transparent and colourless. By slow evaporation it deposits crystals of sugar, with some muriate of potash, muriate of soda, and phosphate of lime. The liquid which remains, after the separation of the salts, is converted, by cooling, into a gelatinous substance. If whey be kept, it becomes sour by the formation of the lactic acid; and it is to this that the spontaneous coagulation of milk is owing. Milk may, after it is sour, be fermented, and it will yield a vinous intoxicating liquor; it is likewise susceptible of the acetous fermentation. In the former state it is used by some of the inhabitants of the north-east of Asia, for intoxicating purposes. The constituent parts which enter into the composition of milk, are water, oil, curd, gelatine, sugar of milk, muriate of soda, muriate of potash, phosphate of lime, and sulphur.

The milk of various animals is composed of nearly the same substances; but the proportions vary so much as to give them very different properties. Every kind of milk produces cream. In that of the cow it is capious, thick, and yellow. Goat's milk produces abundance, and it is thicker and whiter than that of the cow. Ewe's milk produces as much as that of the cow, and of nearly the same colour. The cream from asses' milk is white and liquid. In mare's milk it is very fluid, and similar in colour and consistence to good cow's milk before the cream appears on the surface. Butter obtained from the milk of the cow differs in colour, but has always much consistency. The butter of asses' milk is white and soft, and disposed to be rancid. That from goat's milk is abundant, white, and soft. That from ewe's milk is yellow and soft; that from mare's milk has little consistence, and is readily decomposed. The caseous part of milk varies in different animals. That from the milk of the cow is bulky, and retains much serum. The curd of asses' milk has but a small portion of whey; it is not mucous. Curd from the milk of the goat is abundant, of a firmer consistence than that of the cow, and retains less whey. Curd from ewe's milk is fat and viscid; that from mare's milk is very similar to what is obtained from the milk of the ass. The serum, or whey, constitutes a great proportion of the milk. That from the milk of the cow has a greenish cast, and a sweet taste; containing sugar of milk and neutral salts. The whey of asses' milk is colourless, and contains less salts and more sugar than that of the cow. Whey of the goat is yellowish, and contains very little sugar and saline matter. The latter is muriate of lime. The whey of ewe's milk is always colourless, and contains the smallest quantity of sugar, and but a small portion of muriate and phosphate of lime. That of mare's milk has little colour, and contains a large proportion of saccharine matter, and of saline substances.

When milk is analysed, it is found to contain 87 parts of water, rather more than 4½ parts of sugar, and a little more than 3 parts of butter, something beyond one-half of saline matter, and 4½ parts of cheesy matter (curd or casein). Its weight, whilst holding them in a state of suspension and solution, is about 3 per cent. greater than that of water. The milk of different animals, however, as we have already hinted, contains different proportions; and this differs again according to the breed, treatment, and food of the animals. The following represents a few of these differences:

</table>

The object of the dairyman is sometimes to assist, and sometimes to retard, the natural stages of decomposition into which milk will run when left to itself; and as it is sometimes necessary to defer, as it is equally necessary to hasten these degrees, all the appliances of modern art requisite to perform them are now at his disposal. Heat is necessary to all stages of this action. Hence, in winter, he can easily arrest, and, by artificial means, as easily advance the manipulations of his craft; but, in summer, it is not so easy to effect his
purpose. Thus, he has often to be in his dairy during summer, to see that the rays of the sun are not exercising an undue influence upon his milk; whilst, by other means, he endeavours to preserve it at a temperature that will keep it from receiving such injury as an improper amount of heat may cause to it. The process through which milk must be made to pass, when intended to produce butter, is not the least difficult portion of the business of the dairyman. Commencing with new milk, it is by no means necessary that the cream should be separated from it. For the production of this article, Mr. Milburn observes, that there are two different modes of breaking the globules of caseine. "One is by the application of a gradually-increasing, gentle heat to the new milk, until the buttery matter floats at the top, which is then taken almost in a boiling state, and churned to butter in a very few minutes. The other is, by at once applying the beaters of the churn to the whole mass of the milk; but, as the bulk of liquid is so much greater in the latter case than the former, and skim-milk is of greater value than butter-milk, this is much less frequently resorted to. Generally the cream is allowed time to ferment. This process aids in breaking down the structure of the enveloping skin, in precipitating the caseine of the mass, and thus assisting the maturation and development of the butter. In churning, the heat of the mass rises from 5° to 10°; and, in very cold weather, it is sometimes necessary to pour in boiling-water, in order to attain the necessary heat. This heat is also indispensable in separating the cream. At a temperature nearly freezing, it will rise with difficulty. Perhaps the most regular and healthy temperature is 55°; but, so rapidly does it rise at 76° or 77°, as to require great skill and attention to prevent the whole mass becoming sour. At the first-named temperature it will be perfectly raised in twenty-four hours; but in the latter state of the temperature it will be complete in ten or twelve hours. As the globules have to rise by specific gravity chiefly, it is desirable that the milk should be disposed in shallow dishes. Glass is clean and beautiful, and porcelain is fashionable; but lead is the old-fashioned and useful medium; it retains the heat of the hot water from the scalding process in winter, and slowly conducts the heat after the cooling from evaporation in summer. The desirable temperature in churning cream is 54° to 55°—a degree of heat preservable only in summer by early churning, and in winter by raising the temperature with boiling-water, and heating the cream at the fire before placing it in the churn, or by adding boiling-water to the mass in the churn."

Having noticed several of the different kinds of matter which milk contains, we must not overlook the smell or aroma which it sometimes emits, in accordance with the kind of food consumed by the cow. It is generally supposed that this animal feeds on buttercups, and that these must necessarily taint the butter with some degree of their natural bitterness. The cow, however, in every possible way, does its best to avoid the buttercup, which is a nauseous, bitter herb; and, in walking through pastures as bare as possible, it is left in all its luxuriance. We have frequently watched cows tearing away the grass round a buttercup plant (Ranunculus bulbosus), and leaving it untouched, with every particle of grass cropped close round it. Indeed, pastures may be seen apparently most luxuriant, but, on a nicer inspection, there is nothing but buttercups left. Farmers like to see buttercups, because they prefer good, sound, dry, old pastures, and the remainder of the herbage is generally good. But cows avoid them as much as possible. Along the valley of the Trent this plant remains untouched by cattle; and, during the month of May, field after field may be seen sheeted with its living gold. We do not think cattle reject it on account of its bitter character. Cows eat many bitter and disagreeable plants with avidity. There is a plant, called the bog-bane or buck-bean, which grows in marshy places, having a taste intensely bitter. In spring we have frequently noticed that the cattle tear up every particle as fast as it springs; indeed, it is eaten so fast that they never allow it to flower. There is another plant which is eaten with avidity by cattle, the flavour of which is very disagreeable—the broad-leaved garlic (Allium ursinum). In some parts of the valley of the Trent this plant grows profusely, and flowers about the end of May, or beginning of June. At
CATTLE, AND THEIR VARIETIES.  

CHURNING.]  

this period it causes great annoyance to the dairy farmer, for the cows then eat it, and a very unpleasant flavour is imparted to the milk and butter. We have heard of a person who kept a cow in a meadow where it grew abundantly, and who was obliged, during the flowering season, to take her out and depasture her on the higher ground, as no sale could be met with for the butter on account of its disagreeable flavour. The milk was not discoloured, and the flavour was brought out more strongly by the process of churning.

In the case of turnips, the smell of the milk is very disagreeable; and the butter produced from the milk of a cow fed on these, will even impart a portion of its flavour to any pastry that may be made with it. In order to give butter a pleasing colour, some colouring matter is usually mixed with it. For this purpose, in most cases, annatto is used; but the best colouring is the juice of carrots, which has the advantage of being entirely free from injurious tendencies.

After a cow has calved, her milk is thick, and deeply tinged with a yellow hue, when it is termed the “beestings,” or “beastings.” It is then more abundantly supplied with caseine, or curd, which is sold for the purpose of making cheese-cakes. The strippings, or afterlings, is the last milk which is taken from the udder of the cow, and is by far the most plentifully endued with the cheese and butter elements. From a knowledge of this fact, many dairymen make it a practice always to strip their cows themselves, notwithstanding that the principal part of the milking may have been performed by their servants.

The operation of churning is, when most quickly performed, generally most successful; but, should the cows have been long calved, and the weather cold and stormy, the process becomes considerably protracted, and instead of twenty minutes—the time allowed for a brisk turning in favourable weather—it may extend to ten, twelve, or even fourteen hours. When butter first makes its appearance, it is said to be in “skill,” a technicality expressive of the sensuous matter being separated from the butyricaceous. When an adherence of the small particles of butter with each other commences to show itself, the rapidity of the motion must be lessened, and the butter-milk, to some extent, let off, when the gathering process will begin, and, in about ten minutes, be completed. About 55° is the best heat to churn with; but it sometimes requires more. Respecting the form of the churn, opinions differ; but the grand object in the constructing of this machine, ought to be to secure the greatest facility of operation, combined with a quick, steady, though accompanied with a trembling or quivering pressure of the contents. In churns generally, this is accomplished by various mechanical contrivances, every one of which has its merits. The most common, however, is the form of churn which has a cylinder studded with plates, pierced with holes, attached to its inner surface, revolving round a couple of axes, and admitting of one or two handles, in accordance with the weight or quantity of the cream. Another kind of churn is made with a flapper, which is, with great rapidity, driven through the cream by means of a piston, with a perforated base, and by up and down, or perpendicular motion, either in a cylinder, or vessel similarly formed. Plans have been conceived by which the labour of churning might be lightened; but we are not aware that they have been attended with much success. The American, and the table churns, available for the immediate manufacture of butter every morning for the breakfast of the rich, are so far a step in advance, and a luxury; but for the large operation of the dairy farmer, a better application than the churn of his forefathers, we believe, has yet to be discovered.

The true method of butter-making, is to have the churn, and the temperature of the dairy, arranged so as to preserve, as nearly as possible, the degree of heat necessary to the perfect separation of the cream. It should not be so high as to impart a too great degree of sourness to the contents; but, if it be too cold, the butter will not separate effectually; whilst the operation of churning will be extremely tedious, render the butter full of breaks, make it brittle in texture, and give it a pale colour. These will be the results of a too cold temperature; whilst a too hot temperature will make it both light and oily. Another essential point towards the production of good butter is, that the cows, from whose milk it is to be made, should not have calved.
too long. Should this have been the case, the butter will have a bitter taste, and be desti-
tute of that agreeable flavour which ought to form an important element in every kind of
dairy produce. The best butter is supposed, by some, to be made from one-half of sourd
cream, and the remainder from fresh. The reason assigned for this is, that there is a
sufficiency of the lactic acid in this portion to facilitate the operation of churning; whilst,
in the remainder, there will be enough of the caseous matter to prevent insipidity in the
butyricaceous mass. Let it always be re-
membered, that if a rancid or disagreeable
taste be imparted to butter, it is no longer fit
for the table; it cannot be used for the pur-
poses for which it is essentially made; although
it may be so far restored, or improved from its
disagreeable state, as to become suitable for
pastry purposes. As the unpleasant acids
with which it may be suffused are all, to a
certain extent, soluble in water, the butter
should be immersed in clear, fresh spring
water, then placed over a slow fire, and kept
there until the liquid boils. It should then
be skimmed, and the butter put into fresh
cold water, again to undergo the boiling pro-
cess. After this it should be thoroughly
washed, when it will be freed from many of
its impurities, and may be very well adapted
for pastry, although it will be too insipid for
the table. When butter has to be preserved, or
packed for transportation, the author of The
Cow directs that it should be salted. "If it is
to be moved far, it may be necessary to pack
it well, and exclude the air. Hence, when it
is made on a large scale, it is put in firkins, or
casks, holding from three to five stones, which
are carefully fastened up by the cooper, so as
to exclude the air. Salt is well known to
have the power of preventing animal matter
from falling into the putrefactive state, by
means of its peculiar antiseptic power, which
prevents the caseous matter of the butter
from becoming putrid, and running into decay.
But such is the affinity of salt for the moisture
of the atmosphere, that the outer portions of
the butter soon become subject to the changes
which contact with the atmosphere produces.
In order, therefore, to keep it for any length
of time, it must either be covered with a
saturated solution of salt, or with a syrup of
sugar, which has the same effect. Others so
it must be placed in casks which are air-tight,
or nearly so, with the top and bottom draped
with salt. In fact, the more the moisture is
protected from the atmosphere, the more closely
will the wood of the cask adhere, and rice
versèd. A very important means of preser-
vation is thus afforded to the dairyman, and to
the inhabitants of our large towns; for without
this, even with all our facilities of railway
transit, it is difficult to conceive how a constant
supply could be maintained. The firkins made
in summer are opened in winter; and, though
not so rich in their contents as the fresh
products from the dairy, they form a second-
rate class of butter by no means disagreeable,
called kennel butter. When these are opened
for use, a very free washing should be given
them, to wash out the soluble lactic acid; and
the butter should afterwards be well washed,
and kneaded in new milk. This gives it much
freshness and flavour, which improves and
renders it, if well made and packed, much
more pleasant than some of the turnip-flavoured
fresh butter made in winter."

In France, Bretagne butter has obtained
great celebrity, for which it is almost entirely
indebted to the mode of its manufacture. The
immense sale which it has, necessitates it to
be made in large quantities, and this circum-
stance greatly improves its qualities. The
manner in which it is produced for the market
is by no means complicated. After being
churned and washed, it is steeped, or sprinkled
abundantly with new milk. It is then kneaded
into cakes of a cylindrical form, and placed,
for a few minutes, in a kind of cylindrical
frying-pan, with heated coke both below and
above. After this, it is taken out in a con-
dition ready for immediate use. Although
the flavour of this butter is peculiar, it is es-
pecially rich.

Butter does not seem to have met with the
same favour among the ancients that it has
generally among the moderns. It was late
before the Greeks appear to have had any
notion of butter; their poets make no mention
of it, and yet are frequently speaking of milk
and cheese. The Romans used butter no
otherwise than as a medicine, never as a food.
The ancient Christians of Egypt burnt butter
in their lamps instead of oil; and in the
Roman churches it wasanciently allowed, during Christmas time, to burn butter instead of oil, on account of the great consumption of it other ways.

The principles of Cheese-making, in many respects, are those applied to the manufacture of butter; but the objects being, to a certain extent, different, they are applied in a way quite distinctive from the other. They all, however, centre in the artificial development of the caseine of the milk, whether that be new or skimmed. If left to itself, the lactic acid (into which the sugar of milk is changed), it has been observed, soon begins to form, when the air and temperature have arrived at that condition which is favourable to its development. If to this mixture heat is applied, to such an extent as to cause the caseous matter to expand, genuine curd, fit for the manufacture of cheese, would be the result; but the cheese would be unpalatable, hard, and brittle, and the process too slow for the purposes of commerce. Hence it is necessary to introduce some kind of substance to facilitate the change. Lactic acid, added naturally or artificially, combines with the soda which holds the caseine in solution, and will form lactate of soda. Here the acid will, with the addition of a little heat, be developed; and, in order to accomplish this, various means have been adopted. The usual addition which is made for the effecting of this object, is that of the stomach of the calf, or some ruminating animal. In its natural state, the stomach of the calf causes the milk to curdle, and frequently this curdled milk forms the contents of the calf's stomach. The animal having first had a full meal of milk given to it, is withdrawn, and made use of to turn the milk into that state which is necessary for the ultimate production of cheese. This, however, is not necessary, for the stomach itself will effect the desired change. Let this be well washed and chopped up into pieces. Let these steep in water, say for ten or twelve months, until it is reduced either to a liquid or a powder, and this will turn the milk. Even the skin itself will cause the milk to congeal. An idea prevailed, and to some extent, no doubt, does still prevail, that it is the gastric juice of the stomach which produces the change in the milk; but although that liquid would produce it, it has now been satisfactorily proved that the change is effected by some acid in the structure of the rennet itself, especially in such a case as that to which we have referred—namely, when the stomach is used after having been steeped for twelve months in water. The coagulating process, however, may be effected by other means than by the rennet. Vinegar, tartaric acid, alum, and even milk itself, have all been used with success, under circumstances favourable to the operation. In reference to new-milk-cheese, the whole of the milk, immediately it has been obtained from the cow, and passed through a sieve, is subjected to the action of the rennet. "In cases," says the author of The Cow, "when a full meal of milk will not produce a cheese, the milk of the evening is reserved till the morning, both added together, and the rennet pored upon the mass. As something like 95° is the heat at which coagulation and contraction of the curd is performed with the greatest rapidity, the milk should be raised to about that degree. If more heat than that is given, the cheese will be tough and waxy; if less, there is some difficulty, owing to its softness, in separating the cheesy from the watery matter. In cold weather, a small quantity of hot water has to be added to the new milk with the rennet; but if much water is added, or the temperature interfered with more than necessary, it injures the quality of the cheese." When this part has been satisfactorily effected, the cutting-up of the curd is the next step to be taken in the manufacturing of cheese. This is to separate it from the whey—an operation in which a considerable degree of care is required to be properly done. If affected rapidly, or in a slovenly manner, the mass will burst, and the butyraceous particles be pressed out. This duty must not be postponed after the curd is formed, or the whey will have more butter than ought properly to belong to it. To drain away the whey held loose in attraction by the curd, this must be cut in pieces, and laid in a strainer; then, by light and equable pressure, the remaining portion of the whey must be taken off. In effecting this, the pressure, at first, should be slight, but afterwards it may be increased, as the curd, with the evacuation of the whey, gains greater power to retain the fatty matter.
At the commencement of the process, between forty and fifty pounds is as great a weight as it may be judicious to give the mass. Nearly the whole secret of cheese-making, says Mr. Milburn, "depends upon thoroughly draining off the whey. This carries off the sugary matter of the milk, the lactic acid, and, perhaps, also the rennet. These substances are so liable to undergo changes, that cheese-making altogether depends upon this process being properly attended to. In some places even the curd is washed; for little injury, beyond the danger of washing out some of the butyricaceous matter, would be sustained, compared to the loss incurred, if the cheese were suffered to retain any considerable portion of the whey. Besides, as butter is sometimes churned from this whey, the loss is made up to the dairyman, if not to the consumer, in another way. So powerful is the tendency of the albuminous matter of the caseine to putrefy, that even cheese itself will not keep unless the salting process, in one shape or another, is adopted. This is performed in the manner most favourable to the production of the peculiar kind of cheese for which a district may be famous, and is either added to the curd, or rubbed in after the cheese is made and strained. Such is the affinity of salt for moisture, that it will soon permeate the whole mass of the cheese, and preserve the caseine from putrefaction by its peculiar antiseptic qualities."

In making cheese, the most scrupulous cleanliness should be observed, as the flavour of that article is often much more easily injured even than that of butter. The inoculation of cheese is one of the refinements of modern taste and luxury. A blue mould is, by some, considered the sine qua non of a tasty cheese; while others prefer the decay to be grey, and the cheese to be in a state of putrefaction, so absolute as to be soft and wet—a nidus for mites and thejumpers. If it be desired to give to a cheese, especially a Stilton, the flavour peculiar to one of its kind, it may easily be accomplished. A dozen holes may be made in the specimen to be operated upon, with the common cheese-trier, and the pieces taken away. The same trier may cut as many pieces out of the favourite cheese, and insert them in the places from which the others were removed. This, covered up in a close place for a month, will, if free from mould before, turn out absolutely ripe, and be of the same flavour as the cheese from which it was inoculated.

The Art of Milking.

The art of milking well is not taught in a hurry. It requires long practice to milk properly; and therefore all the young people on a farm ought to be shown how the labour should be done. It is quite important that this branch of the dairy should be particularly attended to, for a good milker obtains at least a quart more from the same cow than a poor milker. The first lesson to be taught to young people is gentleness and kindness to the cows. These never need be treated harshly, if the business is properly commenced. Cows that have been caressed, and uniformly well treated, are fond of having the milk drawn from the udder at the regular time of milking, for it gives them relief from the distension of the milk ducts. Let young people be put to milking the fawcowks first, or such as are to be soon dried, and then the loss from bad milking will be less injurious; the hands should extend to the extremity of the teats, for the milk is then drawn easier. They should be taught to milk as fast as possible. More milk is always obtained by a rapid milker than by a slow one. They should therefore be taught to think of nothing else while milking, and no conversation must be permitted in the milk-yard. They should sit up close to the cow, and rest the left arm gently against her shank. Then, if she raises her foot on account of pain occasioned by soreness of the teats, the nearer the milker sits to her, and the harder he presses his left arm against her leg, the less risk will he run of being injured. Cows may be taught to give down their milk at once; and they may be taught to hold it a long while, and to be stripped indefinitely. The best way is to milk quick, and not use the cow to a long stripping, or an after-stripping.

"The most important part, in the operation of milking," remarks the author of The Cow, "is perhaps to milk clean—to take out the whole of the milk from the udder. Not only is the last portion the richest in cream and in butter, but there is not a more certain way of drying a cow than allowing a part of her milk
CATTLE, AND THEIR VARIETIES.

Milking should always be performed the very first thing in the morning; never later than five o'clock in summer, and six in winter. In the evening it may be done at five; and regularity, in this respect, should punctually be observed. If distant, cows should not be driven home, but the milk should be carried from the field; for a great waste of milk will take place, if they are driven about. If under cover, their food should be given them whilst being milked. It assists to quiet them, and makes them part with the liquid the more freely; and as most milk-cows, in winter and spring at least, have mush, it is desirable to give them this during the milking, the first thing in the morning.

Several attempts have been made to accomplish the milking by other means than the hand. Syphons have been invented, which were alleged to have the peculiarity of emptying the udder without the use of the hand. But they have not been found so successful as to obtain any extensive encouragement. Indeed, we question if they have ever been heard of by many large agriculturists. The syphon was constructed on an erroneous principle, by distending the mouth of the inner duct of the milk in the teats. This subjects the cow to a flaccid state of teat, and is very likely to cause her to commit the fault of milking herself.

There is a plan, in use in the United States, which proceeds on the principles of compression and suction, and which are the only modes of overcoming the tension of the udder. The American instrument consists of four india-rubber bags, which are drawn over the teats, and set so as to be air-tight. "At the lower end of these, metallic tubes, with taps, are inserted. When the adjustment is perfect the taps are turned, and the whole of the milk in the udder is said to be thoroughly exhausted, and in half the time required for hand-milking. It is said that a man can milk ten cows thoroughly in fifteen minutes."

A novel, and somewhat extraordinary experiment on milk-cows, was not long ago made by M. Delamarre, at Paris. After the fifth or sixth gestation, and five or six weeks after calving, the cow underwent an operation, by which she was deprived of her ovaries, in order to render her unfit for subsequent reproduction. This operation, though known to
the ancients, in modern times has only been practised partially for some years. It can now be performed without external incision, and with little danger. By this means the nature of the animal is changed, and the successions of rut, gestation, and parturition disappear. In this new state, the milk becomes regular, and is yielded in full abundance for a whole year, and in smaller quantity, but improved quality, for two, or even three years, provided the animal is not too old. When the lactation ceases, this animal, which, during a calm and tranquil life, has gained the development and fatness necessary for the market, can be delivered to the butcher in perfect condition, its flesh much superior to that of ordinary cattle. Thus, not only is better milk given, but better beef is produced. This milk is more abundant in cream than usual, and it is equally rich in "caseinum," which forms the nourishing principle in milk. The butter extracted from it is exquisite in taste, testifying the abundance and richness of the casein. This milk is found, moreover, excellent for nourishing infants, who instinctively prefer it to any other.

**Preservation of Milk.**

For this purpose, various plans have been adopted, notwithstanding that the ingredients of which milk is composed are so various and changeable in their nature, that it is more difficult than might at first be supposed, to preserve it with success. The Dutch mix their milk with carbonate of magnesia, which thickens it, and prevents it from souring. This, or some other alkaline mixture, has the effect of preserving it for a short time, especially in winter, by forming a salt with the lactic acid, and by keeping the casein in a state of solution. Carbonate of soda will produce a similar action; and it is believed by some to improve the tendency of the cream to separate from the milk. Another plan is to bottle the new milk, and immerse them in a pan of cold water, placing this on the fire until the water boils. The air in the bottles thus becomes rarified; and, if corked up hot, the milk can be kept for a considerable time in a state of comparative freshness, to be used immediately the bottles are opened. The addition of a few grains of carbonate of soda will greatly improve its keeping qualities. It should also, after this, be kept as cool as possible. M. Adépert's method is to subject the milk to a heat so gentle, that the great bulk of the purely watery particles will be evaporated; then to be closely corked up. This has a far greater tendency to resist decomposition than if the whole of the watery particles were still retained as an element in the beverage. If, while hot, it were boiled in the bottles in which it was to be finally corked up, as in the instance above, with a small addition of soda, it might keep in a palatable condition for a considerable period—not indeed to compete with newly-produced milk, but to be a luxury on board a ship far out at sea, without any fresh supply of that nutritious article. Ducholl, a Russian chemist, goes beyond Adépert, and professes to furnish a supply of milk for any length of time, to be used at pleasure. It is by forming essentially a milk powder. He proposes to evaporate from the milk, by a slow fire, the whole of the watery matter, and thus have a solid and pulvulent mass, which may be kept in a small compass in a bottle, and, when required, be dissolved in a proper quantity of water; and, as milk contains water in the ratio of nearly nine-tenths of its substance, it may, possibly, be much reduced in compass, and made capable of being produced extemporaneously at pleasure. This would supply a great desideratum.

**The Dairy.**

The dairy should be kept apart from the house, from open grates and from dung-heaps, and should, as far as possible, be so regulated as to preserve an equable temperature.

What its construction ought to be is thus described:—"As, however, it is much easier to keep a cold building warm, than to cool a hot one, it is desirable that it should be, as much as possible, shielded from the sun's rays. It should have its side to the north, its end to the east, and, if possible, be let into the earth a few feet, but not so deep as to interfere with the drainage. If covered by a large tree, it would be all the better. Around it should be either a hollow wall, or peat earth should be walled round its exterior; or, as another alternative, and possibly the best, but most expensive, it should be surrounded by a
CHAPTER VI.

DISEASES OF CATTLE, AND THEIR REMEDIES.

There is no part of our subject capable of giving less satisfaction than that which treats of the diseases of cattle, insomuch as it is very difficult to know what is the precise nature of the complaint with which any dumb animal may be afflicted, and therefore it is surrounded with a darkness which cannot be dissipated without both an enlarged and an enlightened experience. The extremes of temperature, or the sudden transitions from heat to cold, are frequently the causes of disease in young cattle. It is, in many parts, a common practice to tie up animals, of different ages, in the winter, with the view of depasturing them in the following spring. Generally speaking, cattle buildings are quite inadequate for such a purpose. They are frequently in a wretched condition; there is seldom drainage for the liquid matters below, or free ventilation for the exit of foul aerial matters above. Such a condition of things may do for fattening beasts, because in such a warm, close atmosphere, the respiration is but little exercised, and, the blood being but imperfectly decarbonised, fat will more readily accumulate. Under such conditions the vital processes naturally become weakened, without, perhaps, disturbing any particular organ; and, on the cattle being turned from their warm quarters in the spring into the open fields—oftentimes, too, with very little hair on their backs—for, from the hot-house system of management which they have undergone, they are prematurely preparing to put on their summer coats—disease is induced in various ways. The sudden transition from heat to cold produces internal congestion, of the liver in particular, which has been stimulated throughout the winter with highly carbonised blood; and, hence, diarrhoea and dysentery are a common occurrence. Catarch is also produced from the same influence, and sometimes bronchitis, which is a highly dangerous disease, and requires prompt attention, and all the aid that veterinary skill can afford. When the disease reaches the bronch, the cough has a frequently painful husky sound, and is easily recognised by the anxious, haggard look, and rapid laborious breathing which the poor animal exhibits. In favourable contrast to this mode of wintering store-cattle, is that of keeping them in small yards, having comfortable roomy sheds attached, where they are sorted, according to age, and supplied with a fair allowance of roots, hay, cake, or corn.—In cases of consumption and chronic diarrhoea, there is generally an hereditary taint; and breeders should beware of breeding from stock having such predispositions. It is also a very reprehensible practice to rear calves on skimmed milk, or to supply
them with insufficient or unwholesome food. Many diseases spring from this. By depriving the milk of its cream, the greater portion of the muscle and fat-forming principles is removed, whilst the phosphates are rather in excess; and hence the origin of such a number of sharp-backed, flat-ridden, coarse beasts, which devour more food than stock of a better description, and, when fattened, present nothing but coarse beef, having scarcely a joint fit for the shop of a respectable butcher. Breeders of calves would find it advantageous to accustom them to consume small quantities of linseed cake when about six weeks old, and this increased in proportion as the milk is withdrawn. When the weaning takes place, the allowance of cake should be still further increased, which will prevent the check so commonly produced in their growth at this period, as shown by their large bellies, and dry and thrifty appearance. The cake should be continued until the calves are so accustomed to the grass as to be able to dispense with it. It may be imagined that this system of feeding may increase the liability to inflammatory fever, or felon, to which stock at this age, as well as yearlings, are exceedingly disposed; but, to prevent this, farmers should increase the strength and constitutions of their young stock—a condition not obtained by excess of food at any one time, but by regular feeding and proper management.

An imperfect system of drainage of soil is another fruitful source of disease in calves and yearlings. During periods of moist, warm weather, on undrained soils, a disease called "hoose" frequently prevails. The windpipe and bronchi become filled with masses of worms (Strongylus fibaria) and mucus, occasioning violent inflammation of the membranes of the air-passages. As these remarks apply only to the more prominent of diseases in cattle, we may observe that inattention to first symptoms often terminates in fatal affections. The majority of such cases which occur on a farm, proceed from not attending to the premonitory signs of disease. These, in cattle, are usually recognised by the animal showing a loathing for food; suspended ruminination, or lazily performed; the muzzle dry, instead of being dewed; respiration increased; hair pitched, and not licked. When these symptoms, or any of them, make their appearance, it may be taken as a certain sign that disease is approaching; and it becomes a duty to act without delay, as, by doing so, the disease may be mitigated or arrested. Very little attention to the causes of disease must show that they are commonly the result of mismanagement, rather than of accident or of circumstances which cannot be controlled; even the agencies inducing epizootic and contagious diseases may be guarded against, or considerably modified, by proper and regular feeding, good drainage, and suitable yards, sheds, and farm-buildings. The great secret of keeping all animals, however, is to tend them carefully and keep them well. Let the land, which is thought to be subject to disease, be thoroughly drained as well as farmed; let the bad herbage and cold beds of the cattle be improved, and they will be healthier, and thrive better. It is safer always to pay the cake-crusher or the miller, than to pay the veterinary surgeon, however skilled he may be.

Blown, Hove, or Over-Full.—Sometimes a change of food, or a feed of wet clover, or potatoes greedily eaten, will induce fermentation in the stomach, instead of digestion. The sides will be blown up, until the stomach presses on the skin with a force which renders it hard to the fingers. In treating for this disease, by far the best method is to use the probang. It should be introduced to the stomach by the throat, and then the foul air will generally immediately escape. When this instrument is not at hand, the beast may lie down, and the disease may continue till the walls of the stomach are ruptured. In these cases an ounce of ammonia will often give relief. A pint of vinegar has been known to effect it; but the safest remedy is a pint of linseed oil. Use gentle exercise; but all kinds of violence, and, above all, such doses as tar and salt, given with the idea of making them eject their saliva, can only do harm. When it is necessary to cut into the stomach, employ a veterinary surgeon.

Calving.—Strictly speaking, this cannot be called a disease; but it ought not to be entirely overlooked in a work of this kind; for, in some cases, more especially in the first or second instances of parturition, there is great danger of the birth not being effectuated without.
mechanical assistance. After this, however, the danger is not so probable, provided the proper presentation takes place. It has been said, that such animals as bring forth their young without any attention whatever, do the best; and we have no doubt that much could be said in favour of this observation; but whether it be true or not, there is no question that premature interference is more likely to be attended with unsatisfactory results, than if the animal were left entirely in the hands of nature. The first decided symptoms of coming labour, exhibit themselves in what is called "the waters," after which the calf will apparently feel perfectly at ease for an hour or so, and sometimes eat a little food. The second being thicker and larger, envelops the feet of the calf. When both symptoms appear, a little mechanical assistance may, with safety, be given, should the head be found above and between them. Above all things, time should be given for nature to work out her own operation, and the calf will appear in due time. In cases of false presentation—such as the appearance of the head, a single foot, or the hind legs—it is, at all times, the best plan to call in the aid of a veterinary practitioner. "Some persons," says the author of The Cow, "have the practice of giving every cow a calving drink. We uniformly prefer, as we said, nature's medicine—the licking of the calf—to any and all others which can be given. If it has been a long and protracted labour, a drink of a quart of home-brewed ale, or a pound of treacle, will be found useful. If the cow refuses to lick the calf—which heifers of their first calves will sometimes do—it is seldom necessary to do more than run the hand over the newly-dropped calf, and then pass it across the mouth and lips of the mother.

Abortion.—This is frequent in some individual cows, and is often caused by the disagreeable effluvia arising from the decaying matter which is suffered to pollute both the cow-houses and the yards. Imagination has also a great deal to do with this. Indeed, to such an extent is this the case, that an instance of abortion in one cow, has caused an epidemic of the same kind to affect all the rest in the yard. The cow that has successfully calved, should, therefore, be immediately removed from the others, and placed in a situation of quietness and solitude.

Chloride of lime ought to be abundantly strewn near and about the stall where she was; and the noses of the whole of the others should be rubbed over with tar. Retention of the placenta, or failing to cleanse, sometimes occurs, and is indicative of weakness, and a want of tone in the uterus. Where this is the case, a mild stimulant may be given; and nothing is better than an infusion of camomile flowers—say two handfuls in a quart of water—added to a quart of good boiled ale; and, if necessary, apply an injection of soapsuds, to keep open the bowels, and prevent inflammatory action. Should these fail, call in the veterinary practitioner.

Choking.—Where this has taken place, from the effects of some large root having "stuck in the throat," an effort must immediately be made to relieve the animal. The mouth should therefore be first examined, in order to discover whether the object cannot be extracted with the hand, which is by far the best instrument to use, if it can conveniently be done. Should this not be the case, however, the assistance of the probang, invented by Dr. Munro, must be called in. Before using this instrument, a little sweet oil should be first given; after which it should be carefully passed into the mouth, with the cup end downwards, and gradually moved towards the impediment which has caused the choking. Should this be a turnip, which is not unfrequently the case, and should it offer much resistance, the instrument must be withdrawn, and its position changed. Generally, however, this will not be necessary, as the root will pass down without much effort. Sometimes it may even be got out, by pressing the thumbs up each side of the neck, accompanied with a pressure of the hand.

Coldness.—In calves this disease is sometimes found; and unless it has assumed a very severe form, it is not necessary to have recourse to medicine. An ounce of fat bacon, boiled with a handful of onions, will, in all probability, act as a suitable relief; whilst its nourishing properties cannot injure, but may improve the health of the animal.

DISEASES IN CALVES.

Young calves are not subject to many diseases, and medicine is very seldom necessary
to restore their health, provided they have been well-managed, not neglected and half-starved. Diarrhoea, or the sour, is usually the most fatal disease with which they are attacked; and, as this is usually the result of some acid or foreign matter in the bowels, it is generally mitigated or removed in a short time, by giving them a tablespoonful of sulphur in their milk. Should the attack continue after this, administer a tablespoonful of tincture of rhubarb with a teaspoonful of laudanum. Mr. Milburn tells us that he once had a calf nearly dead of diarrhoea, which was so violent as to defy all the efforts of medicine. It was all but dead, when he gave it a bottle of port wine, expecting its death next day. In the morning, however, it was well, and crying out for its breakfast. Mr. Milburn adds, that a pint of good old port will often work wonders, when all other remedies have failed, both in man and beast.

The Epidemic.—The symptoms of this disease are characterized by their affecting the mouth with blisters, and the feet with inflammation and pain, and is very troublesome.—In treating for it, give, in the first stage, a dose of Epsom, or Glauber salts, accompanied with bran-mashes and shelter. This will generally prevent dangerous results; but, should the foot break out, or an eruption occur, treat as in the case of foul in the foot—which see.

Felon.—Mr. Karkeek considers the outset of this disease to be a febrile condition, induced from a sudden excess of food at a period when the tone of the vital principle is unequal to the work. The capillary arteries are more numerous and active in the early period of life than at any other, while they are carrying on and completing the organisation of the frame. They are, in fact, the masons and architects of the system; but, if a larger supply of building materials is forced into these vessels than can be efficiently used up in reparation and growth, active congestion takes place almost everywhere; the vital principle is suddenly reduced; the body becomes amenable to the ordinary chemical affinities; destruction of the living parts ensues by decomposition, even whilst the animal is alive, shown by the extraction of gas from the cellular membrane, and by the extensive sloughing process in the skin. The great point, then, in the rearing of calves, is to take care that the vital powers are predominant, which condition is only obtained by a proper supply of food, proper temperature, and proper exercise. The complaint, however, is common in all kinds of cattle, especially in the tender breeds, and proceeds from cold and exposure. It is accompanied with low fever and loss of appetite. The coatostares, the eye is heavy, the nose dry, and the back sore. The animal will shrink from the touch, and the teeth will be felt as if they were loose. The remedy, therefore, is in the use of stimulating cordials.

In treating for it, first house and give the animal a drink; then administer 1 oz. of turmeric, 1 oz. fenugreek, 1 oz. liquorice, 1 oz. aniseed powder, in a quart of ale. This will generally prove effective; but, if not, repeat the dose. A very common and very safe process is to separate the nerve of the under side of the tail, which relieves the back, and fastens the teeth. To perform this operation, feel for a soft place on the under side of the tail. The knobs are the joints; the soft place is the bone. Cut the skin across at the soft part, and it will bleed for eight or ten minutes, when the tail should be tied up with a piece of linen cloth. Great relief will be afforded by this.

Foul in the Foot.—To this disease large heavy milk-cows are specially subject. It is to the cow what foot-rot is to the sheep. There is inflammatory action between the parts of the hoof; it begins to discharge fetid matter; and is a source of pain and irritation, which often dries up the milk, and becomes very difficult to cure.

In treating for it, let the foot be first well cleaned and fomented with warm water, and all loose flesh cut or clipped off. The foot may then be poulticed for one night with linseed-meal, and again fomented and anointed with tar. If it should smell very offensively, a little charcoal, or a few drops of chloride of lime, may be added to the water. Next day the inflammation will be lessened, and its discharge rendered more free by the tar. The foot may then be dressed with butyr of antimony (chloride of antimony) night and morning, and the tar applied afterwards. The foot should be confined in a boot or stocking, and kept free from dirt. A little linseed oil or
CATTLE, AND THEIR VARIETIES.

Milk fever.—Cattle, but tacked liable. pain, given mint-water, hind staggers, by incapacity takes ruminating home-brewed aloes, has Barbadoes rapid are, given of disease; has always taken. Mint-water—Pleuro-Pneumonia.—There is no specific remedy, with which we are acquainted, for this disease. A gill of spirits of turpentine, and a gill of spirits of sweet nitre, has been successfully tried; but it is a desperate resource; and should the animal be fat, it is wiser to dispose of it at once, before the flesh gets tainted with the disease, and partially corrupt.

Quarter Felen.—This is one of the most stubborn of all the diseases to which cattle are subject. It is called Inflammatory Fever, or Quarter Ill; and, although there are instances of its having been cured, they are rare, except in cases where the disease has been early arrested in its progress. It makes its appearance usually before the calves are a year old—seldom after; and, from its being extremely contagious, it has been known to pass through an entire herd before they had reached that period of life. Its first evidences make themselves known by the calf beginning to lose its food, and becoming stiff or lame in one of its feet; and, although the foot may be examined, and no cause of lameness visible, yet the disease will very soon become general. Air-bubbles form between the skin and muscles; and there is a crackling sensation to the hand, on passing it over the skin, especially in the legs. Inflammatory fever is disorganising the body. Either for prevention, or as a remedy, no specific for it has yet been discovered. The following has been recommended.

Preventives—as the seton in the dewlap, bleeding in autumn, doses of dyers' madder, &c., are favourite remedies. The seton can do no harm, but it may be tried.

Red Water.—In some kinds of pasture, cows are, in summer, frequently attacked with this disease. In treating for it, give—a dose of 8 oz. of Epsom salts, dissolved in a pint of water. This, if taken in an early stage, will almost invariably set the beast right. If not at hand, 1 lb. of common salt may be given, and the dose repeated in case of need.

MILK FEVER.

Salts should be given, in order to keep up a gentle state of activity in the bowels.

Gripes.—Young calves are frequently attacked by this disease after having sour milk given to them. It is attended with acute pain, as may be inferred from their pawing the ground, and kicking the belly with their hind legs.

In treating for it, give—a cupful of peppermint-water, and a teaspoonful of laudanum.

Inflammation.—This disease indicates itself by a coldness in the horns and extremities, and by the animal exhibiting symptoms of enduring both acute and continued pains. Attempts to cure it should never be made but by such as have a thorough knowledge of nature. It is, therefore, indispensable to call in a veterinary practitioner; and the same should be done in all cases of acute disorders, such as strangury, staggers, &c.

Jaundice, or the Yellows.—This is one of those forms of felon to which cattle are very liable. It is found more particularly to attack white cattle, and is easily recognised. Its signs are marked by a yellowness of the eyes, and also under the anus; when costiveness takes place, the appetite becomes dull, and rapid debility ensues.

In treating for it, give—1 dr. ginger, ½ oz. Barbadoes aloe, 4 oz. common salt, 1 quart home-brewed ale, made into gruel.

Loss of Cud.—This disease sometimes affects ruminating animals, and is indicated by the incapacity of the stomach to throw back into the mouth the half-masticated food which has been swallowed, to be again chewed.

In treating for it, give—6 dr. Barbadoes aloe, 1 oz. allspice, 3 dr. ginger, 6 oz. common salt, in a quart of gruel.

Milk Fever.—Cows, which are deep milkers, are, especially in summer, very liable to this disease; to prevent which the utmost care should be taken. When it has occurred, it is always best to call in the assistance of the veterinary practitioner, rather than for those who, not having much experience to deal with it themselves. The recommendations given by the author of The Cow, are—to milk the cow, before calving, regularly three times a day, provided the udder be much distended. To keep her as cool and as quiet as possible, and to give her mash of bran only, for a few days after calving. This is cooling, and somewhat laxative. If the udder should be hard—which it should not be after this treatment—it may be rubbed with marsh-mallow ointment. A gentle dose of purgative medicine can be given if the cow is in very high condition; and she should be driven a few miles every day before calving.

Pleuro-Pneumonia.—There is no specific remedy, with which we are acquainted, for this disease. A gill of spirits of turpentine, and a gill of spirits of sweet nitre, has been successfully tried; but it is a desperate resource; and should the animal be fat, it is wiser to dispose of it at once, before the flesh gets tainted with the disease, and partially corrupt.

Quarter Felen.—This is one of the most stubborn of all the diseases to which cattle are subject. It is called Inflammatory Fever, or Quarter Ill; and, although there are instances of its having been cured, they are rare, except in cases where the disease has been early arrested in its progress. It makes its appearance usually before the calves are a year old—seldom after; and, from its being extremely contagious, it has been known to pass through an entire herd before they had reached that period of life. Its first evidences make themselves known by the calf beginning to lose its food, and becoming stiff or lame in one of its feet; and, although the foot may be examined, and no cause of lameness visible, yet the disease will very soon become general. Air-bubbles form between the skin and muscles; and there is a crackling sensation to the hand, on passing it over the skin, especially in the legs. Inflammatory fever is disorganising the body. Either for prevention, or as a remedy, no specific for it has yet been discovered. The following has been recommended.

Preventives—as the seton in the dewlap, bleeding in autumn, doses of dyers' madder, &c., are favourite remedies. The seton can do no harm, but it may be tried.

Red Water.—In some kinds of pasture, cows are, in summer, frequently attacked with this disease. In treating for it, give—a dose of 8 oz. of Epsom salts, dissolved in a pint of water. This, if taken in an early stage, will almost invariably set the beast right. If not at hand, 1 lb. of common salt may be given, and the dose repeated in case of need.
THE CATTLE PLAGUE.

In the July of 1865, the population of London were generally startled by the appearance of a disease which was decimating the cattle of the country, and of which tens of thousands of them had never either heard or dreamt of. In the previous month a note of warning had been given, that some certain calamity was about to deprive them, to a large extent, of "the roast beef of England;" but as the aggregate nervous system of this great and active city is not easily disturbed by things at a distance, its inhabitants still continued to eat their beef, without troubling themselves, in any visible way, about what was to befall them by being deprived of it. In a short time, however, they heard that a species of murrain, or plague, had been imported, it was supposed, from Russia, and soon assumed the most alarming characteristics. This disease was subsequently called the rhinderpest; but it soon became generally known throughout the country as the "Cattle Plague."

As the origin of all diseases is attributed to predisposing or exciting causes, a majority of evils require several agencies acting in combination to produce them. There are some, however, which can only be developed by one invariable and specific means; and this has received the name of contagion. For example, a sheep can only become scabby by the influence of the scab-insect crawling, and multiplying, over its body; as a dog can only become mad by the virus or rabid poison of some other mad animal, inflicting a wound on, or by some other means, entering its body. From a knowledge of these well-established facts, men of science have come to the conclusion that cattle can only be attacked with the rhinderpest "as the result of direct, or indirect, communication of the rhinderpest poison to a healthy from an unhealthy animal."

General anxiety, from the dreadful strides with which this malady advanced, gradually rose higher and higher; when the government, also, excited by its manifest progress, issued, in the latter end of September, a commission from the crown, authorising certain persons therein named to investigate the origin and nature of the disease; and to report upon the mode of treatment best adapted for the cure of the infected animals, and the regulations proper for preventing the spread of the plague, or its future recurrence. The commissioners, urged by the evident necessity of the case, lost no time in prosecuting their inquiries; and having taken evidence from the most competent persons, upon whose information they could rely, made their report within the compass of a month from the date of the commission. This important document contains the best authenticated information relative to the origin, progress, and treatment of the disease; and is replete with the most important facts respecting it.

According to the commissioners, the "plague" was first observed in this country towards the close of the month of June, 1865. About that period a couple of English cows had been purchased (the actual date was June 19th) in the Metropolitan Cattle Market, by a cow-keeper residing in Islington, in whose sheds they were when the symptoms of the disease first attracted (on the 27th) the notice of the veterinary surgeon in charge of the general stock. The same surgeon observed similar symptoms of the disease on the 28th, in a cow which belonged to a dairyman in Hackney; and which had been purchased in the same place, and on the same day. Two Dutch cows, in a Lambeth shed, likewise purchased in the Metropolitan Market on the 19th, were attacked on the 24th, and immediately afterwards the plague spread through many of the London dairies. As an appalling evidence of the remarkable virulence of the distemper, we may observe, that the Islington cowkeeper lost her whole herd, amounting to ninety-three; she also bought more—lost them also; making 107 in all. An inspector, who had charge of a great part of the north-east of the metropolis, stated that, in his own district, more than four-fifths had either died or been slaughtered; and the general average, within the precincts of the metropolis, was, in all probability, at least as high. Very early in July it appeared in Norfolk, and likewise in Suffolk and Shropshire; then in one county after another; when it was found, that the rapidity with which it had diffused its desolating breath over the country, had enabled it to enter Scotland. By the 14th of October it had extended to
twenty-nine English counties; two in Wales, and sixteen in Scotland; and was still advancing. From the Metropolitan Market it crossed the sea into Holland, with some Dutch oxen which had been shipped from Rotterdam to London, and had been exposed during three successive market-days, when, not being sold, they had been re-shipped from London to whence they came. It is unnecessary here to follow its further progress; but we may state that, at the Smithfield Club dinner, at which Earl Spencer presided, Mr. Clayden, chairman of the "Agricultural Company," &c., after speaking of the advantages which had resulted to the farmers of England generally by the operations of the club, said that the noble president had drawn a melancholy picture of the state of the agricultural interest from the effects of the cattle plague. He observed, that "30,000 animals had perished from the effects of that incurable disease; whilst whatever efforts had been made to discover an effectual remedial agent, had, in so far as the best-informed and most scientific agriculturists in the world yet knew, signally failed."

It is reasonably to be expected that such an alarming condition of things would originate, among the veterinary faculty, many theories for its prevention, as well as its cure; but the hopelessness of all these, as well as of every kind of medical treatment, was thus set forth in a letter to one of the newspapers, by Dr. Watson, a gentleman who ranks amongst the most eminent of his profession in London. He says—"The disease is a very fatal one. Its death-rate is appalling—00 in 100, they say; and it is absolutely incurable. With or without what is called treatment, a small number of recoveries happen; but there are no cures. Probably (but this is mere opinion), of the sick animals subjected to treatment, a larger proportion perish than those which are left to themselves. I do not mean that medical care is useless or inexpedient. There are measures relating to food, temperature, cleanliness, support, even medicine (measures that are defensive against all weakening influences), which, sometimes, may turn the hesitating scale, and give the victory to the restorative force of nature. But there is no specific plan or antidote that can stop or chase away the disease, any more than there is for the cure or the cutting short of small-pox; this is alike true of all the specific fevers. They run a definite course."

The conclusion to which this gentleman came was thus given, and largely adopted—"If all this be so, surely it is time to turn our thoughts from the sick and the dying to the animals that are yet left among us alive, in health, and uninfected; to abandon the vain search after impossible specific remedies, and to adopt the true and sole nostrum—which is, prevention. This is still within the scope of our power, and it is daily becoming more diffused."

To give entire force to the meaning of the word prevention in this passage, it may be added that it is designed to express complete isolation; the entire and perfect separation of the healthy from the unhealthy animal; the diseased from the undiseased; the clean from the unclean. This was conceived to be the most effectual, as it has proved the only real, remedy for staying and finally eradicating an evil so desolating to our herds. The consequence has, for some time, been an entire riddance of the "Cattle Plague," which is always spoken of as a thing of the past, there not having been, for a considerable time, a single known instance of its existence in this kingdom. The alarm which it created, however, necessitated the most decisive measures to be adopted for its extinguishment.

The death of 30,000 animals, within the comparatively limited period of two years, was a cause sufficient to raise anxiety amongst even a larger population than that of Great Britain and Ireland; yet, in the latter country, the flocks continued to increase rather than diminish or remain stationary. This, however, did not lessen the dread of the extension of the "Cattle Plague" in England, nor hinder the adoption of those strong measures of isolation or prevention to which we have alluded, and which, in the absence of all certain medicinal remedies, proved effectual in eradicating it from the country. Super-added to prevention, constant attention should be paid to cleanliness, and keeping the sheds well aired; whilst lime-washing should not be spared. Where cure is doubtful, prevention should be vigorously resorted to.
DIVISION V.

SHEEP.

CHAPTER I.

FOREIGN BREEDS OF SHEEP; THE RASS; THE SIBERIAN ARGALI; THE KAMTSCHATKAN ARGALI; THE ARMENIAN ARGALI; THE NAHOOR, OR SHA; THE SHA; THE CORSICAN MOUFLON; THE WALLACHIAN SHEEP; AFRICAN SHEEP; THE TARTARIAN SHEEP; THE PERSIAN SHEEP; ICELAND AND FAROE ISLAND SHEEP; THE ALPACA AND LAMA; THE SPANISH MERINO SHEEP; THE SAXON MERINO.

FOREIGN BREEDS OF SHEEP.

Of all our domestic animals, the sheep is that of which we have the earliest notice; as we are told that "Abel was a keeper of sheep." It was reclaimed in the primordial era of man's existence on the globe, and we must look to Western Asia as its original habitat. From this centre it has, more or less, gradually spread by the agency of man; and, under the influences of climate, food, and treatment, has ramified into numerous varieties.

In the Zoological Proceedings, there is a paper by Mr. Blyth, entitled "An amended list of the genus Ovis;" in which he tells us, that in the narrative of the celebrated Venetian traveller, Marco Polo, upon the elevated plain of Panir, eastward of Bokhara, and 16,000 feet above the sea-level, wild animals are met with in great numbers, particularly sheep of a large size, having horns three, four, and even six palms in length. More recently, an animal called the Rass has been indicated, from a report in Sir A. Burnes' Travels in Bokhara, and its horns have been transmitted to the Royal Asiatic Society. He confirms the narrative of Marco Polo; says the flesh is much prized; and that the people shoot the animal with arrows. "The Rass is said to delight in the coldest districts; a common-sized individual will require two horses to bear its flesh from the field." The horns, following their curvature, are nearly five feet in length.

THE SIBERIAN ARGALI.

This noble sheep is described by Pallas, and has a much wider range of habitat than the Musimon; whilst its general characteristics bear a striking resemblance to those of the sheep. Its natural abode is on the tops of mountains in cold latitudes, and it is common in Siberia.

THE KAMTSCHATKAN ARGALI.

M. Eschscholtz, who describes this species, states it to be very numerous on the mountains of Kamtschatka. In summer it resides upon the snow-clad heights; but, in winter, it descends to the lower regions; and, according to Kotzebue, is remarkable for its agility. In America there are two species very closely allied to the Siberian Argali—the Rocky Mountain Argali (Ovis Montana), and the Californian Argali (O. Californiana, Douglas); besides which there is the Caucasian Argali (Ovis Cylindricornis, Blyth), hitherto confounded with the Siberian Argali.

THE ARMENIAN ARGALI.

This is the Ovis Gmelin of Blyth, of which specimens were sent from Erzeroum to the Zoological Gardens in London. According to Gmelin, this species is found only in the highest mountains in Persia. The males, he informs us, are very quarrelsome amongst each other, insomuch that he had been at one place where the ground was strewn with horns that had been knocked off in their contests. It is allied to the Corsican Mouflon. Sir John McNeill informed Mr. Blyth that it appears to be the common species of the mountains of Armenia; occurring likewise on the north-west of Persia; but the wild sheep of the central parts of Persia is evidently distinct, having horns much more resembling those of the domestic ram, being spiral, and completing more than one spiral circle.
SHEEP, [THE MOUFLON.]

THE NAHOOR, OR SHA.

The Nahoor, or Sha, of Tibet (Ovis Nahoor, Hodgson), is a native of the Kāchar region of Nepal, and the glaciers of the Himalaya. Of this sheep there is very little to be said; but it has a near alliance to the Burrel—Ovis Burrel of Blyth—which inhabits the loftiest crests of the Himalayan chain. Here it is said to bound "lightly over the encrusted snows, at an altitude where its human pursuers find it difficult to breathe. It has the bleat of the domestic species, as indeed they all have, and is very shy and difficult of approach. Flocks of ten or twenty, conducted by an old male, have been observed to make for the snowy peaks upon alarm, while their leader scrambled up some crag to reconnoitre, and, if shot at, would bound off a few paces, and again stop to gaze. They pasture in deep and hollow grassy glens." A former specimen, in the Museum of the Zoological Society, was shot near the Doorendo Pass, at an altitude of about 17,000 feet.

THE SHA.

This is the Ovis Tighez of Blyth, a Mouflon inhabiting the mountains of Little Tibet and the Salimani range, between India and Khorassan. Vast numbers of this species are driven down by the snow in winter, to the branches of the Indus, where the river breaks through the chain of the Himalayas. The wild sheep of the Hindoo Koosh mountains, described in the Journal of the Asiatic Society of Bengal, is either this or a closely allied species. Its climbing powers are extraordinary.

THE CORSICAN MOUFLON.

This is the Ovis Musimon of Linnaeus, a native of Corsica and Sardinia. Speaking of it, Mr. Blyth remarks—"It has always appeared to me, however, that the specific distinctness of the Mouflon is very obvious; and I doubt whether it has contributed at all to the origin of any tame race. That it inter-breeds freely with the latter, under circumstances of restraint, is well known; but we have no information of hybrids, or Umbri, as they are called, being even raised from wild Mouflons, though the flocks of the latter will occasionally graze in the same pasture with domestic sheep; and all but mingle with them. The male of this animal is denominated, in Corsica, Mufro, and the female, Mufra; from which Buffon, as is well known, formed the word Mouflon. In Sardinia, the male is called Murvoni, and the female Murva; though it is not unusual to hear the peasants style both indiscriminately Mouflon, which (as Mr. Smyth remarks, in his description of that island) is a palpable corruption of the Greek Ophion. It is sometimes stated, but I do not know upon what authority, that a few of these animals are still found upon the mountains of Mareia."

This would seem to be the same as the Ovis Mouflon of Buffon, found in the islands of the Grecian Archipelago, in Sardinia, Greece, Asia, and in the western part of European Turkey. It is two-and-a-half feet high, and about three-and-a-half long. It has large semicircular and wrinkled horns, bending gracefully backward, resembling, in some degree, the black-faced sheep of the Highlands. They are, however, much thicker, usually measuring from twelve to sixteen inches at the base, and sometimes as much as twenty-two inches in length. The colour of the animal is grey; and it is covered with hair, of a curly and woolly kind. There are a few black hairs about the head. When the female has horns they are very small, but she is frequently entirely destitute of them. They always browse upon the sides of hills, or upon their summits, in very temperate latitudes. They are gregarious, herding together for the purposes of defence; and, like other sociable animals, place themselves under the protection of the largest and the strongest of their rams. When the females are in season, they separate into smaller flocks, and this is the signal for the wars of the males. The females usually throw two lambs in the month of April or May, and these the dams defend with indomitable courage in any emergency.

According to Cuvier, these animals are very dull and untameable. He says that "domestication has had no influence" in taming them; "it merely accustomed them to the presence of new objects; and they are no longer afield at the sight of man, but rather seem to acquire more confidence in their own powers as they become more familiarised with him. Instead, therefore, of avoiding their keeper, especially
the males, they attack him with fury." There is another peculiarity belonging to this species. Their flesh is well-flavoured; but they are always in lean condition. Their skins are so thick as to be almost impervious.

In this review of Mr. Blyth's paper, we have omitted the Ixias Probation, Ogilby (of which a unique specimen exists in the museum of the Zoological Society, London, and the history of which is obscure), and the Aoudad (Ovis Tragelaphus, auct.), which we refer to the goats. From none of the species here enumerated can we confidently select the type of the domestic sheep (Ovis Ariës, Linnaeus); but, "applying our knowledge as obtained inferentially from the most ancient records," observes the author of The Cow, "we find incidental notices tending to fix the character of the earliest sheep, of which history informs us, with the one or the other of the class of animals above referred to, but especially the latter." Abel had "firstlings of his flock." Hence he possessed domesticated animals. The lambs of the Argali would be a ready means of procuring a flock, as they are even now easily domesticated, and which would hardly be the case with the untameable Musmon. Abel also offered fat, which is a secretion common to the Argali, but of which the Musmon is said to be destitute. The sheep of the Patriarchs, too, had horns; at any rate the rams had that distinction. Nor could they be simply upright; as a ram, it will be remembered, was "caught in a thicket by his horns," when the staying angel arrested the hand of Abraham. The curvature of the horns being much more nearly complete in the Argali than the Musmon (which are merely bent back), renders it the most likely of the two to be entangled in a thicket. That sheep were, some of them, brown in Jacob's day is quite certain, from their being set apart for his wages; and this again agrees with the colour of the Argali. That the covering of the skin was something better than hair, even in early days, is quite evident from Laban's shearing his sheep; for it always indicates, at least, a woolly texture rather than a hairy one, which requires the application of the shears. Job, who lived, it is supposed, in early patriarchal times, evidently made use of the wool of his sheep. His flock consisted, at one period, of 7,000 sheep; and, at another, of double that number; and he thus reminds his friends of his benevolence:—"If I have seen any perish for want of clothing, or any poor without covering; if his loins have not blessed me, and if he were not warmed with the fleece of my sheep."

The Mouflons and Argalis—that is, the wild species of the genus Ovis—are covered with a harsh kind of hair; having beneath it, at its roots, a short spiral wool, which, in winter, becomes longer and fuller. Mr. Bell, indeed, considers the harsh hair as essentially wool in its structure, presenting the imbrications which the microscope shows to be the characteristic of wool, and on which its felting property depends; and he regards the short under-coat as composed of hair, and not of wool. Mr. Youatt makes the contrary statement; and, notwithstanding the appearances noticed by Mr. Bell, we incline to Mr. Youatt's opinion; for, be it observed, in the Cashmir and the Angora goats, the long outer garment is hair; the short under-coat, exquisitely fine wool. In other wool-bearing animals, as the beaver and otter, the same arrangement prevails; and, in some neglected breeds of common sheep, the wool becomes mixed with long hairs (not short and fine), which more or less obscure the wool.

Dr. John Davy, in the Philosophical Journal, furnishes a striking instance of the effect of climate in changing the character of covering on the body of a sheep. He says—"The sheep from Barbadoes, originally from an English stock, affords a striking example of the change that may be effected by climate, in a few generations, in the character of the hair of an animal. In that island, instances are frequently to be seen of sheep in which hair has so taken the place of wool (using the terms in their usual acceptation), that, were it not for the form of the animal—and that is not altogether free from change—it would be impossible to suppose that they belonged to the same species as our English sheep." He carefully examined two specimens of hair—one from a sheep of two years old, the other from one a year old. Both were of the same colour—a light reddish-brown—and the same length. "The hair of the three-year-old," he proceeds to say, "was coarser than that of the one-year-old; it consisted chiefly of harsh fibres, slightly
tortuous, each about the 180th of an inch in diameter—some cylindrical, others more or less flattened—all looking towards a point at their distal extremity. The hair of the one-year-old consisted of coarse and fine fibres in about equal portions, the one about the 363rd of an inch in diameter, the other the 1333rd of an inch; the former resembling the hair of the older sheep, the latter having the appearance of wool, both in its fineness and general aspect, whether seen with the naked eye or under the microscope. The presence of a portion of wool underneath the hair of the younger sheep, accords, I may remark, with the belief of my friend, that all the very young lambs of the island have wool, which gradually passes into hair as they grow older." This, the Doctor thinks, is the fact. He then expatiates on the care "Divine Providence exerts in changing the clothing of an animal to be suitable to the climate it inhabits."

The causes which have rendered the fleece of the European sheep what we now find it, are involved in obscurity. We attribute much, in the first instance, to the effects of temperature; for though the merino sheep of Spain (a race originally imported from England), and the flocks of Australia and Southern Africa, are pre-eminent as wool-bearers, yet it would seem that the predisposition to develop wool at the expense of hair, is acquired only in temperate, elevated, or even cold climates. For instance, we learn from Mr. Hodgson, that the wool of the Bhotean domesticated sheep, called Huniah, is superb; and, he adds, the animal is suited only to the northern district of Nepal, suffering much from the heat of the central district. On the other hand, it is clear that, in the early ages of man's history, the shepherds must have selected, for breeding, those individuals on which the wool predominated; and that, by following up this system, the sheep gradually attained its present condition, so that a wool-bearing breed became, at length, permanently established. Originally, perhaps, the sheep, then a wool-bearer, and long domesticated, was of a brown or rusty-black colour—a hue still lingering on the faces and limbs of many of our breeds, and sometimes appearing as the general tint of individuals, thus conspicuous in the midst of their white-fleeced companions. Nine out of ten of the sheep of Dukhun are black, with short, crisp, coarse wool. As the primitive fleece of the sheep was a mixture of hair and wool, we cannot be surprised to find races domesticated, in which the hair predominates over the wool, and that so greatly, that they may with propriety be termed hairy. Sometimes the hair is like that of a spaniel dog, long and silky; and many of the flocks of the Bucharian Tartars are thus clothed. To this breed may be referred—

THE WALLACHIAN OR CRETAN SHEEP.

This is the Ovis Aries, var. Strepsiceros, common in Crete, Wallachia, Hungary, and the western parts of Asia. A splendid ram of this variety, from Mount Parnassus, was presented by Dr. Bowring to the Zoological Society, London. Its was vicious, unruly, and of amazing strength. Its horns were very large, and spirally contorted, adding greatly to its striking and picturesque appearance. Its fleece consisted of hair and wool, the former being of great length, perfectly straight, close-set, and beautifully fine, falling from the middle of the back on each side of the animal, almost to the ground. On the face the hair was short, and of a rusty black; on the body it was white. In general, the horns in the male rise almost perpendicularly from the skull, making a series of spiral turns in their ascent, the first turn being the largest; while, in the female, they diverge, taking a lateral direction. In the specimen, however, to which we have alluded, they extended laterally from the skull, and, after the first turn, took a downward sweep. Variations in these points may be expected in domesticated animals. "The Wallachian sheep is a remarkable animal," says Mr. Milburn; "and altogether the most beautiful, as a picture, of all the various breeds. They are common in the whole of Southern Russia. The horns of the ram are of a peculiarly tall and spiral form. The wool is of a hairy character, but beautifully white. The tail, however, is the peculiarity. Kohl, in his Russia, says, 'it really carries its fat about in its tail, which grows into a shape something similar to a pear, swelling at both sides to an enormous size, and tapering to a point at the extremity.' The Russian shepherds are a very dull and helpless race of men; and more credit is due to the dogs and goats which accompany the flocks, for
their care of the animals, than to these serfs, who are indolent, and dull of comprehension. About four goats are associated with a flock of every hundred sheep to brave the Pontine hurricanes, and to lead the sheep over ravines, and by the sides of steppes, which otherwise neither the sheep nor their shepherds would face. The sheep follow the courageous goats; and, on once making the effort, they have powers quite equal to the task. The shepherds are strictly nomadic. They wander from pasture to pasture, accompanied by their dogs and a waggon, which is their kitchen and bed. The sheep are collected for the night into as narrow a compass as possible. The dogs watch them, each sleeping on a mat; and with this the flock is generally secure from the wolves, who prowl about in the hope of finding some stray or sickly animal on some unguarded point. This race of sheep has spread for a great distance over Hungary, Bohemia, and Austria. The peasants still use the shaggy skins for coats, which are an ample protection from the cold blasts of the northern climate. The tail is large and fat, almost more from its length than its breadth—a characteristic in which it differs from the African sheep, to which we shall now allude.

AFRICAN SHEEP.

In the specimens of Guinea sheep which we have seen figured, the limbs are long, the body gaunt, the ears pendulous, the forehead arched, and two fleshy excrescences hang from the throat. A smaller hair-clad breed extends along the Slave Coast. The Pesson sheep, of which we have seen examples, closely resemble the Guinea sheep, but have a pendulous dewlap instead of the tassels of skin on the throat. They are gaunt, coarse-haired, ill-formed animals, with high withers like a buffalo. The males have small horns. In Madagascar the sheep are covered with short hair. The South African sheep is of the fat-tailed species; but instead of the long, pendulous, and conical tail, it is broad and flat. All other parts of the body are wolf-like and lank, with the flesh flabby and thin. The tail of this animal is the great furnace which supplies it with heat against the chill and rainy seasons, when calorie is requisite to resist the cold effects of the atmosphere. Barrow, in his work on South Africa, says—"The tail is short, broad, and flat; naked on the under side, and weighs the amazing weight of from six to twelve pounds. It is of a thin oily consistence, and is sometimes used as a substitute for butter. This tail is from twelve to eighteen inches long, and tapers downwards, being five or six inches thick near its setting-on at the rump." The animal is covered with long curly hair, of a powerfully resistive texture, which, from its elasticity, is used for making cushions. The wool varies from black to grey; is often spotted, and sometimes dun and brown. Little care is taken of the breed, which furnish the Hottentot with a large proportion of his food. Nor is their covering more carefully preserved; it being usually allowed merely to drop off in the autumn of the year. Some individuals have a second or under coat, which has a great resemblance to fur, and is used for making coverlets by the superior classes of Boers. A similar sheep occurs in the same or higher latitudes, and they are found in Madras and Bengal. In Northern Africa there is an animal similarly formed, especially in Barbary. It has three, and sometimes four horns; but its tail is thinner and fatter than the variety of South African. Its colour is mostly white; and while the anterior parts are covered with soft hair, the posterior are clothed with fine wool. The ears are pendulous.

THE TARTARIAN SHEEP.

In Tartary, Persia, and other parts of the East, there has long existed a singular variety, with a great deposit of fat on the tail and cropp, giving an unsightly appearance to the animal. The tail itself is short, and seems buried in the mass on each side; and the body is generally white; the head and neck black. Of the variety Ovis Aries, var. Sleatogypus, we have seen a specimen. The fleece of the sheep consisted of short, coarse wool, mixed with hair. This sheep is hornless, and thin and gaunt in its general contour. Its ears are pendulous, and reach to the bottom of the jaw. Its shoulders are thin and small; and its head somewhat deep, but not forward. Behind the shoulders it is small. The legs are also short and thin, as regards the muscular parts; but the whole vital power of the animal seems to tend to the production of the
perfect cushions of fat by the sides of the tail, which absolutely bury it. The female has smaller horns, or is altogether without them. The colour varies, but is usually roan, or of a light brown, mixed cast, while the ewe is black. The wool is somewhat short, and fine in quality. The weight of fat about the rump will be nearly as much as thirty to forty pounds. It must be kept in mind, however, that the fat of the rump of this species is different from the fat of our mutton. On this subject, Dr. Anderson observes—"There is no meat on the body of our common breeds of European sheep, which, in many of its distinguishing characteristics, resembles that of the tail of the broad-tailed sheep of the southern parts of Africa or Asia; far less does any part of the flesh of our mutton bear the smallest similitude to that of the hemispherical bumps on the bullocks of the Stenopagau breed, which so much abounds in the northern parts of Asia. The bumps are called fat, because they resemble that substance in colour and consistency, more than the lean of mutton; but it differs externally from the fat that is found on any part of the body of our sheep."

**THE PERSIAN SHEEP.**

The *Persian Hornless* sheep is one of the fat-rumped varieties, and is very different from every kind of sheep we have yet described. It is short-eared, and the head and neck are without wool. The body is both deep and cylindrical; whilst the breast is considerably rounded in front. The legs are small and thin; but this is compensated by the rumps, which literally make a pair of cushions of fat, and almost entirely conceal the tail, notwithstanding its great size. The wool is as white as snow, but is short, and not very fine. In the Mosical sacrifice, there is incidental allusion made to the rump, Moses having taken the fat, and the rump, and all the fat that was upon the inwards. Mr. Youatt quotes this as indicative of the Jewish sheep having been of the fat-rumped variety. The author of *The Cope* gives reasons which induce him to come to an opposite conclusion. There were six parts of the ram to be burned:—1st, the fat; 2nd, the rump; 3rd, the fat of the inwards; 4th, the caul above the liver; 5th, the two kidneys, and the fat that is upon them; and, 6th, the right shoulder. "Now it appears to us," continues the same author, "that these directions rather oppose than support the conclusion that the rump was covered with fat. If so, why did they not specify the fat covering the rump, in the same manner as covering the kidneys? And if the mention of the rump along with other fat parts is to convey the idea that it was fat also, the mention of the shoulder would convey the same impression, which would not be at all accurate. The assumption that the fat was accumulated on the rump and legs, would operate in favour of its also being equally deposited on the shoulder. We imagine that all that was intended was, that all the best parts were to be sacrificed in the 'ram of consecration.' The internal accumulation of fat, too, is opposed to much external formation."

Another fat-tailed variety of the Persian sheep is mixed up with others which develop the fat in other parts of the body. Its wool is of a long hairy grey, and extremely coarse. It, however, has horns. The tail consists of a large accumulation of fat, tending to the pendulous, and has a somewhat conical form. The wool is of a much finer staple than the Wallachian, and is of two kinds—long and hair-like, but thinly scattered, and wiry. There is an under coat, from which the finest class of wools are obtained; and these are said to be equal to Cashmere in their fineness of texture.

The *Abyssinian* sheep is the same as the Persian; and, according to Mr. Milburn, is but one remove from the Argali, even at the present time. Its habitat is along the shores of the Red Sea. Its tail is somewhat short; its wool coarse and heavy, and of a greyish or brownish colour. The horns diverge from their roots, and are bent so as to make the large form of a circle. The relationship is very close; and it is thought not to be difficult to imagine this long-legged, horned, hair-covered sheep, to be a variety of the Argali.

Among other strange varieties of sheep, may be here noticed the sheep of Syria and Egypt, with a long tail loaded with fat, which sometimes even trails on the ground. In the Egyptian animals the tail is broad throughout, but in the Syrian it narrows to a point. The ordinary weight of the tail is fifteen pounds; but,
in some of the larger kinds, well fattened, the tail will weigh seventy, eighty, and it is said, even 150 pounds. Ludolph saw, in Egypt, a sheep's tail of eighty pounds' weight. This overgrown appendage is a great inconvenience to the animal; and, in order to prevent injury to it, the shepherds are often obliged to fix a thin piece of board to the under surface of the part that trails on the ground, to which small wheels are sometimes added. The caudal deposit of fat in these varieties of sheep is oleaginous, being of a consistence between fat and marrow, and is often used in the place of butter: when the animal is young, this fat is stated to be little inferior to the best marrow. The long-tailed breed (var. Macrourus) is not only found in Arabia, Syria, and Egypt, but is very numerous in the interior and southern parts of Africa, and is covered with a mixture of coarse short wool and hair.

Aristotle speaks of the Syrian sheep in his day, and names a variety which had tails a cubit broad. Such a naturalist ought certainly to be credited. Dr. Russell describes the tails of modern Syrian sheep as weighing fifty pounds; but these are house-fed animals, and exceptions to the general rule. The head is bare, and the horns semicircular, and bending downwards. The ears are pendulous, and the face free from wool. The throat is covered with long shaggy hair, projecting almost as far forward as the mouth. The posterior parts are woolly, and the tail reaches nearly to the fetlock joint; but, before it extends that length, it makes an upward turn at its pointed tip.

THE ICELAND AND FAROE ISLAND SHEEP.

Leaving the regions of the East, and coming nearer our own island, we find that in Iceland and the Faroe Islands, there are two races of sheep—one of a small size, and of a dun or rust-black colour; the other of larger size, and white. Both of these races are remarkable for the number of their horns, varying from three to eight. Four, however, is the usual number. The larger race are strongly-built animals, with a coarse fleece, consisting of long hair externally, and an under-layer of close wool, impenetrable by the heaviest rain. The wool, however, is of little value, being fit only for horse-cloths and common rugs. These sheep yield an extraordinary quantity of milk, far superior to that of any of the more southern breeds. Von Troil, in his Letters on Iceland, states that a single ewe will yield from two to six quarts a day. The Faroe Island race of sheep is of great antiquity, and wild. They are covered with black, short, curled wool, and their flesh has a peculiarly dark appearance, and venison-like flavour. When Mr. Trevelyon visited these islands, he found the remnants of this wild race in no way dependent upon or under the control of man. They are sometimes caught by dogs; but can seldom be obtained, except by being shot, or intercepted in a narrow space, and driven over the cliffs.

THE ALPACA AND THE LAMA.

The alpaca and the lama, or Peruvian sheep, are natives of the Andes, in South America. The lama is somewhat taller than the alpaca; and, though in some respects a remarkable animal, its peculiarities are not such as to render it, for purposes of practical utility, so especially interesting as the alpaca, out of its native regions. The alpaca—which it is proposed, under the most respectable auspices, to domesticate in Britain—is an animal combining the appearance of the common European sheep with that of the goat, and partly of the deer and camel. Like the sheep, it is languid, or wool-coated; in its general structure it is light, and possesses limbs adapted for springing and leaping like the goat. It resembles the deer in skin, flesh, and general appearance; and though without the camel's deformities, it is gifted like him with patience and docility, being often used as a beast of burden by the natives of South America. The height of the alpaca is from three to four feet, when measured from the ground to the top of the back; the eyes are large, black, soft, and expressive; the animal has no horns; the neck is long, slender, curved backwards, and finely set; the head handsome, and the muzzle and ears lengthened. To common observers, the alpaca might seem to be a fine tall goat, with small head and no horns, but of more gentle and fleecey appearance than that animal. The fine quality of its wool forms, of course, a point of peculiar importance, taking into view the fact of its having been introduced to Europe. The flesh is also delicious. The experiment of keeping these animals in Great Britain has
been tested, and with some success. The Earl of Derby has, at Knowsley, a flock of
lamas and alpacas, which not only live, but multiply. The wool, it is said, is improved by
our pasture. These animals also adorn the
pleasure-grounds of the Marquis of Bread-
bane, the Duke of Montrose, and other no-
blemen and gentlemen. Their first introduction
to Europe is due to the Spaniards.

The alpaca was, after great difficulties, and
many misadventures, introduced to Australia,
in 1855, by Mr. Charles Ledger, an English
merchant, established many years at Tachna,
in Peru. In 1852, this gentleman proceeded
to Sydney, for the purpose of fixing on the
most favourable localities for the pasturage
and breeding of alpacas. Having satisfied
himself as to the capabilities of the country,
he returned to Valparaizo in 1853; crossed the
Cordilleras in the same year, and rejoined a
flock of about four hundred, which he had
purchased previously to going to Sydney.
Overcoming a thousand obstacles, he succeeded
in procuring about three hundred and fifty
more of these precious animals, in order to
supply the place of others he had lost during
his absence, by the neglect of those whom
he had left in charge of them. This great
reverse, which would have overwhelmed any
ordinary mind, acted on him as a stimulus to
renewed exertions. He was, however, at this
stage, brought to a standstill by want of pecu-
niary resources; and, to his great regret, com-
pelled to return to Valparaizo. Here he
speedily procured the amount required, and
undertook, with greater confidence than ever,
new wanderings through the desert solitudes
of Peru and Bolivia, in order to recruit his
diminished flock. Finding himself under the ne-
cessity of deceiving the different governments,
in order to withdraw his flock from the Peru-
Bolivian territories, Mr. Ledger divided his
alpacas into three divisions, and commenced
his march, by different roads, to the Argentine
Republic. The details of this remarkable
journey, the obstacles, both natural and arti-
ficial, which had to be overcome, form the
subject of a journal full of incident and hard-
ships of all descriptions. After losing nearly
one-half of his alpacas in a very severe snow-
storm, which, lasting without intermission for
nine days, placed the lives of even the drovers
in jeopardy, Mr. Ledger succeeded in re-
uniting two parts of his flock in the province
of Sulta, Argentine Republic, during the
month of August, 1855. During this part of
his journey, he had to be constantly on his
guard against the machinations of the Bolivian
authorities, who were uniting in their efforts
to procure the destruction of the flocks. The
most active agent in endeavouring to carry
out this malicious purpose, however, was de-
feated in his object. In the same month, the
third division of his flock was seized in San
Pablo (Bolivia); but at length, in February of
the following year, he was enabled to deceive
the vigilance of the espionage under which
he was placed, and escaped with his alpacas
from the Bolivian territory. Mr. Ledger now
commenced his march on the valley of Cal-
chaquies, his object being to proceed to a spot
where "alfalfa" was cultivated, in order to
habitate the animals, by degrees, to this
species of pasture, both fresh and dry; thus
preparing them for their ultimate shipment, by
giving them a little dry food every day. Whilst
resting, after the accomplishment of this por-
tion of his task, a terrible calamity overtook
him, and upwards of two hundred of his
precious flock died suddenly, after drinking
the water of one of the lakes, which was
infested with leeches. This great loss involved
the necessity of once again setting out in
search of a more suitable locality; and although
Mr. Ledger had been separated twenty-two
years from his native land, and more than
five years from his home and family, he
determined to devote another year to the
purpose of recruiting his diminished flock.
The enterprise was one well worthy of the
labour and difficulties which it involved, being
nothing less than transporting, from the loftiest
peaks in the world, and introducing to Aus-
tralia, an animal which appears destined to
work out two great revolutions—the one in the
breeds of wool-producing animals, the other in
the fabrication of woollen textures. On leaving
the valleys, he kept the mountain sides, avoiding
the leech-infested lakes, and giving his flocks
the advantage of the invigorating air of the
highlands. Here he recommenced his wan-
derings, travelling very slowly, notwithstanding
the extreme severity of the weather, which
tried him greatly both by day and night; and,
finally, arrived at Laguna Blanca. Being satisfied that he had now arrived at a desirable spot for the propagation of the species, not only did he, in time, acquire a new flock of alpacas, acclimatised to temperatures less pure and rigorous than those in which their predecessors had been reared, but succeeded in educating them, to a certain extent, for the great voyage which lay before them. For himself and people he built a hut of stones, which furnished an indifferent shelter from the inclemency of the weather. For the animals, large yards were enclosed, and provided with troughs, in which they were supplied with their daily rations of dry alfalfa, cut up and mixed with bran, to which they became gradually accustomed. Twice was Mr. Ledger arrested by the authorities, and twice did he effect his escape—one by exercising his medical skill in the cure of the wife of the detaining prefect, and next by mixing laudanum with the grog of his military custodian.

The safe arrival at Sydney of the flock of alpacas was a great evidence of the skill, daring, and perseverance of Mr. Ledger, and deserves grateful acknowledgments on the part of a discerning public. "We hope," says the editor of the Sydney Morning Herald, "that it will be found that the enterprise will pay in some measure for the labour and the sacrifice. It is, unfortunately, too true that benefactors are themselves rarely benefited; that the cost of experience, and the toil of primary steps towards success, often obtain no return for those who first adventure on a new undertaking. Thus, the fate of inventors and discoverers is proverbial. It requires time to test the value of their labours—to silence detractors—to realise the fruits of their enterprise—to place their merits conspicuously before the world; and it often happens that those who have most served mankind, never hear the unmixed melody of praise: their services are only appreciated when it is impossible to reward them." The government of New South Wales purchased Mr. Ledger's flock for £15,000, and secured his services for five years, allowing him £1,300 per annum for their maintenance and superintendence—Such is a condensed narrative of only some of the difficulties which attended the introduction of this valuable animal to the shores of Australia.

THE SPANISH MERINO SHEEP.

Among the breeds of Europe which have attained to the highest celebrity, and by means of which, through judicious crossing, the sheep of Saxony, Prussia, Austria, and England have been greatly improved as respects the quality of the fleece, is the far-famed Merino of Spain. The term "Merino" alludes to the over-sea origin of the race; and there are good grounds for believing that these Spanish sheep are originally of British extraction, being of the old Ryland or Cotswold stock. Stow and Baker, in their Chronicles, say—"This yere (1461), King Edward IV. gave a licence to pass over certain Cotteswolde sheep into Spain." Baker adds—"King Edward IV. enters into a league with King John of Arragon, to whom he sent a score of Costal ewes and four lambs."

This is a breed so far superior to all others of the ovine race, for the production of fine wool for the manufacture of our most costly cloths, that its breeding and culture have received the greatest attention in every quarter of the globe. There is no country where these efforts have better succeeded than in Spain, except, perhaps, in Australia, where the breed has been brought to the highest perfection. The origin of this breed is involved in darkness; but it is supposed to have been introduced from Barbary, probably about the time when the Saracens were making their conquests in the Iberian peninsula. This, however, is mere conjecture; but Spain has long been distinguished for the excellent quality of her wools. Ancient writers make several allusions to this fact; and Columella mentions a cross made with the Tarentine breed by his uncle, a farmer or herdsman of Batti. This was effected with some wild rams of an extraordinary colour, which had been imported to Cadiz from Africa. The Batti, or Guadalquivir, was said to have brown or grey wool; and Pliny remarks that it had a red covering. Martial was a Spaniard, and he praises the wool of Battia; whilst Strabo, speaking of that of Turdetania, says—"Much cloth used formerly to come to this country. Now, also, fleeces come from it more than from Corax, and they are exceedingly beautiful, so that rams for breeding are sold for a talent each. Also the fine webs are very famous,
which are made by the Saltatize." From all these testimonies, it may safely be concluded that Spain has long been celebrated for its wool, for which it, no doubt, owes something to climate, as well as to the constant care, and the admirable management in the feeding and breeding of the flocks. This once famous country, however, has fallen from her high estate in the scale of nations. She no longer conquers, but succumbs; whilst her cloth manufactures have almost ceased to exist.

There are other breeds of sheep in Spain, besides the Merinos, more or less intermixed with them; but of the pure race, it is calculated that there are about ten millions, which, excepting, perhaps, the flocks of Leon and Estremadura, are migratory, and termed transhumantes, being periodically conducted from one part of the country to another, and back again. These transhumantes are divided into flocks, which, under the care of a mayoral or chief shepherd, and assistants, migrate from the mountains of the north to the plains of the south in winter, and return to the mountains in summer. The flocks follow the shepherds, who lead the way, and direct the length and speed of the journey. A few wethers, perfectly tamed, tread in the footsteps of the conductor, and the rest follow in due order. A powerful breed of dogs accompany the shepherds, in order to defend the flock from wolves; and a few mules carry their provision and other necessaries, as well as materials for making up the fold at night.

This migratory system is regulated by a tribunal termed Mesta, which is of such long standing as to be traced back to the middle of the fourteenth century, at which period definite laws with respect to it were enacted. These enjoined, that persons were not to travel along the course of the route pursued by the flocks while the sheep were in motion; they also established a right to graze on all the open and common land that lay in the way; and, moreover, assigned a path, ninety yards wide, through all the inclosed and cultivated country. The journey taken by the Merino flocks is upwards of four hundred miles, which they accomplish in six or seven weeks, and the same time is spent in retracing the route; so that, in every year, about fourteen weeks (or nearly a quarter) are spent in these toilsome journeys. Popular prejudice, in Spain, attributes the superiority of the Merino wool to this practice—a practice injurious to the agriculturists, through whose corn-lands and vineyards the flocks pass, and injurious to the keepers of stationary sheep; inasmuch as the common and pasture lands are completely eaten bare by the multitudes that slowly pass over them; while wilfully, or through carelessness, serious damage is done to farms, plantations, fields, and vineyards, for which no redress can be obtained. It is, however, much to be doubted whether the Merino wool owes its superiority, as is asserted by the Spaniards, to this system. The stationary Merinos in Leon and Estremadura, produce wool equal in quality to that of the migratory flocks; and these are again exceeded by some of the German Merinos, which never travel. Thus it would appear that the advantages of the Mesta system have been overrated; while the evils resulting to the flocks from fatigue, and the injury done to the lands in their course, have been treated with indifference.

The Saxon Merino Sheep.

This is the same breed as the preceding, differing from it only in accordance with the different management adopted in its rearing and tending. It is not very migratory, and it receives far more attention than the Spanish Merino. The flocks are clothed and sheltered, and furnished with covered buildings provided especially for them; and, like the horse of the Arab, are esteemed as nothing less than members of the shepherd's family. In summer they are depastured in the open air during the day; but when night comes on, they are either clothed or driven into their sheds. This is a very ancient practice. In the days of Columella, the Tarentine sheep were covered with skins, and denominated "soft," but whether the term is meant to apply to their wool or their constitutions, appears uncertain. In a modern sense, we should think it was meant to designate the latter. Columella says that these animals were principally reared in the house; that great care was necessary to be bestowed upon them in regard to warmth, food, and cleanliness; and that, in his time, a similar practice was pursued in Spain, and adopted by the Romans who settled in the north of Gaul.
With a view to acclimatising this valuable breed of sheep in England, frequent attempts have been made. The first took place in the reign of George III., who, himself, made the experiment, and took a deep interest in its naturalisation in our island; but the fates proved adverse. The losses were so great as not to be compensated by the extra value of the wool; while the absence of mutton would have been a want to which the English flesh-loving people would never submit. They preferred the fine and short wool of the Darn, though far inferior, because it was accompanied by a superior class of mutton. The wool did not, however, degenerate; but the lowland pastures of England, with their rich luxuriant grasses and succulent herbage, were too strong for the Merino. The first experiment was made in 1791, from a very fine flock presented to his majesty; but in this country they degenerated, and seemed to become less hardy than when they were imported. The next was made by the then Marquis of Breadalbanean, who resolved to adopt all the skill and care that could be suggested, in order to secure the safety of the flock. The sheep were housed, or shedded, at periods when other breeds were exposed. They had the best of keeping—perhaps an error arising from the endeavour to increase the mutton; but the three shear wethers could not be made to exceed 64 lbs. each, except in very rare cases, and these not more than 72 lbs.; while less pampered breeds realised nearly double these amounts of weight, and at an earlier period of their lives. The humitiy of the climate seemed to bear hard upon their constitution, as they became weak under it. Lord Western also devoted considerable time and attention to the breeding of Merinos in this country. His chief efforts were directed to crossing with the Leicester; but while the frame and mutton of the animals seemed to improve, the wool in some degree varied. He obtained it, however, of a beautiful texture, and of great length; but it was not quite the Merino wool.

An experienced and well-known agriculturist favoured Mr. Milburn with the following remarks on the Merino breed, which are worthy of the deepest consideration:

"Although the importance of this breed of sheep, at the first glance, may not be fully recognised (for they are little known; and, since the deaths of Lord Western and Mrs. Dorien, have only been bred by Mr. Sturgeon, of Grays), a little reflection will show that it can hardly be overrated; for it is this which supplies our colonists, at the Cape and Australia, with the fresh blood which the nature of their climates renders periodically necessary. In the latter colony gold may now absorb the greatest attention of its population; but we must not forget that wool was the foundation of its rapid growth and prosperity, nor overlook its importance in finding employment for our ships and our manufacturing artisans, by its successful cultivation. The Merino sheep is more distinguished for the quality of its wool than for other excellences. It presents a very peculiar appearance—the face is beautifully soft and white; a little rise is perceptible on the points of the shoulders, as also on the back of the head; the knees incline slightly inwards, and the legs are covered with wool to the feet. The rams are horned, and the ewes almost invariably polled. The Merinos exhibit a remarkable tendency to throw out horn, their feet growing so rapidly, that it is necessary to use the knife where they have not travelled much—a provision of nature, seemingly designed to fit them for the migratory life of their ancestors. They endure wet weather, or low situations, with difficulty; but, in hot weather, no sheep appear in better condition."

It is stated by Mr. Sturgeon, that our climate seems to affect both the carcass and wool of imported sheep. Nature would, therefore, appear to refuse to give the finest wool to the largest carcass. Mr. Sturgeon's exertions, for many years, appear to have induced some relaxation in his favour; for on sheep that would, if fattened, weigh ten or twelve stones, we find a quality of wool that can hardly be surpassed; and such sheep as (possessing the requisites of size and form, and the constitution peculiar to English-bred animals) must always be in request by our colonists, and have the preference over the German-bred animals, which seem to want the size, form, constitution, and length of staple they are sent to restore. Mr. Sturgeon's Merinos were the result of an amalgamation of the flock of his majesty George III., with those of Lord Western and Mrs. Dorien.
In Spain, as in the East, from the earliest times, the shepherd leads his flock. In Italy, in Greece, and some parts of France, it is still the custom; and the reed-pipe of the shepherd may be heard calling the flock together, or the troop be seen following him as he leads them to their evening folding-place. In Greece, it is usual, as formerly, to give names to the sheep, which they know, and will answer, coming to the shepherd when called.

Before closing this chapter, let us revert to our starting-point—the question as to the origin of the domestic sheep? It is clear that we cannot identify it with any wild species with which we are yet acquainted. If such exists, it is most probably to be found on the mountains of Armenia—but this is problematical; and there is some ground for supposing that, though the sheep of every region intermingle with each other, they have descended from different primitive origins. The subject is full of obscurity. It is, indeed, strange, that while history teems with the accounts of battles, massacres, invasions, the reigns and the crimes of kings, it throws no light upon the domestic animals which man has reclaimed. The motives which led him to attempt this important work, the manner in which he accomplished it, the characters and native abodes of the species selected, are buried in oblivion. The subject was too mean for history—the actors too humble to be noticed; but it is always the case, that the glare of mighty deeds offscies the record of the useful, the beneficent, and the truly great; whilst that which is in reality mean, is magnified.

CHAPTER II.

BRITISH SHEEP. LONG-WOOLLED BREEDS.

PRELIMINARY REMARKS.

TRADITIONAL testimony, as well as the oldest records, are very unsatisfactory regarding the existence of the sheep in Britain; and no early historian whatever deigns to take the slightest notice of them. Whether this neglect has arisen from their, perhaps, comparative unimportance in those times in this country, it is now impossible to say; but even Caesar, who enters at considerable length into a description of the manners and customs of the ancient Britons, does not make the most distant allusion either to the sheep or its wool. When he mentions the cattle of the ancient Britons, however, it is probable that he meant sheep to be included; as Herodotus, when speaking of the Persians, says—"The wealthy provide an ox, a horse, a camel, and an ass, roasted whole in furnaces; and the poor provide the smaller cattle." This is said in allusion to the feasts of that people. After the subjugation of Britain, the Romans turned their attention to the improvement of the country, cultivating the soil, and gradually bringing about an order of things very different from that which had hitherto existed. Among other acts, they established a woollen manufactory at Winchester, which, as a matter of course, must have been supplied by native fleeces, as there was no other source whence these could be obtained. This speculation succeeded so well, that, in a very short time, the woollen cloths of Britain entered into competition with those of the Roman empire, and early began to excel them. This was soon evidenced by the fact, that the finest and most costly dresses made use of on days of ceremony and festivity at Rome, were the product of British wool. The sheep employed in furnishing the material for these manufactures, were the short-wooled breed—Winchester being situated in the centre of a county which was then favourable to the support of that kind of sheep alone. From this period a darkness falls upon the history of the sheep and its productions for some centuries, until an old chronicler appears, and gives a
pleasing picture of the manners of the age in the time of Alfred, of whom it is said—

“His godmother often sent gifts to him she kindly took.

For to love other ples and loke upon his boke.”

This godmother seems to have had a just appreciation of the genius of Alfred, and is said to have been skilled in the spinning of wool, and to have busied herself in training her daughters to the same employment. From this circumstance, it would appear that the long wool had now begun to be employed, although the manufactures of the Winchester mills continued to be held in due estimation. In point of fact, remote as this period is, the woollen manufacture may be said to have already begun to assume a considerable degree of importance, as various breeds of sheep were cultivated, and different kinds of cloth made, so as to constitute it the principal source of employment and wealth in the country. At the time of the Conquest, we find it stated, that an acre of land and four sheep were about the same value. In the Saxon period, sheep were valued at one shilling per head until fourteen weeks after Easter, when, in all likelihood, they had attained to a higher condition from the grass having sprung up, and, consequently, affording a better supply of pasture. Both in 1011 and 1125, a great destruction took place among sheep on account of some destructive epidemic; and this might be one reason why the price of sheep, subsequently, became much higher. In the reign of Henry I., the price rose to 20s., and in that of Henry II., 25s. In the earlier part of the fourteenth century, a variety of breeds had been cultivated, and the prices for the different kinds of wool varied considerably. The produce of the Shropshire sheep was sold at £9 9s. 6d. per sack; whilst the Cornish wool, no doubt the produce of a mountain or forest breed, was only £1 per sack.

The first determined and general improvement of the sheep took place in the reign of Henry III.; but the great impetus to sheep-farming was given by the introduction of turnips. This well-known plant is cultivated for its bulbous roots, both in the garden and the field, and was originally introduced from Flanders into Norfolk two centuries ago, and from Norfolk was carried into the south of Scotland and the north of England, about a century after. In 1684, we find Mr. Worlidge saying—“Sheep fattened very well on turnips, which prove an excellent nourishment for them in hard winters, when fodder is scarce: for they will not only eat the greens, but feed on the roots in the ground, and scoop them hollow even to the skin. Ten acres sown with clover and turnips, will feed as many sheep as one hundred acres would have done before.”

Previous to the introduction of this invaluable root, it is not easy to see how large flocks of sheep could be kept alive throughout a long winter. It must be remembered that flocks were so extensive as to require a vast amount of provender. Harrison, who wrote a century before Worlidge, says that the farmer possessed as many as 20,000 sheep, notwithstanding that an act had been previously passed restricting one man to the number of 2,000. In 1662, according to the Berkeleyman MSS., the price of a “sheepe was vi.s.s.;” and, according to the same authority, in the time of Edward I., “a fat sheepe was worth from xvii.d. to xx.d., a lambe x.d.;” “a weight of wool,” in Richard II.’s time (twenty-one pounds) “was v.s.” Distinctions between grass-fed and corn-fed sheep—winter and summer mutton—were made by act of parliament in 1314. It determined the price of a “corn-fed sheep.” “A lambe” is spoken of as being worth x.d. or xii.d. in the reign of the first Richard. In 1699, there were said to be twelve millions of sheep in Britain, and the carcass value of each was 7s. 4d. The fleece averaged about 10s. 4d.; and the boast of the writers of the period is, that “no country but England and Ireland, having a sward or turf, would bear sheep producing the wool of which the English draperies were made.” They were willing to let the Spanish wool have the palm for the costly dresses of the peer; but it was insignificant—“not above 9,000 pieces of these Spanish cloths were sent abroad;” and these were only for the “wear of the richer sort.”

We will now consider individually the various breeds which have obtained amongst us, and which we will class separately, under the heads of long-wooleted and short-wooleted species. Before doing this, however, we will
give, from Mr. McCulloch's *Dictionary of Commerce*, the following compendious view of the more prominent characteristics of the various breeds:

THE TEESWATER.

Properly speaking, the long-wooled breeds of sheep originally belong to the rich and marshy pastures of England, whence, with the advances gradually made in agriculture, they have extended to all parts of Britain; and, in many localities, have encroached on the land previously appropriated to the short-wooled breeds. From this circumstance they have, for many years, been increasing in numbers, while the others have been either decreasing or remaining stationary. This is to be accounted for by the fact of the long-wooled varieties being more profitable than the short-wooled, provided they are pastured upon such land as may be found agreeable to their nature. When this is the case, they produce a much greater weight of fleece, which yields as much per pound as that of the others; while the earlier maturity, and the superior fattening qualities of one particular variety, render them a much more preferable stock to the others.

Yet, it has been observed, that whilst many of the mountain or up-land breeds have been preserved in a state of purity from remote ages, most of the ancient long-wooled breeds have either altogether disappeared, or been preserved, by the curious, in individual flocks; they have either been changed by extensive crossing with the New Leicester breed, or altogether supplanted by it. A distinction has been made of two classes of long-wooled sheep; one belonging to the fens and marshes, and the other to the inland plains. The former embraces the Teeswater, the Leicester, and other varieties; and the latter, the Lincoln and the Romney Marsh.

The Teeswater is a very large breed, and may, in some degree, be considered the giant of the fleecy tribes, as it will frequently attain to the heaviess of 50 lbs. per quarter, or 210 lbs. weight. The fleece is long, very open, and somewhat coarse. It weights from 9 to 12 lbs. This breed of sheep is very old, and, for a long space of time, has been located on the banks of the river Tees, whence it takes its name. Most writers class it with the Lincoln sheep, from which it is supposed to have derived its origin. This, however, is very uncertain. "The principality of Durham," says Mr. Milburn, "celebrated for its native wild cattle and pigs, had doubtless its own peculiar breed of sheep and cattle; and the old Teeswater sheep had as much a habitat in those rich pastures as the wild cattle of Branspeth, or the deer at Auckland Palace. The great peculiarity of the animal was its slow growth, and, at the same time, its large size and bone, its heavy, thin, and coarse wool. The length of the legs, in particular, gave it an imposing and somewhat ungainly appearance; while its thick skin made it a slow feeder in any but its native pastures—the alluvial washings of many generations." At one period, this gentleman obtained two lambs, as a great favour, from a flock of pure Teeswaters. The farmer forbade mistaking two of his best animals, and he had to be contented with one. He selected another, so close in the pelt, and so unsymmetrical, that he decided in putting it off. "The best was well kept, and astonished both himself and his visitors by its amazing size, and the great weight and quantity of its wool; but, just before shearing, it died the victim of wool and mutton. As it was skinned, and not shorn, there was no mode of weighing the fleece; but it could not be lighter than 12 lbs. The load of fat, added to the envelop of heavy wool, seemed to have suffocated the animal, for it was exceedingly well kept.

Pure Teeswaters are now very scarce. As
wo have already observed, they have all, more or less, been improved by crosses with the Leicesters; and a more beautiful cross can hardly be seen. The Leicester shortens the leg; but it also shortens the wool. Still, the cross so far keeps up the character of an open fleece, that it is excellent in a point where the Leicester is somewhat deficient. The cross is always the substitution of a Leicester instead of a Teeswater ram to a Teeswater flock of ewes. The finest animal shown at a meeting of the Royal Agricultural Society at Liverpool, was one of these crosses; but it was excluded because it was not a pure Leicester. "Long-woolled," however, was a term soon after substituted for Leicester, so as to admit sheep of this description to compete. The old Teeswater was a large, full sheep, of ungainly form, with a coarse head, rounded haunches, and long and large limbs. Other large breeds formerly existed in the midland counties, but most of them were smaller than the Teeswater. These and similar breeds, however, have now altogether disappeared in England.

The Teeswater sheep thrive best in small flocks, and when they are dispersed over pastures with other stock, rather than when they are crowded on the ground. The ewes are very fruitful, and usually produce two, and often three lambs at a birth. They are excellent mothers, and famous milkers; and though almost incapable of being brought up to a state of fatness at one year old, they will weigh 25 to 30 lbs. per quarter at the shear without difficulty. The contest respecting large and small sheep on good land, and the most politic course for breeding and fatting, is by no means settled.

KENTISH OR ROMNEY MARSH SHEEP.

The Kentish, or Romney Marsh sheep is not, in its external characteristics, unlike the Teeswater: it inhabits a locality to which it is peculiarly adapted. In the northern and eastern districts of this county, there is much open ground, covered with short pasture, upon which this variety thrives remarkably. Sir Richard Phillips says of them, in his day—"The marsh lands of Kent, used for breeding sheep and fattening cattle, are 82,000 acres; of which Romney Marsh is 41,000. It has fourteen miles in length, and ten in breadth, and for the greater part consists of a rich clay soil, well adapted for rearing a large breed of sheep. This had been reclaimed, at some time, from the sea." Sir Richard again says, "that four sheep will live on an acre of moderate land in summer, and two in winter." The proportion is now quintupled, but the season is reversed. He then laments "the deterioration of the wool of the Romneys; for the wool of sheep deteriorates as the sheep's carcass increases; hence, for some years, owing to the enlargement of the English sheep by new breeds, the wool has become too long and coarse for fine cloths. Our long and coarse wool will not unite or produce the required substance for clothing."

The head of the original Romney Marsh sheep is large and thick, and covered with a white woolly tuft. The forehead is flat and broad, the neck long, and somewhat small for the size of the animal. The loin and back are wide, but the sides are flat, and the belly is deep. This exaggerates a naturally narrow, and not very deep chest, so as to make it appear still less favourable. The legs, speaking of them in the sense of mutton, are large and broad; and the hind quarters generally are better developed than the fore. The wool is long, but fine, and very suitable for combing. It weighs about nine pounds per fleece. The mutton is good in quality, and the weight is often 140 lbs.; and, in some cases, 150 or 160 lbs.

The race can bear cold, wet, and eastern exposure. Formerly they were fed, both winter and summer, on grass and a little hay, and were seldom provided with shelter; so that, not unfrequently, the lambs all died, and the ewes suffered from the cold and wet. The long-established custom of the Romney breeders has been to send their lambs to the farmers on the uplands, to be fed during the winter; but they are usually kept very hard, chiefly on the stubbles for a long time, when they are often greatly debilitated before they are transferred to the pastures. They are rarely allowed hay—a kind of economy which sometimes proves very destructive to the stock. In the management of the ewes in the marshes, the same negligence and want of care are apparent. However severe the weather may be, shelter is very rarely afforded them; but
where this is done, it amply repays the cost and trouble in the lives which it saves. The breed, however, is now seldom found in a pure state, as it has been extensively crossed with the New Leicester, which has greatly improved its form. The effusion of Leicester blood, says Mr. Milburn, "effectively changed, possibly for the better, on the old Romney Marsh sheep. It made a finer animal, reduced the quantity, but not the quality, of the wool; deepened the chest, and increased its width; rounded the rib, and lessened the bone generally; drew up the belly, and destroyed the tuft of hair on the top of the head; so that it made the sheep altogether a better feeding animal, without destroying its suitability to the soil and climate which it had inhabited for years. With its other improvements, the cross had also the effect of reducing the period of bringing the animals to market. They were usually three years old before they were sold to the butcher for killing. They are now prime for the London market at two; and as this enables the feeder to turn over one-third more capital in sheep-fattening, it is a great advantage, though he has possibly somewhat injured the hardihood of the animal; and it now requires a greater amount of care and skill for the bringing up of the lambs. Nor has the wool been so far injured as to prevent the breed from being classed among those celebrated for this commodity. The Leicester may have shortened a little, and made the fleece set closer on the body; but it has neither destroyed its fine texture, nor prevented it from standing high in the estimation of the manufacturer."

THE LINCOLNSHIRE SHEEP.

This breed bears a strong resemblance to both the Teeswater and the Romney Marsh or Kentish sheep, and, in all probability, had a similar origin to them. The Lincolnsheep fens extend into Norfolk, Cambridgeshire, and the adjoining counties, and are well suited for the rearing of a large race of sheep; and, accordingly, they form the native habitat of the Old Lincoln—a breed in its pure state, we believe, now almost quite extinct. They were of a large and coarse make, with hollow flanks and flat sides, large legs and feet. Their fleece almost touched the ground, was long and

oil, and weighed from 10 lbs. to 12 lbs., and upwards. They fed slowly, but accumulated a great deal of internal fat, and were, on that account, much sought after by the butcher. This was the Old Lincoln, the progenitors of the present existing race, which has been improved by extensive crossing with the New Leicester, and which Mr. Milburn describes as having been of great value. He says that they have smaller faces than the Romney Marsh sheep, and are altogether lighter in flesh. The carcass is large and coarse; the length, from the head to the tail, measuring, in some cases, four feet six or seven inches. It is to this great length that he attributes the apparent hollowness which this variety has in its back. The ribs are flattish, and not covered very thickly with flesh; whilst the belly is deep, and the shoulders so forward as almost to hide the breast. The neck is thick and large, and is encumbered with a deep and flabby dewlap. The hind quarters are full and fat, with a tendency to accumulate fat at the rump. The legs are fleshy and deep. The whole animal is of an ungainly form, taking the standard of connoisseur taste as a criterion; but, when the wool covers the animal, the whole of his imperfections are hid. He is one living square of wool, ranging from fifteen to eighteen inches long; and more of this material is clipped from the Lincolnshire sheep than from any English sheep whatever. The fleece varies from 12 lbs. to 14 lbs. weight, which, when it sells for 15d. or 18d. per pound, is equal to the value of the whole carcass of some of the smaller breeds of sheep. Nor is it far behind in mutton. The wether will weigh from 30 lbs. to 35 lbs. per quarter, sinking the odd, or a nett weight of mutton, per sheep, of 140 lbs.

The effect of crossing this animal with the New Leicester has been to reduce the size, diminish the length, and to restore the power of internal accumulation of fat, and also to deposit it externally on the sides and back of the sheep. Messrs. Kennedy and Grainger state, that the sheep bred in the wolds are deeper crossed with the New Leicester than those in the marsh lands, which may account for the fleece of the latter being heavier. "The breed of sheep generally," they observe, "has been greatly increased since the turnip husbandry has been introduced. Those bred in the wolds,
and, indeed, in every part of the district where this system is pursued, are reared chiefly on artificial grasses. There are, however, great numbers bred on old pastures, the best of which are kept for the purpose of fatting sheep." The effect on the wool, as to quantity, certainly depends on the degree of Leicester blood infused. The lowland sheep, when the infusion prevails to a smaller extent, have a large massy frame of flesh, covered and grained with fat. They are compact and kindly feeders, though they require more food than when a larger proportion of Leicester blood prevails, and cannot either be put on land so inferior, nor on any land in the same average quantity. Their produce of wool is very great. A wether killed at Grantham, one of an equal lot of twenty-seven, clipped 17 lbs. of wool, and weighed almost 305 lbs. The sheep are always sold at two shear, and the united clip—the one made as a shearing, and the other at two years old—will often average 20 to 25 lbs. When fatted to the utmost extent, a wether has been known to weigh 300 lbs. and a ewe 262 lbs. Such instances exhibit the power of these large-framed sheep to produce both wool and mutton. Assuming a choice specimen to be two shear, his whole produce will be:

Total £14 2

With higher prices, of course, the value of the animal would be more; but this is sufficient to show that the Lincolnshire sheep, when not far removed from its original stock, is an animal very remunerative both as to wool and mutton.

THE DISHLEY, OR NEW LEICESTER SHEEP.

The Leicester, or the New Leicester sheep, had its type in the Teeswater, the Lincoln, and the Romney Marsh breeds. It was a large, heavy, coarse sheep, with a disposition to feed favourably, but with much grossness about it. Its wool, however, was excellent for combing. The rams would weigh, when fit, 40 lbs. per quarter; and the fleece would weigh 13 or 14 lbs. It was on these animals that Bakewell began his experiment, with a view to improvement; and, in 1760, he commenced the system of letting rams, as distinguished from selling.

The usual course was for the farmers to save the best of their several flocks, and reserve them uncastrated, as male lambs. Bakewell began a letting system; but so little was it liked, and so little was thought of his rams, that he let one in that year, for the season, for only sixteen shillings; and it was not till twenty years afterwards, that anything like a remunerative price was received. It was then only ten guineas for one ram; but it afterwards rapidly increased, till, in 1786, he received 300 guineas for one ram; and, three years afterwards, he realised no less than 6,200 guineas, thus rewarding him for his unwearyed perseverance, under almost every species of discouragement and opposition. Subsequently he established the Dishley Society, with the view of extending the breed, preserving it pure, and benefiting the members of it. As an improver of the breed of sheep, this gentleman stands alone; but how he accomplished the great points he achieved, remains a secret, for the plan he adopted died with him. It is certain that he reduced the size of the native animal, and gave him small offals, induced him to lay on flesh and fat all along the breech, the sides, the shoulders, the flank, and the neck; opened his wool, and also reduced it in weight, and a little in length. He likewise increased the tendency to lay on fat in proportion to the food consumed, and made the animal take on fat a year or two earlier at least, and thus enabled two or three animals to be fed where one only could be kept before. All this he did; and the same breed of sheep has, for a century, not only maintained its position, but has been employed, with more or less success, to improve nearly every breed of sheep in the United Kingdom, and, at the same time, has more or less displaced almost every other breed.

The various points of the New Leicester have been thus accurately set down by Mr. Low:—"The head should be hornless, long, small, tapering towards the muzzle, and projecting horizontally forwards. The eyes should be prominent, with a great expression; whilst the ears should be thin, somewhat long, and directed backwards. The neck should be full and broad at its base, where it proceeds from the chest, but gradually tapering towards the head, and being particularly fine at the junction of the head and neck; the neck
SHEEP,

breeder, was known to select and purchase choice ewes from all parts of the country, chiefly from Melton. He had a breed which were great favourites before Bakewell was heard of. Specific characteristics we cannot very easily define. Mr. Youatt shuns even Mr. Allom, in a note; and, in the text, says, 'Up to this period (the middle of last century) very little care had been bestowed in the breeding of sheep.' Mr. Marshall goes to the other extreme, and says that the origin of Bakewell's improvements are due to Allom. The truth is probably between the two. Allom's stock might be made available to Bakewell's purposes; and his practice might set the latter to work in more zealously improving the breed.'

Another cause was also in operation towards the same end; and, doubtless, gave another opportunity for Bakewell's selecting his specimens to improve his breed. In 1747, there were some successions of bad seasons, which so operated on the succulent grass of Leicestershire, as to sweep off nearly the whole of the sheep on the lower clay soils of that county. This banished the more wealthy farmers from the district, and they had to take refuge on the wolds of Yorkshire, and then purchase some small-horned, fine-bred sheep, for a supply to their decimated flocks. The trade of jobbing thus commenced; and it is said that Bakewell employed the jobbers, who brought down, from time to time, these Yorkshire wold sheep, to allow him to cull the best, before they offered them to the farmers. He thus obtained compact, square, rapidly-feeding animals; and persevered, year after year, in selecting the best, in his judgment, from his own flock, until he had obtained the celebrity which has handed down his name as the greatest improver that ever lived; and the once new Leicestershire sheep has become the Leicestersh eep; so completely has it eaten out its progenitors.

Although this breed has been intermixed with many other breeds, in almost every kind of degree, it still, in most respects, holds its ground. Breeders, however, now incline towards the production of a large animal, as being more profitable. Thus, the improved Cotswold—frequently designated the New Oxfordshire—and some of the heavier species, have
become successful rivals of the pure Dishley breed. The Leicester, however, still commands a large extent of the most fertile districts of England, and has long been introduced to Scotland, where it has been cultivated with the utmost care and success. In both countries it is chiefly restricted to the lowlands, or to land of pretty good quality. In the *Journal* of the Royal Agricultural Society of England, we find an account of the modes of management pursued in Roxburghshire, on the borders of the Tweed and the Teviot, which might be taken as the system generally adopted in the superior districts of both countries. "Before the commencement of the present century, the Cheviot were almost the only sheep found in Teviotdale and Tweeddale; whilst, within the space of thirty years afterwards, the Leicester breed, with few exceptions, had the entire possession of these districts; and they not only greatly exceeded their predecessors in numbers, but still more so in weight. On nearly all the farms of any considerable extent in breeding, a stock of these sheep is kept; and from the ewes, three successions of lambs are taken; the dams being sold off at the close of their third breeding season, or when four-and-a-half years old. In general, the whole produce of these ewes is retained upon the farm on which they are bred; a proportion of the ewe lambs, when gimmers, coming in to take the place of the old ewes sold in each year. The wether-lambs, again, are disposed of as fat; many of them, immediately afterwards, being deprived of the first fleece; and the remainder, after being fed on turnips, in the winter or spring of the second year. Not unfrequently, however, upon farms where a large proportion of turnips cannot be raised, the whole wether-lambs, and, sometimes, part of the ewe-lambs, are disposed of at weaning-time; and those ewe-lambs kept beyond the number required to maintain the complement of the year, are sold when gimmers, usually at about eighteen months old. These young sheep, being thus so early matured for the butcher, are maintained from their earliest time on full feed; it being a great object to prevent them losing any of the condition they generally possess when taken from the ewes. With this view, also, they are early put upon turnips, as it is very desirable they should be well acquainted with this their essential means of support, previous to any failure in the nutritious properties in the grass, or the occurrence of severe weather. To the young stock, intended to be kept for breeding, fewer turnips are commonly allowed, although they are seldom, during any part of the winter, entirely without this useful assistance. The ewes having, at this season, the range of the whole pasture, are only allowed auxiliary food during the severity of a storm, and in hard winter weather, until towards the approach of the period of lambing, when a proportion of turnips becomes indispensable to maintain them in sufficient condition to bring them well through this critical and interesting season. In general, more sheep are fattened than are bred in the district." This system, with some modifications, caused by the qualities of the land, prairies, with little difference, throughout the midland districts of England.

The Leicester, as a *turnip-feeder*, is, perhaps, the most successful of all breeds of sheep. The fat is in greater quantity, collected on the surface, than any breed whatever; and it will accumulate as much fat, if not more, for the food consumed, than any other kind of sheep. A better proof of the value of the Leicester could not be adduced, than is found in the fact of their having superseded a vast proportion of the sheep of this country, under every circumstance of pasture, range and climate, and established themselves in their stead. They have also been used to improve the desirable points of almost every breed, which still at all keeps its ground. In fine, the Leicester is the only sheep which can, with any degree of success, be fattened at one year old.

**THE COTSWOLD SHEEP.**

Cotswold is one word produced by the union of two, and signifies a sheep-fold and a naked hill. The breed of sheep which goes by this name is both ancient and celebrated. The hills which were its original habitat are of no great elevation; but they enjoy a fragrant herbage; and though, at one time, consisting only of bleak marshes, have, in the course of years, undergone great improvement. Relative to its breed of sheep, Camden speaks of it as furnishing wool both fine and soft: whilst
Drayton writes of its abundance. Speed, writing upwards of 200 years ago, speaks of the wool as similar to the Ryeland, and rivalling that of the Iberian peninsula. Indeed, some have gone so far as to say, that the Cotswold is the progenitor of the Merino sheep, as, in 1464, Edward IV. permitted a number to be exported to Spain, where they multiplied and spread. Before this period, however, Spain enjoyed a celebrity for her wools. The Cotswold is a large breed, with a long and an abundant fleece. In the time of Queen Elizabeth, when Markham wrote, he describes them as a long-woollen race. The ewes are not only prolific, but good nurses. At one time they were bred only on the hills, and put to fatten in the valleys of the Thames and the Severn. Since the enclosure of the Cotswold hills, however, coupled with the improvement in their cultivation, they have been reared and fattened in the same district. This species has a great tendency to accumulate fat upon the back; and whilst its breast is not so wide, deep, or prominent as that of the Leicester, it is of larger bone. Its sides are flatter, but it is neither so broad nor so prominent in the shoulders and legs. The fat and flesh are laid in the back, in a large and unyielding mass; whilst the Leicester has a soft elastic firmness, in every way agreeable to be touched. This may arise from the fineness of the pelt. The Cotswold, on the contrary, has a thicker pelt, and the wool mats itself near the skin, and is more straggling at the edges. The head is white, and so are the legs; while the ears are small, and fall downwards and outwards. The top of the head is a mass of soft bushy wool. The weight of the animal will sometimes reach 28 lbs. per quarter; but 28 to 30 lbs. will be a nearer average for two-year-old sheep. At a year and a quarter they will, when properly fattened, be found to yield 19 lbs. per quarter, and sometimes attain to 20 or 21 lbs. Their yield of wool, which is fine and light in proportion to its bulk, is from 8 to 9 lbs.

The gradual infusion of Leicester blood is general amongst the most celebrated and extensive flocks of the Cotswold breed, otherwise there would be longer wool, more hardness, less early maturity, more bone, and somewhat lighter fore quarters. The Leicester mixture, however, is not excessive, and occurs, perhaps, in a very remote degree. The sheep is still and quiet in its habits, and is one of the best kinds for carrying out the board or hurdle feeding. In Gloucestershire, the Cotswolds, now almost lost in the Leicesters, have multiplied to a degree which would hardly have been believed to be possible in this part of the kingdom; and the short-wools are nearly driven out of this district. Writing upon this breed, Mr. Spooner says, that “the superior hardihood of the improved Cotswold over the Leicester, and their adaptation to common treatment, together with the prolific nature of the ewes, and their abundance of milk, have rendered them, in many places, rivals of the New Leicester, and have obtained for them more attention to their selection and treatment, under which management still further improvement appears very probable. They have also been used in crossing other breeds, and have been mixed with the Hampshire Downs. It is, indeed, the improved Cotswold that, under the term of New or Improved Oxfordshire sheep, are so frequently the successful candidates for prizes offered for the best long-woollen sheep at some of the principal agricultural meetings or shows in the kingdom. The quality of the mutton is considered superior to that of the Leicester, the tallow being less abundant, with a larger development of muscle or flesh. We may, therefore, regard this breed as one of established reputation, and extending itself throughout every district of the kingdom.”

THE DARTMOOR SHEEP.

This is one of the principal forest breeds of the West of England, and it bears a strong resemblance to the Dorset. Its habitat is found in the higher situations of Devonshire and Cornwall; and, from the hardness of its nature, it is well adapted to the poverty of the pasture which the forests of Dartmoor and Exmoor afford. They have white faces and legs; have horns generally; but some are without these. The head and neck are small, and so is the bone in every part of the animal; whilst the carcass is narrow, and the sides are flat. When fat, they weigh from nine to twelve pounds per quarter. In the yolk, the place is three or four pounds in weight, and the wool is somewhat short, with a coarse top. It is
EXMOOR SHEEP. AND THEIR VARIOUS BREEDS. [HAMBOROUGH SHEEP.

classed, by some writers, among the middle-wooled breeds; but, in our classification, we have followed McCulloch, and made only two distinctions—namely, a long and a short, for the sake of simplicity. Large numbers of them browse on the hills and the commons of the heathy parts of Devonshire; but the ewes are taken into inclosures to lamb. For the sake of their wool, the wethers are kept on the downs, until they are five or six, or even eight or ten years old, save when the winters are severe, when they are inclosed to prevent their being lost in the snow. Their mutton is delicate, and, in the metropolis, procures a ready customer. Their wool, however, is not very fine. Indeed, from an early period, the Devonshire produce of this article has had but an indifferent character. In a note in the work published in the Library of Useful Knowledge, it is stated to have been inferior even in the days of Edward IV., when the Devon manufacturers petitioned him to permit them to mingle fleeces with their wool, in the making of their serge cloths, because the material was so gross and stubborn, that cloth could not be made thereof, without mixing it with fleeces. Since the introduction of the Leicesters, however, a better article has been produced. It is mostly used for the manufacture of livery-cloths.

THE EXMOOR SHEEP.

This species is very like the Dartmoor as to conformation and character, but it is of a still smaller size. The males have hair under the chin, like goats, and bear a striking resemblance to these nimble-footed animals in their activity and boldness. They are milder than the Dartmoor breed, and their flesh is equally good. The horns are large, and very peculiar, spreading at the roots so much, as nearly to touch each other, and proceeding backwards, and growing outwards, so as to be somewhat spiral. The little ears peer out of these folds, and a dull, heavy-looking head is situated between. The throat is flabby and hairy; the breast narrow and thin, sinking backwards, almost behind the fore legs; and the fore quarter is short. There is a falling of the back behind the shoulder, and a rise at the rump. They are now much improved by the infusion of a little Leicester blood. They are the sheep of Cornwall, which, in early times, were remarkably small, and their fleeces so coarse, that the wool bore no better title than that of Cornish hair. Under that name, the cloth made of Cornish wool, was allowed to be exported without being subject to the customary duty paid for woollen cloth. When cultivation began to extend, and the cattle to improve in size and quality, the Cornish had the same poundage conferred on them by grant from Edward the Black Prince, the first Duke of Cornwall, on condition of their paying 4s. for every hundredweight. These sheep principally occupy the heaths and downs of every part of the county, even as far as the sandy hills, which hardly have a covering of green towards the Land's-end. We have seen many of them cropping their scanty herbage in these parts, where they are highly valued, on account of the peculiar flavour which their mutton has, from the numerous aromatic plants with which this part of England abounds. The native breed is considered to have reached its maturity at four years old; and the average number of twin lambs produced, is about one in six.

THE HAMBOROUGH SHEEP.

This is both a short and long-wooled race, very peculiar and valuable, says Mr. Milburn; and yet it is scarcely named by half the writers on sheep. It makes mutton readily, and produces a valuable wool. It is bred in the south-eastern parts of Northumberland, and north of Durham—in fact, from the Tweed to the Tyne—and the regular fair for their purchase is Rodbury. The fleeces are remarkably like each other, having flat level backs, being good grazers, producing 6 lbs. of wool of a strong but close quality, and weighing 22 lbs. per quarter when fat. The heads are placed horizontally, and the animals rapidly accumulate fat. With ordinary keep the ewes are always fat. They are excellent feeders, and consume a great deal of food. The fat is laid on internally to a large extent, but it is duly mixed with the muscle; and consequently the mutton is somewhat insipid. In feeding, they grow more fat and less muscle, perhaps, than any other breed. From their great resemblance to each other, they seem to be a distinct breed, and are a good deal grazed, the ewes being purchased for lambing in Yorkshire. After the lambs are weaned, the ewes soon become fat.
on grass in summer, and the lambs rapidly feed for the butcher.

THE BERKSHIRE SHEEP.

About the centre of Berkshire, its old breed was wont to be found, with their Roman noses, black faces, long tails, and black and mottled legs. Some of them were polled, but most of them were horned. Their strength, activity, and height were considerable; whilst they folded well, and, when fattened, assumed large proportions; but to bring them to this condition usually took a long time. Mr. Herbert says, that "they were next in weight to the old Leicester breeds, but higher than them on the legs. The wethers, when moderately fat, weighed from ten to thirteen stones; and when fattened for prize show, they weighed from sixteen to twenty-two stones." This breed was first improved by a cross with the Wiltshires, and subsequently with the Southdowns, which are now the prevailing breed in the county. The blood of the old race may be said to have become so deeply amalgamated with the Southdowns, that they have lost their original character.

THE BLACK-FACED, OR HEATH SHEEP.

This peculiar breed of sheep inhabits the lofty, but barren and hilly lands which, commencing in Derbyshire in the south, run thence into Scotland, through Lancashire, Yorkshire, Cumberland, and Westmoreland. It is questionable whether they are the aboriginal breed of these districts; but whether they are or not, they have extended themselves into the mountains of the Highlands, and even penetrated to the Orkneys and Zetland, where they have taken the place of the original and more inferior breeds of these parts. They are celebrated for the excellence of their mutton, but their wool does not rank so high. There is no doubt, however, that a breed of sheep producing wool of a superior kind to that now yielded by the black-faced sheep, was at one period common in Scotland. Hector Boethius, who wrote about the year 1460, speaks of the fineness of the wool produced in various parts of this county. Remarking on the sheep which inhabited the vale of Esk, where, until the introduction of the Cheviots, the rough-woollen, black-faced sheep alone were found, he says, as given by Hollinshed—"Whose sheep have such white, fine, and excellent wool, as the like of it is hardly to be found again in the whole island." Sebastian Munster, in his Cosmographia Universalis, published ninety years afterwards, says—"The sheep pasture in each country (England and Scotland) is such, that nowhere is there better or finer wool." Dr. Anderson proves, that three or four centuries ago, a fine-wooled breed of sheep was common in Scotland. In Galloway, Annandale, and Niddesdale, it was found in the greatest numbers; but it remained longest in some of the mountainous districts of Aberdeenshire. Not a century ago it existed in Fife; and if any of it now remains, it is perhaps in the islands of Shetland.

Returning to the black-faced sheep, however, we find it observed by Mr. Torr, that it is a breed which possesses characters that distinguish it from every other species in the British Isles. It belongs to the smaller races of sheep in regard to the weight to which it attains; but is not only larger, but more robust than the Zetland, the Welsh, and the ancient soft-wooled sheep, which it displaced. It resembles the Wallachian, which has an affinity with the Persian; and, like it, a conjecture might be ventured that it came originally from the East. Its peculiarity is its extreme hardiness, as it will subsist where many other races would literally starve. It is left to shift for itself amongst the heather and furze; and, when unmolested, wanders almost wild among the hills, picking up such herbage as it finds suitable or agreeable to its palate. Thus it is reared at very little expense, until it is transferred to richer pasture, or till turnips are given it, with the view of its being fattened for the butcher.

The face and neck of these sheep are usually black, though sometimes they approach to grey; and, a little before shearing-time, become brown. Elegant and graceful horns grow from each side of their heads, and usually bend backwards and downwards. The specimens on the heads of some four-year-old wethers, have been pronounced really beautiful. The head is broad, and the back straight and broad; the chest deep, and the legs straight and fleshy. The wool is long and pendulous, and
considerably curled. The eyes are full, and expressive of life; whilst the carcass is round-barrelled, with well-arched ribs. The lines down the hams and the breast are straight and perpendicular. The neck is fine and clean. The lean Highland sheep are usually bought at Falkirk trysts, where myriads of animals cover the moor. As many as 80,000, and even 90,000, are sometimes exhibited at the October tryst. Twenty thousand is a common number at the other trysts. About half this number are wethers of the shee; the remainder are two-year-olds, for further picking on the moors, and for store or for feeding, and a few rams. The year-old wethers are either purchased there to fatten, or are run on in winter in any low pasture with rough grass, and fattened in the summer of the following year on grass. During the winter these will subsist, and even improve, on very inferior grass; such, indeed, as almost every other animal will refuse; and if they are not crowded on the ground, they will manage to get through the winter. Many persons imagine, that it takes four, or even five years, before the full mutton-development of the black-faced sheep takes place; but this is not the case. Heated fed sheep, fed in the second winter after they are lambed, are, when rapidly fattened, in as good condition as they can be at any subsequent period. "This breed," observes Professor Low, "does not appear to amalgamate well with other races, so that crossing has not generally been successful as a means of permanent improvement. It has been frequently crossed by the Cheviot, but the descendants have been found inferior in weight, form, and quality of wool, to the pure Cheviots, and to the black-faced heath breed in hardiness and aptitude to thrive in an upland country of heaths. But as it is not always deemed safe to change a stock of sheep, habituated to their locality, the practice of a continued crossing with the Cheviot, until the flock has acquired the characters of the latter, has been sometimes adopted; so that the original black-faced stock has become, in time, almost Cheviot. Another species of crossing has become remarkably successful—namely, the employing of males of the Leicester or Southdown for a first cross. The lambs—the result of this mixture—are excellent, rising to a much greater weight than those of the pure black-faced blood. Of these crosses, the best has been found to be with the Leicesters. That with the Southdown produces very handsome sheep, having perfectly black faces and legs, and a close good fleece; but they scarcely attain the size of the Leicester crosses; and the latter, accordingly, are preferred for the special purpose for which this species of breeding is designed."

To keep black-faces properly, or well, they should not be crowded, or too much overstocked. They are capable of bearing very hard treatment; will stand almost any degree of cold, and any quantity of wet, whilst supporting themselves on the poorest of pasture; but they are seldom tried with this; therefore, age has to make up for previous neglect; and they must be kept longer than any other kind of sheep, to bring them into suitable condition. Heavy stocking will, nearly always, make the difference between good and bad produce; as it will diminish the size of the sheep, throw it back in its feeding, and the breeder and the feeder will be a much greater time in bringing up their produce to that condition which may be called ready for the market.

CHAPTER III.

SHORT OR MIDDLE-WOOLLED BREEDS OF SHEEP.

THE DORSETSHIRE SHEEP.

What some designate the middle-woolled sheep, comprise the Dorset, the Southdown, the Norfolk, the Suffolk, and Cheviot breeds, with some others, which were all formerly short-woolled. For the sake of simplicity, we
have retained their original distinction, as their wool has been lengthened only by the improvements made in breeding. The Dorsetshire sheep is a breed of itself, although it is now greatly encroached upon by the Southdowns. It is a valuable breed; and where pure, is entirely white, with a long and broad face, and with a tuft of wool on the forehead. The shoulders are broad and low; the chest deep; the back straight; the loins broad; the legs somewhat long, and the bone small. They are a hardy and useful race, folding well, and yielding excellently flavoured mutton. When three years old, they average from 16 to 20 lbs. per quarter. "The great peculiarity of the Dorset sheep," says Mr. Milburn, "appears to be, that while other breeds receive the ram only at one and the same season, the Dorset will take him all the year round, and even while the lambs are suckling. There is thus the power of supplying lamb at any season of the year for the pampered appetite of the epicure; and vast sums are thus realised by those who keep them for the purpose. Nor is this peculiarity one which at all applies, as might be supposed, to the mild climate, or favoured pasturage, of Dorsetshire. The breed possesses the same peculiarity in all parts of the country, even in Scotland; though it must be obvious, that the rearing of lambs at the period of midwinter, is far more likely to proceed favourably in the mild and genial south-west of England, than in the colder and more northern climes. The ewes take the ram in May, so that they will produce in October; and the early lamb at Christmas, in London, is obtained from this late produce." These lambs are house-fed—a practice which is not now so common as it used to be; but the manner in which it was, and still is, partially pursued, in the districts near the metropolis, has been thus described by Mr. Middleton. He says, that "the ewes are always, without exception, of the Dorsetshire breed, and the early lambing species are sought for, throughout the country, with great diligence; for it is thought that not more than one in three will lamb sufficiently early for the purpose. Those of large size, with white noses, are most in esteem; and anything like black on that part would occasion their being rejected. The colour of the flesh of those lambs, when butchered, is, also, a matter which, in a great measure, governs their value; and, therefore, those which can be warranted to die fair always bear the highest price. This, evidently, cannot be guaranteed when produced by ewes which have been promiseously purchased at the fairs; those breeders with whom the sucklers usually deal, are, consequently, careful in the selection of the rams, the issue of which is said to be known by certain marks in the mouth, even before any previous knowledge of their progeny. The rams and ewes should be put together at such a time that the lambs may fall at the proper season—say, somewhere about Michaelmas—from which period there is usually a succession of them, until towards Christmas. The ewes, both some time previously to this, and during the whole period of suckling, are kept in a croft, adjoining the lamb-house, and must be well-fed, in addition to after-grass, cole, cabbage, or any succulent roots which may be in season, together with brewers' grains, pollard, ground oats, or barley-meal, pea-meal, and linseed, or, in short, any food which will best promote an abundance of milk, and the consequent growth of fat in the lambs. The lambs are separated from their dams, and put into the house, which should be well-littered with clean wheat straw, a little of which should also be placed in racks, with the ears downwards, in order to amuse themselves, and prevent them from gnawing each other's wool. Some chalk, baked in an oven, should likewise be put in the troughs, both in lumps and powder, in order to guard them, as much as possible, against looseness; and the most scrupulous attention should be paid to cleanliness, as they do not leave the house until sent to the butcher. To prevent them from playing, and thus insure quiet, light is excluded from the house, until partially admitted at such times when the dams are brought to suckle them, which, in most cases, is three, or even four, times in the day. If the house, however, be large enough to admit of the ewes being allowed to remain with them during the night, the usual plan is to admit them at sun-down, and turn them into the pasture soon after the dawn of day; in which case, they should be again brought to them about noon. The lamb-house is, however, generally too hot; and this successive change from hot to cold is so very injurious
to the ewes, that it is no uncommon thing for a ewe or two to die in the night. When the ewe is capable of supplying as much milk as the lamb will consume, such as have lost their own, or which have been sold early, are brought in and held by the head, or put into a yoke, till the lambs, by turns, suck them dry. They are then turned into the pasture, and, at twelve o'clock, the dams are driven into the lamb-house for an hour, in the course of which time each lamb is suckled by its mother.

At four o'clock, all the dam-ewes—as those which have not lambs of their own are called—are again brought to the lamb-house, and held for the lambs to suck; and the mothers of the lambs are afterwards brought to them for the night. Lambs thus treated, and kept free from all disturbance, will, in about eight weeks' time, become sufficiently fat, and their flesh extremely white and delicate." Should a lamb die, the ewe is still retained to milk the rest in turn; and stands are made with stocks, into which she is fastened until her udder is thoroughly drained. This is done previous to each lamb being allowed to suck its own mother; and thus the loss of a few lambs is not so much felt, as the whole stock then derives a larger proportion of the fattening milk. The price at which the lambs are sold will vary; but sometimes they produce as much as £3; though £2 is possibly nearer the average, which is a large sum for the care, and short period of time (about eight weeks) which they take to be fattened. When grass lamb is to be produced, the ewes are put to the ram at a later period, so as to have the offspring dropped about March, and they are only partially provided with shelter. The ewes are kept in the same liberal manner; but the lambs have more liberty, and are much less trouble to their owners. Ten or twelve days after lambing, whilst being fed on such nutritious food, they will again often admit the ram, and thus will bear lambs twice in the year. Such as are house-fed, have by far the best chance of successful breeding, as the second time of producing the grass-fed lamb would be at an inconvenient portion of the year, and the young would be likely to suffer damage from flies, and other insects, from the restlessness which these little torments cause them at this early period of their lives.

THE WILTSHEIRE SHEEP.

The old race of Wiltshire sheep formerly extended over the greater portion of the county, but they may now be said to be extinct. The present race is the largest of the fine wool-bearing animals; and what it produces is extremely fine, and weighs 2½ lbs. per fleece. It is described by Mr. Milburn as having horns rising near each other, and bending backwards and downwards, close to the head of the animal. The hair on the face and legs is perfectly white. The bones are large; and, although the animal, comparatively speaking, makes little flesh, it eats voraciously. The belly is destitute of wool; the head is long; the nose somewhat arched; and the nostrils open, wide, and prominent. The fore quarters, especially the breast and shoulders, are light; and there is a considerable dewlap. The hind quarters are better developed, and the saddles and legs very good. The back is black in the middle, and the shoulder-points project upwards. On the whole, it is a clumsy sheep, and is only preserved in an unimproved and native form on a family farm near Hendon, where the stock is kept pure, under the provisions of a will, which permits the farm to be held on this special condition. The old Wiltshires were, to a certain extent, improved by selection of the smaller, the better formed, and the more generous feeders among the native breed; but they were chiefly indebted to the Southdowns, by which they were crossed again and again, until almost every trace of the old breed had been eradicated, and a useful variety of the Southdown took its place. This variety was distinguished from the true Sussex sheep by being of a larger size, having a lighter and finer fleece, and being of a lighter colour.

THE SOUTHDOWN SHEEP.

This sheep is, in England, what the black-faced sheep is in Scotland, being, as a mutton-producer, held in the highest esteem, especially for the tables of the rich. Nor can there be mentioned a breed which has undergone more improvement than these beautiful sheep. The advancement of the old short-wooled sheep into a middle-wooled race, is an advantage in
every sense, particularly as the short wool, used exclusively in the manufacture of fine cloths, is abundantly supplied by foreign "growers." Of this race, one of the first is the improved Southdown breed, depasturing on the long range of chalky hills extending from the sea-coast of the Isle of Thanet, and the cliffs of Dover, through Kent and Sussex. Formerly this breed, as Mr. Ellman states, in the *Library of Agricultural Knowledge*, was a small size, far from possessing a good shape, and late before they were capable of being fattened; now, however, they are greatly improved, both in shape and constitution. "They are smaller in bone, equally hard, with a greater disposition to fatten, and much heavier in carcase when fat. They used seldom to fatten till they were four years old; but it would be a rare sight to see a pen of Southdown wethers at market more than two years old, and many are killed before they reach that age." The Southdown sheep is, in fact, the model of what a hill sheep ought to be, and the flesh, in fineness of grain and flavour, is peculiarly excellent. The wool is of a very useful quality, but is both larger in fibre, and less numerously serrated, than the short Saxony, and does not, therefore, possess such a felting power; hence it is rarely used in the manufacture of fine broad-cloths. Still, from its fineness and felting powers, compared with the wool of many other middle-woolled breeds, it is highly esteemed; and for flannels and worsted goods in general, is extensively employed.

In describing it, the hair on its face is black or brown, even, short, and fine. The wool is short, close, and remarkably fine in texture and quality. It lies thick over the whole body; and has, when touched, a feeling of great softness, accompanied with a high degree of elasticity. The top of the head is free from wool, and the countenance is fine and placid; the eye is full and expressive, yet mild and gentle, and somewhat prominent. The ears are small, and fall backward and a little upward. The legs are short, especially from the knees to the feet. The breast is full, round, and moderately wide; the neck thick and short, but free from loose fleshy skin. The top of the back is straight and flattish, but not remarkably broad; whilst the belly is nearly straight, but a little tucked in behind the shoulders. The wool is remarkably fine, and is the only kind of English material altogether suitable for the finer class of cloths. The breed is without horns, and comparatively hardy, occupying the downs of Dorset, and now gradually extending into Norfolk, Yorkshire, Hampshire, Kent, &c. In the London market, where their mutton is considered superior to all other kinds, they are in great request. This is the improved Southdown; but the older breeds were low, and light in the fore quarters, although they were backed with good saddles and legs. The improvements have not been effected by crossing from other breeds, but from selecting the best, and breeding carefully from them; and while the symmetry and points of the animal have been so much improved, the quality and grain of the mutton, the equal distribution of fat and lean, the marblings of the flesh, and the internal fulness of tallow, have all been fully sustained. An earlier maturity in the breed has been attained, and the fattening process has progressed. The wool is longer, being about four inches, though not yet long enough for combing. The fleece usually weighs from 2½ to 3 lbs.; and the average weight of the carcase may be taken at 18 lbs., though the improved breed will often weigh from 20 to 23 lbs. per quarter. Mr. Ellman, of Glynde, was the great improver of this breed. Two of his rams were bought by the emperor of Russia, to try the effect of a cross on the Northern sheep. This honour was appreciated by Mr. Ellman, who requested the Duke of Bedford to put a price on them, as he did not wish to charge a sovereign a greater price than any one else. The duke accordingly fixed the price of the two at 300 guineas, and purchased a pair for himself at the same rate. In order to thrive well, and grow in mutton, the breed requires a dry, chalky limestone, or gravelly soil, with fine short herbage. The ewes are prolific, two bearing twins to one being single; and the draft ewes are usually sold off, at four years old, to feed in the turnip districts of Norfolk and Suffolk. The care of the sheep is nowhere better understood than in Sussex, where they are housed and sheltered in severe weather, at and near the lambing season. When the lambs are a-foot, they are
well provided with shelter, and their dams with nourishing food. The Southdown is a sheep remarkably free from disease, especially the sturdy and the rot.

**THE NORFOLK SHEEP.**

This breed was formerly extensively diffused throughout the uplands of Norfolk, Suffolk, and Cambridgeshire; but it is now fast disappearing before the Leicesters and the Southdowns. They are a hardy race, and have a striking resemblance to the black-faced, or heath sheep, being similarly marked in the face and legs, with long, spiral horns, large bones, long bodies, flat sides, high backs, narrow loins, and light and somewhat short wool. The mutton, however, is of rich flavour, such as is usually found to be the characteristic of all wild and semi-wild animals. They are of a wild and roving disposition, and will leap over the ordinary fences; and their long continuance in the county is probably one reason for the somewhat elevated embankments on which the fences are generally planted. Owing to this disposition they are now mostly fed on the large open heaths, which, strange to say, are still prevalent in Norfolk, notwithstanding its fine climate, and general capability of improvement. When fattened they are usually folded, and will weigh from 16 to 20 lbs. per quarter; will fatten at two years old, and are famous travellers.

The principal value of the breed, however, is in their haunches of mutton, and their deer-like, graceful heads and horns. The mutton, when long kept, perhaps more closely resembles venison than the flesh of any other breed. The horns are nine or ten inches in circumference at the base, and as much as thirty-six inches long. Lord Leicester, if not the first, greatly helped to effect a change in this breed. "When he found that the Norfolk sheep," says Lord Spencer, "were a very unprofitable sort, the same reasons induced him to try the New Leicester breed, a variety of sheep probably as ill calculated to succeed on such a soil as the one he occupied, as any breed which he could have selected. He, at last, found that the very best sort of sheep he could adopt were the Southdowns. In this, however, as in every other of his farming experiments, Lord Leicester acted with great caution, and did not make the changes which he contemplated, till thoroughly convinced by practical experience that they would answer. Accordingly, for several years he had upon his farm, at the same time, Norfolk sheep, New Leicester, and Southdowns; he also tried the Merinos, but he did not persevere long with them." Subsequently, this celebrated agriculturist kept no other sheep but Southdowns. The Norfolk breed were speedily abandoned by the neighbouring farmers; and in a very short time, from Lynn to Holkham, there was not such an animal as a Norfolk sheep to be seen. The Southdowns entirely superseded them.

**THE CHEVIOT SHEEP.**

The Cheviot breed is very distinct from the common mountain, or black-faced race, with which it is, on all sides, immediately surrounded, these two races dividing the north between them. The Cheviot is hornless, and the general contour is excellent; the shoulders become full, the body round and long, and the limbs small-boned. The mutton is in great esteem; and the wethers average 16, 18, or 20 lbs. weight per quarter. It appears from the testimony of practical farmers, that the attention paid to the improvement of this breed, in reference to the condition of the carcass, has been followed by a deterioration in the quality of the wool, which is said to have been formerly capable of entering into the manufacture of fine cloths. Still, however, the wool is good, though inferior to that of the Southdowns. It far surpasses that of the black-faced breed; and as the Cheviot race is equally hardy, and as capable of sustaining cold as the former, and is content with the alpine plants of the bleak hills and mountains, it must be expected to supersede the black-faced breed, as it has already done in the forest of Ettrick and the whole of Selkirkshire, and even Sutherland. The fore-knowledge which these sheep possess of approaching storms, and the assiduity with which, while the shepherd dreams of no impending evil, they will seek a place of shelter and security, are curious traits in their character. It is thus that they often warn the shepherd, by the display of this instinct, wisely implanted within them, and lead him to add his precautions to those which they
have themselves adopted. In spite, however, of the vigilance of the shepherd and the instinct of the sheep, many of them often perish beneath towering snow-drifts, and sometimes whole flocks are lost. It often happens, that when sufficient shelter cannot be obtained, the flock crowd together for the purpose of mutual warmth, and are soon covered with the snow. If this does not occur, the lambs, unable to endure the severity of the storm, perish; and the mothers, bewildered, wander about seeking their offspring, till they themselves sink exhausted with their efforts and distress. With but little food, sheep can remain for many days buried beneath the snow; but where this cannot be obtained, the period of endurance is proportioned to the strength of the animal's constitution and the intensity of the cold.

One winter, a sheep, near Kendal, was buried in the snow for thirty-three days and nights, without the possibility of moving, and yet survived; and a sheep in Cumberland was buried for thirty-eight days. When extricated, it was found to have eaten the wool off both its shoulders, and its frame was reduced almost to a skeleton. By due attention, however, it gradually recovered. The Cheviot has a white face and legs, somewhat resembling the cover of the hills during the greater period of winter; but the grand characteristic of the Cheviot flocks is their extraordinary likeness to each other, how many soever there may be. Their imperfection is a narrowness of the back, ribs, and shoulders, from which arises their incapacity of carrying a large accumulation of mutton. Judges, therefore, choose those with broad faces, because this, they think, is indicative of a large bony development. In selecting lambs, or even sheep for fattening, the hand of the grazier grasps the back-bone, over the kidneys, and forms his judgment by its broadness, whether it be sufficiently capacious to carry the complement of flesh and fat which he calculates should be put upon it. The eyes of the Cheviot are small, prominent, and lively. The body is long; the fore quarters somewhat light; the legs clean, and small turned; the feet thin; the wool close and fine, but neither so soft nor so elastic as that of the Southdown. It is also too thick for combing. The improvements in the sheep have added a little to the breast and shoulders, without diminishing the feeding qualities, or injuring the wool. The neck and shoulders are fuller. The breast has assumed greater prominency, but is still narrow. The back retains its narrowness; but the fall behind the shoulders, common in the old breeds, has been removed. The ribs are flatter than either the Southdown or the Highland. The animal combines fat with muscle, and is, when well brought up, covered internally with tallow. They are remarkably hardy animals, and live on very poor and stunted food growing on the mountains of Northumberland. Their hardiness has induced many of the Scotch farmers and breeders to locate them on the Scottish mountains, where, even on the hills of Sutherlandshire, they are to be found successfully bred and thriving. They have also an extensive range on the Yorkshire hills.

The Cheviot hills form a part of that extensive and lofty range which, commencing in Galloway, runs through Northumberland, into Cumberland and Westmoreland, to the extent of from 150 to 200 miles. The majority of their summits end in points, and form terminations to a series of conically-shaped mountains. The sides of these are covered with smooth, short herbage, and have a considerable degree of steepness; whilst, at their bases, they nearly join each other. With the exception of the summits the soil is fertile. On these hills the Cheviot mutton is reared, celebrated for its tenderness, sweetness, and delicacy. The sheep are now sometimes fattened at one year old; and the flesh, in appearance, has, when well kept, a striking resemblance to the Welsh mutton; but it is more tender, and not so high in flavour. The bags will weigh 14 lbs. or 15 lbs. per quarter; and the two shear-wethers will sometimes weigh as much as 22 lbs. Instances are mentioned where they have been brought to weigh 25 lbs. per quarter; but these are extreme cases. The improvements of this breed have chiefly been effected by a mixture of the Leicester blood. This has been done with great caution, as the Leicester is a tender and delicate sheep, not well adapted to cold regions, such as the snow-clad moors of Northumberland, of Westmoreland, and of Scotland. While a single dash of Leicester, however, improves the frame, lengthens the wool, and increases the
feeding tendencies, it is not so severe (if the impression be carried rapidly back to the Cheviot race) as to weaken materially the vital power of the animals. The period, when Cheviot and black-faced sheep should be selected for breeding and rearing on mountain pasture, is given by Mr. Milburn:—When the produce of the hills is simply black furze, or heather, the black-faced Highland sheep will be preferable. When the grass is green, though ever so poor, the Cheviot will yield a greater amount of profit. The following, taking this principle, will be about the comparative merits of the two breeds:

The balance, on the whole, on suitable lands, seems to be decidedly in favour of the Cheviots.

THE RYELAND SHEEP.

This sheep is another old, if not original, breed, and takes its name from a district in the southern part of Herefordshire, where a large quantity of rye used to be grown, and where many of this kind of sheep were reared. It is a small breed, rarely exceeding more than fourteen or fifteen pounds the quarter in the wether, or from ten to thirteen pounds in the ewe. Its wool is white, and covers the sides of the face, coming over the top of the head in a bushy tuft. It is in great favour for carding; superior, indeed, for this purpose, to all other kinds of British wool, and almost rivals the Australian. It is, therefore, put down as essentially a wool-producing animal. As the desire for mutton began to extend in the country, and improved turnips, cultivated in the light lands, enabled farmers to produce more of that material, the breeding of the true Ryeland sheep somewhat declined. So far back as 1843, it was noted for its wool; but even then it does not seem to have been considered the most valuable of the British fleeces. The Shropshire, Staffordshire, and Oxfordshire, were all sold at a higher price than the Ryeland. "It is difficult to account for this inferiority," says a writer on the Sheep, in the Library of Useful Knowledge, "at that time; for our earliest writers on the sheep, speak of the Ryelands as standing at the head of the short-wooled breeds. If, however, the opinion of Mr. Herbert be correct, some light is cast on the subject. He believes that the Ryelands, almost exclusively, in early times of sheep-husbandry, extended longitudinally through those districts, from the Thames to the Tyne; and the Cotswolds were produced by a cross between the Ryelands and some heavy sheep. The Herefordshire, Shropshire, Staffordshire, and Oxfordshire wools, spoken of in this record, were only varieties of the Ryeland, and of which the Herefordshire happened at the time to be the worst. In the course of years, however, the Ryelands were gradually displaced by a heavier sheep over the greater part of the other counties, but continued to be cultivated in a portion of Herefordshire." Formerly these sheep were taken great care of, and regularly housed at nights—a practice which, no doubt, arose with the view of preserving the sheep from the inclemency of the weather, as well as of improving the quality of the wool. The race is small, but it attains an early maturity. The head and face, from being covered with wool, have a large and heavy appearance, compared with the short leg and compact carcass of the animal. The ears are somewhat thick and erect; the chest deep, but not broad; the barrel round, but the back by no means flat. The fat of the animal accumulates mainly on the rump and tail, but not to such an extent as to interfere with its activity. It is extremely hardy, and is supposed to be capable of living on less food than any English breed; but requires it to be of a fine quality. Like all the old races of sheep, it has a tendency to accumulate fat internally.

To improve the Ryeland, the principal object has been to assist the development of fine wool by crosses with the Merinos. Years ago, Dr. Parry, of Bath, M.D., stimulated by the venerable Bath and West of England Agricultural Society, crossed the ewes with the Merino; and the first cross was most successful. The fleece was increased one pound per animal; the texture was finer; and the carcass was considerably enlarged; while the flavour of the mutton was said not to be deteriorated.
SHROPSHIRE SHEEP.

The wool, indeed, was pronounced as fine as the pure Merino. But an error was committed by interbreeding with the crosses themselves; hence, in three or four generations, they fell off so much, that the Anglo-wool became so inferior as to be nearly unsaleable. Having once crossed, they ought to have carried back the cross to the one pure breed or the other; or, what would have been, perhaps, better, they should have kept a stock with which to cross, and thus have preserved a fresh and continuous breed of newly-crossed animals. Attempts to improve the size of the sheep have been made by crosses with the Leicesters, Cotswolds, and Southdowns; the results of which were the destruction of all the peculiarly desirable properties of the Ryeland, as well as the obliteration of several of the others. The breed has therefore been abandoned for more profitable mutton-producing kinds of sheep.

THE SHROPSHIRE SHEEP.

In the centre and north-western districts of Shropshire sheep predominate; the north being principally devoted to the dairying of cows, and the breeding of cattle generally. Formerly, there were several varieties of sheep in this county, but modern times have brought them to a greater equality of character. The old Shropshire sheep had black or mottled faces and legs, and were horned. They were about the size of the Southdowns, but the neck had greater length, and the carcass was not so compact. They inhabited a区-producing district, probably the Morfe-down, consisting of about 4,000 acres of common land, near the Severn, which yielded a short and stunted, but fine grass. The fleece is about the same weight as that of the Ryeland—2 lbs.; but the staple is particularly fine. They are seldom kept till more than five years old; and the ewes will not weigh more, when fat, than 9 or 10 lbs. per quarter. The wethers will weigh 13 or 14 lbs. Modern tastes and habits, however, will not allow of sheep being kept for 2 lbs. of wool, and 40 lbs. of mutton; and hence the altered demands and wants of the population are fast banishing all these original breeds. The Cotswolds and Leicesters having been introduced into Shropshire, both pure, and in various crosses with each other, they have changed the character of every short-woolled sheep. The Shropshire short wool, however, was, at a former period of our history, held in very great estimation. The author of a work on the commercial policy of the times, in 1694, speaks thus of it:—"It is no small advantage to trade, to be fitted with a complete assortment of goods, abounding in the middle sorts of wool, excellent of its kind, and suitable to a middle sort of people, which are far the greater number; and herein chiefly is our strength: not that we, in the least, fall short in the merits of our fine wool; our Herefordshire and our Shropshire wool is not to be equalled, in its kind, by any part of the world, and suitable to almost any degree."

THE WELSH SHEEP.

This is held as the most excellent of all the mutton-producing race, owing to its flesh being so highly-favoured, and so fine in the grain. They are the very converse of the Lincolns, and are truly Lilliputian breed. They are the most remunerative of any kind of mutton sold in the London market, and are thus described by Mr. Milburn:—"The two haunches are usually cooked together, undivided, and present a most uncommon appearance. The wethers are killed at four or five years of age, and will then weigh, when fat, only 8 or 9 lbs. per quarter. The ewes usually weigh 2, or even 3 lbs. per quarter less. The sheep, when alive, is a goat-like animal, somewhat resembling the gazelle of the Nimrod sculptures. The ram has two crumpled horns, rising upwards, and falling backwards again to the neck. The ewes are usually hornless. The neck is long; the shoulders high and thin; the breast small, narrow, and backward; the legs and loins full and broad. The ribs are flatish, and the belly a little depressed; the tail long, and bushy towards the extremity, nearly down to the middle of the hind legs. The bones are remarkably small. They are the most active and sure-footed race of sheep we know. They are essentially wild in their habits, and clip about 2 lbs. of somewhat fine wool. The ewes are sometimes milked by the Welsh farmers; but this pulls them down, and is very injurious to them. Some persons clip them twice; that is to say, they shear them at the usual time in June, and again take off part of the wool from the fore quarters in the month.
of October, alleging that they are less liable to have it torn off by the furze and briars, and more able to forage for their daily supply of scanty herbage amongst the bushes in winter."

**The Herdwick Sheep.**

This is the most valuable sheep on the mountains of Cumberland and Westmorland; and their origin is thus given by an admirable writer on the sheep. In the beginning of the last century a ship was stranded on the coast of Cumberland, and had on board some Scotch sheep, which seem to be now unknown in that country. They were got on shore; and being driven up the country, were purchased by some farmers, who lived at Wasdale-head, in the neighbourhood of Keswick. They were small, active, polled, and their faces and legs speckled, having a great proportion of white, with a few black spots strewed upon it. They were turned, at once, upon the neighbouring hills. They had not been long there before they evinced a peculiar sagacity in foreseeing the approach of a snow-storm; for, a little before its coming, they clustered together on the most exposed side of the mountain, and where the violence of the wind usually prevented the snow from lodging. This instinct caused them to be regarded with a degree of interest, and almost of superstition; and their excellent qualities and adaptation to their new situation, became speedily evident. Their fleece was considerably finer than that of the common black sheep, and the matted quality of the wool enabled them to endure any severity of weather, and even to pass the whole of the winter without the smallest quantity of hay being expended upon them. They were continually moving about, and, therefore, rarely or ever overwhelmed by the snow; and, by their ceaseless activity, they scraped away the snow, however deeply the herbage might be buried under it. The ewes weigh from six to eight pounds per quarter, and the wethers about eleven. The wethers are slaughtered at four or five years old, and seem not only to thrive best on their native pastures, but, when the ewes are driven away, they will invariably return at lambing-time to their old quarters, however distant they may be. This shows a remarkably wild instinct, and is of the same character as that of the black-faced Highland sheep—flocks of which will sometimes actually swim across the Firth of Forth to find their way to their native mountains.

The ewes breed for fifteen or twenty years, and are always kept as long as they will continue to do so; the sales being made of the fattened wethers. When killed at home, the legs are usually cured and dried; and it is jocosely said that the inhabitants of these uplands never eat mutton but when they find a fallen sheep, which, when they do, they shake by the leg, and if it drops to pieces it is rejected; but if not, it is carried home, dressed, and eaten. Their flesh has a strong gamy kind of flavour, much relished by the epicures of large towns. The animal is said to have fourteen instead of thirteen ribs, which is the number possessed by all other species.

Having thus specified some of the more important of the middle-woolled breeds of sheep in our island, most of them, or all, derived from the old short-woolled breeds by a system of judicious management, we have now to state that the middle-wool varies in different breeds, in fineness and in its power of felting. Long wool is much more uniform, and for this reason—that it is the produce of the Leicester race, and of races with which the Leicester race has become completely intermingled. "All long-woolled sheep," says Mr. Youatt, "both in appearance and in fleece, are becoming one family." Long wool, which is now very much improved, it being the aim of the breeder to render it finer (at the expense of its length, which it will bear), is characterised by strength and transparency, but it is deficient in the power of felting. Its average length is about eight inches. This applies more particularly to that sort called the long-combing wool; there is, however, a variety of long wool which approximates to the middle wool, and termed the short-combing wool, which is somewhat shorter than the other, finer, and more disposed to felt. The long-combing wool is used in the manufacture of hard yarn, and for purposes in which length and firmness are essential; the other is used for stuffs of a soft texture, and for hosiery goods. We have alluded to the Leicester breed as the typical example of the long-fleececd races; but it is to be observed that this breed is an improvement upon the heavy.
ill-made, and coarse-woollen race, formerly spread all over our midland counties. Lincolnshire also had a breed of sheep celebrated for its fine long wool; but this breed, defective in form, and yielding mutton of inferior quality, is now greatly improved.

There is one question which suggests itself, and which we cannot omit to notice. As far as records serve us, it would seem that a long-woollen and a short-woollen (now middle-woollen) race of sheep have tenanted our island from the earliest times. To what causes, then, are we to attribute this original difference? Are the two races descended from different primitive sources, or have food and soil gradually produced the differences which have been so long maintained? No one, we think, will hesitate to say the latter; impossible as it may be to follow step by step the progress of the change, or to determine the modus operandi of the causes contributing to effect it. It is, however, very remarkable, that it is only in animals which have been so long domesticated that we cannot tell their primeval origin, and which there is reason to think are factitious beings (that is, the produce of different, but still closely-allied species commingling together), that these extreme variations as to size, figure, and length and quality of fur, are most decidedly observable. We see these varieties in the dog—from the silky, long-haired spaniel of Spanish race, to the close-haired old setter of the same country; from the woolly French poodle, to the mâtin; from the rough English water-dog, to the mastiff; so, in the sheep, we find a short-fleeced breed, with the filaments of the wool peculiarly fine, and numerously serrated; a still longer-fleeced breed, again subdivided into many minor varieties, and having the wool fine, and more or less capable of felting—or, in other words, more or less numerous serrated; and a long-woollen race of old standing, in which the wool, but thinly serrated, is inferior in felting properties, but of great value to the woolcomber. But further, as the mixture of a long and silky-haired breed of dogs with one of close hair does not improve the coat, the young resembling, some the male, some the female, but not equalising them in their excellences; so the crossing of long-woollen and short-woollen sheep leads to no good results; and, as it is with dogs, the improvement of each breed depends on a judicious and careful selection of the best and purest of that breed, by which the properties distinguishing it may be developed to their maximum in their progeny. In England, the sheep is now only valuable for the sake of its wool and flesh; but in various parts of both Europe and Asia, the milk of the ewe has been used from the earliest times, either pure or curdled, as an article of diet. Formerly, in many parts of England, cheese was made from the milk of the ewe; and the ewes, to the injury of the lambs, were milked regularly, as described in the Odyssey, and, at a later era, by Virgil:—

"He next betakes him to his evening cares,
And sitting down, to milk his ewes prepares;
Of half their udders cases first the dams,
Then to the mothers' teats submits the lambs.
Half the white stream to hardening cheese he press'd,
And high in wicker baskets heap'd; the rest,
Reserved in bowls, supplied the mighty feast."

To the process of shearing we need scarcely allude; all are familiar with the manner in which the removal of the fleece is effected; and it would seem that, in the earliest patriarchal ages, the same process was in use. Among the Romans, however (and the practice has been but lately discontinued in the Orkney Islands, and is, perhaps, still prevalent in Iceland), the wool was torn off the animals; and, as Pliny states, they were kept for three days previously without food, in order that the wool might be the more easily detached, their bodies being exhausted. In his time, however, the practice of shearing had begun to supersede this cruel and unjustifiable method. It gave, however, origin to the word *vellos* (fleece), from *vello* (to pull away); and the hill termed Velleia was the ancient spot on which this cruelty was perpetrated.

With us, the season of sheep-shearing is a season of rejoicing; and the manner in which the important work is conducted, and the dexterity of the shearsers, are, to those not accustomed to rural life, replete with interest and amusement. It is, indeed, a pleasing spectacle to see a large flock of snow-white sheep collected together, and, in turn, losing their soft fleece, rolled into an unbroken and well-arranged whole, beneath the shears of the shearer. The picture is poetical, and has been the subject of many pleasing representations.
CHAPTER IV.

HISTORY OF THE WOOLEN TRADE.

Professor Owen defines wool as "a peculiar modification of hair, characterised by fine transverse or oblique lines, from 2,000 to 4,000 in the extent of an inch, indicative of a minutely imbricated, scaly surface—when viewed under the microscope—on which, and on its curved or twisted form, depends its remarkable felting property." In a state of nature, many animals have a covering both of wool and hair; the former underlying the latter; but a single fleece, whatever its character, yields many varieties of wool, which seems to have been the staple material of the primitive weavers of Palestine, Syria, Greece, Italy, and Spain. Previous to the art of manufacturing in wool, however, man, to clothe himself, made use of the skins of animals; and even in the patriarchal times, we find that the skin of the goat was used by Jacob. At this period, however, or very little later, the fleeces of animals came into use; for we find that Joseph had a coat of many colours, made him by his father, who would seem not only to have understood the proper application of the fleece, but, also, the art of dyeing it. Still later, we find Job saying to his three friends—"If I have seen any perish for want of clothing, or any poor without covering, if his loins have not blessed me, and if he were not warmed with the fleece of my sheep." Here is direct evidence that the fleece of the sheep was now used for the purposes of clothing. Weaving, in its rudest form, was probably pursued as a domestic employment at this time; for there is no handicraft more ancient, and none more universal. The allusions to this art in the Scriptural writings, have made us all familiar with it from our childhood. "My life is cut off as by the weaver," says Isaiah. "My days are swifter than a weaver's shuttle," says Job; and as weaving was, from the remotest antiquity, the occupation with which women engaged themselves, it has supplied the old epic and lyric poets with many a beautiful figure, and the ancient dramatists with some of their most touching incidents. The antiquaries who have unfolded the ceremonies of the Egyptian mummy—the travellers who have devoted themselves to the exploration of Central Africa—the missionaries who have familiarised us with the habits and traditions of the more than semi-savage South-Sea Islanders—all testify to the antiquity and the universality, in some form or other, of textile industry. It is apart from our province here to enter upon the history of such an art; but it is full of interest as developing the inventive faculties of man, in his onward progress towards a high and refined civilisation. Its history links itself with the colonisation of the Greeks; with the dissemination, throughout the new-born Italy, of the industrial arts of Constantinople; with the rapid rise of the Italian republics; and with that—more marvellous still—of the great commercial city of the Netherlands. When the textile industry of the Italians and of the Flemings passed over to France and to Britain, its development came to be intimately connected with three questions of state policy—namely, the good or ill treatment of aliens; the liberty or thraldom of religious worship; and the restriction of the enfranchisement of trade. With the mode of handling these three questions by government, the fortunes of weavers have been singularly involved. It is probable, however, that, contemporaneous with, or possibly antecedent to weaving, the process of felting was adopted. If wool be pressed together, or considerably heated in junction, or otherwise be brought in very close contact, it becomes a thick impervious mass, very difficult, if not impossible, to be separated again. This is owing to the structural conformation of the wool. Though the absolute cause was not known, the fact was understood and described at a very early period. The wool is covered with a complete series of scales, or serrations. These are capable of being opened and compressed; and felting is no more.
than the junction of these, and their compression with one another. So far will this go, that even the smallest particle of wool seems to possess the above quality.

"It is to this felting property," says Mr. Milburn, "that we have long been indebted for our hats." It is mentioned in the Iliad of Homer. Plato speaks of it as "cloth made by the thickening of wool." Pliny, describing it with the more practised eye of an observing natural historian, says—"Parcels of wool, driven together by themselves, make cloth." Herodotus, when he describes the clothing of Xerxes' army of Persian soldiers, says, they wore "light and flexible caps of felt," which he also describes as used by the Medes and Bactrians. Julius Caesar, finding his soldiers annoyed by the arrows of Pompey's army, describes them as making shirts or clothing of felt, to protect them from the archers. Thucydides mentions a similar device to protect the body from the effects of arrows. The more peaceful Greeks used the wool for a more pastoral purpose. They clothed their sheep with felted wool, according to Aristotle, in order to produce an impression on the texture and colour of the fleece. Tasso mentions that the Attic sheep were clothed to improve and preserve their fleeces; and Demosthenes calls them "soft sheep." It was the impossibility of felting the hair of the goat and the camel, doubtless, which first suggested the idea of weaving.

Tasso says—"As the sheep yields to man wool for clothing, so the goat furnishes hair for the use of sailors, and to make ropes for military engines and vessels for artisans. The goats are shorn in a great part of Phrygia, because they have long shaggy hair. Cilicia (hair-cloths), and other things of the same kind, are commonly imported from that country." The character of this cloth is intimated in the prophetic symbols of the signs of the second advent:—"The sun shall become black as sackcloth of hair."

Dyeing seems to have been of very ancient origin; and nature appears to have suggested the idea in the rearing of black, white, and party-coloured sheep. But a taste for brilliant and glaring colours has prevailed in all countries and in every age; and although the art of dyeing is, like many other arts, indebted to chance for its origin, still it can be traced up to a very remote antiquity. We have already alluded to the "coat of many colours" possessed by Joseph; and as the Israelites, soon after their departure from Egypt, understood the art of dyeing scarlet and purple, or crimson, it is obvious, that at least 1,500 years before the birth of Christ, dyeing was practised among the Egyptians. The probability is that they derived it from some one of the Indian nations with whom they traded; but, be this as it may, it appears by Pliny, that the Egyptians even knew the use of what are called mordants, in fixing or modifying the colours which they made use of. "Tyrian purple" is alluded to by Juvenal. The Greeks seem to have been slow in acquiring this art, as, in the expedition of Alexander into India, it was so little known in his army, that the soldiers were surprised at seeing ensigns of so many colours used by their opponents. After its introduction to Greece, it passed into Italy, and thence into other European countries. Batis had fleeces possessing "metallic tints," especially the prized "golden hue," and also the sober native hues of "Betic drab or grey." The two colours of Spanish wool were said, in 1607, to be—one a golden yellow, and the other a ferruginous or brown colour. These colours probably depended on the soil on which the animals fed. Ancient monuments attest the remote period at which the wool trade was cultivated. On a Roman altar, dedicated to Hope, above the emblematic ears of corn and the bee-hive, is a distinct bale of wool. On the altar to Silvanus, is the caduceus of Mercury and a bale of wool, evidently tied with twisted and knotted cords, as if packed up for exportation. Amongst the Belgae and the Gauls, woollen manufactures seem to have been common. The latter is alluded to in contrast to the proud purple, or Tyrian, and designated "goss Gaulish grey." In Juvenal's ninth Satire, allusion is thus made to Gallican manufacture:—"Some coarse brown cloak I may happen possibly to get—some Gallic fabric, as a defence from the rain."

At the Roman conquest of Britain, Cesar describes the inhabitants as a pastoral people, possessing cattle, clothed in the skins of animals, and subsisting on flesh and milk. This description especially applies to those who
lived north of the Thames. The inhabitants of Kent are described, by Strabo, as excelling the Gauls in their manufactures. Emmeius, in his eulogium on the Emperor Constantius, in 310, says—"And fortunate Britain, now the happiest country upon earth; for thou hast been the first to see Constantine made emperor. * * * Thy woods contain no savage beasts; thy land no noxious serpents; but an innumerable multitude of tame cattle, distended with milk, and loaded with fleeces."

Mr. Milburn thinks that there cannot be a doubt that, at the time of the invasion of Caesar, there were two kinds of wool produced in this country, and two kinds of garments manufactured by the polished Belge, who inhabited Kent. The one kind was thick and rough, calculated to protect from the cold, and common to northern countries; the other, a fine soft material, resembling the Highland plaid. Doubtless the one symbolised the wool of the Teeswater or the Cotswold, and the other of the Southdown. That fine wool was then known, amply appears by the quotation of old Holinshed from Dionysius Alexandrinus, who said—"The wool of Britain is often spun so fine, that it is in a manner compared to a spider's thread." The decay of the arts, consequent on the irruption of the barbarians into Rome, does not appear to have extended to the woollen manufacture, as clothing continued to be made in most of the countries in which the Romans had established colonies. The wool employed was, at first, the produce of their own country; but they afterwards imported wool from other countries, and carried on the manufacture to such an extent, that the Low Countries became, in a great measure, the clothing district for Europe. Spain produced cloth for herself, and, about the thirteenth century, acquired considerable reputation for the beauty of her fabrics. Consequently, we may presume that the fine wool which the Spanish sheep have, for centuries, produced, is the best. The Italians and French entered on this manufacture at a later period. In the time of William the Conqueror, an inundation which occurred in the Netherlands, drove many of the clothiers into other countries; and some of them came to England. William of Malmesbury says, that the king, glad of such an accession, placed these Flemish clothiers first in Carlisle, and then in the western counties. From that time the mention of clothiers is frequent in the old chroniclers. London, Oxford, Lincoln, York, Huntingdon, Nottingham, and Winchester, are enumerated as towns wherein the manufacture was carried on; while, at other towns, there were cloth-dealers who paid a licence duty to the king for the privilege of buying and selling dyed cloths. Although, however, clothiers are frequently mentioned, it was not until 1110 that any very definite or distinct allusion is made to the British woollen trade by any historical document. In that year a petition was presented to King Stephen, soliciting the power to enable them, by his charter, to form themselves into corporations or guilds. The object of this petition was to possess, under the monarch, self-government; to have the power of appointing their own members, and subjecting them to such orders, laws, and regulations as they, from time to time, saw expedient.

The guild of Winchester, the old established seat of woollen manufacture, paid one mark (about forty shillings) for the power of self-government; and an annual payment of £16 is afterwards noted. The London weavers paid a similar sum; while that of Oxford paid forty shillings. Others paid even larger sums; which lead to the conclusion that these guilds had arrived at a considerable degree of importance. The Worcester guild paid 100 shillings for certain specific privileges; and, in ten years' time, the decaying London guild paid £12 only. In 1172, prohibitions against mixing Spanish with English wool were issued, probably from a desire to stimulate improvement in the native material. If this were really the intention, it had the effect of throwing the British on their own resources for the manufacture of broadcloth; and from that day they acquired the power of manufacturing it independent of Spain.

The religious crusades of the middle ages drained the country alike of its fanaticism and its money. So impoverished was our Richard I., that when he was imprisoned by the Duke of Austria, he had his heavy ransom of £300,000 paid by levies on the plate of the avaricious monks; and when they had no plate, they had to send one year's produce of wool. Into their hands the best of the sheep
lands, and most of the silver, were very rapidly finding their way; and hence they afforded a ready means of raising the ransom of their king from the hands of the freebooter. In the reign of Henry I., another inundation in the Low Countries brought more Flemish weavers to Britain, and gave a new impetus to the cloth manufacture. The Gilda Sellariarum is of this reign, and is the oldest of the London companies. It possesses a charter of Henry I., which exacts that none but members shall have the power to intermeddle with their craft within London, Southwark, or the parts adjacent. This charter was confirmed by Henry II. and by Edward I.; but in the fourteenth of Edward II., the privileges claimed under it were brought into question by a writ de quo warranto. The consequence was, that the company had to moderate its pretensions; but it continued to exercise an important jurisdiction for several centuries. During the struggles of the barons with the monarchy, the woollen trade seems to have become depressed; and Sir Matthew Hale says, that in the reigns of the two first Edwards it was "wholly lost," and the money for wool was made by exportation. The Flemings had again established their manufacture, and beat the English out of the market. The third Edward set about restoring it by vigorous means. Aware of the impetus given to it before, by the importation of Flemish weavers (or from their present skill in beating out the English manufacture), in 1381, he brought John Kemp, with seventy Walloon families, from Flanders, and an act of parliament was passed to encourage them. Flemish or other foreign goods were also prohibited by statute; and, to crown all, exportation was altogether prohibited; although it had before raised the sum of £534—a large sum in these days—equal, perhaps, to £8,000 of our money; and this at a period when population and trade were equally scanty. The promises made by Edward to the Flemings, during his visit to the Duke of Burgundy, were faithfully kept. Part of them were located in Kent—the seat, no doubt, of woollen manufacture before the Roman conquest. Some settled in the valleys of the Severn, where they established the celebrated manufacture of West of England cloths; while others went to the valleys of the Aire, where they found situations and water suited to their requirements. The two latter localities are still the seats of woollen manufactures in this country. "Happy the yeoman's house," says old Fuller, in his characteristic way, "into which these Dutchmen did enter, bringing industry and wealth along with them. Such as came in strangers, soon after went out bridegrooms, and returned sons-in-law, having married the daughters of their landlords who first entertained them; yea, those yeomen in whose houses they harboured, soon became gentlemen, gaining great estates." Edward strengthened both his purse and his country by these judicious steps. He found that the woollen trade he had encouraged, afforded the sinews of power in his wars with the French; and when English wool again found its way to Flanders, in 1337, it sold for £400 per sack; and 10,000 sacks were sold at that time in Brabant. In 1312, the king exported to Cologne a great number of sacks of wool, in order to redeem Queen Philippa's crown, which had been pawned there for £2,500 sterling. The average of wool at this time, was 1s. 3½d. per lb. Previous to this period the wool had been weighed by means of steel-yards, of nearly the same construction as those used in some country places at the present day; and hence the yard in which the merchants usually met was designated "steel-yard." In 1352, the weighing by the steel-yard was prohibited, on account of the deception practised with it, and an equal balance was introduced.

The reign of Henry VIII. imparted an impulsion to cloth manufacture, though his enactments appeared calculated to repress it. Still, when one man (John Winchcombe) could equip sixty soldiers at his own expense, and maintain them at the battle of Flodden Field, it is evident that his one hundred looms had realised him a considerable profit. This was a way in which the manufacturers were able, when willing, to assist their monarchy. The privileges to certain cities, for services rendered, doubtless had an origin somewhat in this manner. York had an exclusive monopoly granted in the manufacture of coverlets; and worsted spinning was limited to Norwich. Another impetus was given to the trade by Elizabeth; whilst the severities exercised by
and the cruel Duke of Alva on the protestant manufacturers of the Netherlands, caused many of them to emigrate to this country. To these it was the policy of Elizabeth to extend her protection, well knowing the skill which they had in weaving, and the improvements which they were likely to introduce amongst her own native subjects. Five hundred of these refugees settled in London; and the southern seats of manufacture had large ascensions of weavers. The scarcity of hands complained of in the reign of Henry VII., was no longer heard of; and Norwich was not necessitated any more to deplore the paucity of manipulators in her manufactures. In this reign, trade with Russia, and the formation of a Russian trading company, followed, and still further increased the foreign relations of the country. The Turkish Company was established in 1581; the African Company in 1585; and the East India Company in 1600.

In 1667, importation of foreign dyers took place. They arrived under the guidance of a person of the name of Brewer. The principal English dye had hitherto been wood; but he taught them all the mysteries of dressing cloth as well as dyeing. In the reigns of Charles I. and II., the public turbulence and arbitrary interference seem to have crippled the trade. By Charles II., as well as by the Commonwealth, the exportation of wool and sheep was strictly prohibited. But in the reign of William III., manufacturers made steady progress. Considering Ireland to be a linen manufacturing country, he discouraged the woollen manufacture there. Florentine wool manufacture was stimulated by every means, legitimate and otherwise, and Sweden began to rival England; the silk trade was pushed, and a general activity pervaded all classes of the community.

The Georges encouraged the woollen trade; and they were indebted to it in more ways than one. Manufacturers and staplers raised troops to assist them to repel invaders. John Routh, a stapler of Thornfield House, in Yorkshire, raised a troop, and had colours presented by his sovereign, George II., for his loyalty. The king also granted a charter, conceding freedom of tolls to John Routh and others, on the Aire and Calder rivers—an immunity of great value to a wool-stapler. In the reign of George III. our manufactures rose to their pinnacle of greatness; and, though heavily taxed, we were enjoying the blessings of peace when all the rest of the world was at war. A large portion of our national debt doubtless passed into the hands of the British manufacturers for the cloths they made; and fortunes were realised, which created the millesimacy of England. In this reign, inventions in mechanical appliances, stimulated, doubtless, by the vast demand for woollen goods during the war, raised the English clothier to the highest opulence. At this period we obtained wool from Australia, Germany, Spain, Russia, the Cape of Good Hope, South America, and the East Indies. In England, the woollen manufactures will always be intimately bound up with its pastoral character. Though dependent on foreign countries for a large amount of the raw material, it still produces within itself a vast proportion of what it requires; and the paying character of sheep, both directly and indirectly, has a great tendency to maintain mutual dependence and reciprocity between the wool grower and the manufacturer. The present extraordinary rage for cleanliness is amongst the most wonderful tendencies of the age. It is inducing the English manufacturer to make up fabrics mixed with cotton, and to work up wool-dust, which is not only unprofitable to the wearer, but must ultimately have a tendency to bring discredit on himself, and those with whom he is connected.
CHAPTER V.

BREEDING AND REARING OF SHEEP.

Whatever may be the object of the scientific, wealthy agriculturist in cattle or sheep breeding, it is evident that, in the case of the farmer, it resolves itself into a question of plain pounds, shillings, and pence. In breeding the sheep, however, the same principles which regulate the production and improvement of any other class of animals, must, in a great measure, be acted upon; and should one person be more successful than another in the production of stock, that person will be found to have given greater attention to the subject, to have been more persevering, and to be possessed of qualities better adapted for carrying out the object in view than the other. The question for the consideration of the farmer is, what kind of animal will ultimately become the most profitable? This is the all-important interrogatory which he must put to himself. The present or immediate he must sink in the comparatively distant; and, whatever may be his disappointment, he must persevere, and try again and again, until the arrival of the triumphant day which is certain to crown his efforts with success. It was thus that Bakewell acted. It was by unwearyed perseverance that he succeeded, at last, in producing his New Leicester, which, in the end, rewarded him for all his labours.

The New Leicester and the Southdown are the two breeds which have occupied the attention of the agricultural world in putting forth their claim to favour. As far as a tendency to fatten and to arrive at an early maturity are considered, there is no doubt that the Leicester stands foremost in every known breed of sheep whatever. For the attainment of these qualities, its form is a perfect model of adaptation; and all other breeds which most closely resemble this form, will possess these qualities in a more or less degree. Even the Southdown is no exception to this rule; for if one of the improved, and another of the neglected specimens were placed together, the excellences of the former would at once appear to lie in those points which had the nearest approximation to the Leicester. The production of wool, too, is also to be considered; for the fleece of the Leicester is much longer than that of the Southdown. Where, therefore, the pasture is favourable, and the sheep taken care of, and not unduly exposed to cold and wet, the Leicester must be esteemed the most remunerative of the pure breeds. What, however, are its drawbacks? These are, says Mr. Spooner, the incapability of the animal to bear exposure, for travelling, or living hard, being weak in constitution, and very liable to inflammatory disorders. From these circumstances, it is unfitted for folding purposes, or to stand the exposure of the Southdowns, and still more for bearing up against the severities of the Grampian Hills, or the Welsh mountains. In the climatic variations of these localities, the sheep would soon perish. Besides these drawbacks, their mutton is by no means so good as that of the Southdowns, which, however, is partly owing to the early period (twenty months) at which they are ready for the butcher, and partly to the very large quantity of tallow they make in proportion to the lean. Their mutton, therefore, is not much esteemed in the London markets. Accordingly, the first cross between the Leicester and the Down has been raised instead of the Leicester; and it is said that this first cross is the most profitable sheep that can be fattened, making greater and more rapid progress than the Down, and yielding a better quality of meat than the Leicester.

The improved Southdown is also possessed of most valuable qualities; its tendency to fatten being inferior only to the Leicester. It is also later in coming to maturity, taking from thirty to thirty-two months; but it is an excellent traveller, holds well, is handy, compared with the Leicester; can live on short pastures; and is, perhaps, the best of all the breeds for the Down farmers in the south of
England. With the exception of the small mountain sheep, its mutton has a higher reputation than any other; and these qualities, with the wool it produces, have enabled the breed, also, to hold a foremost place in the favour of the public. With these two valuable breeds, each adapted to different pastures, it may be asked, what need is there for any other? It will, however, be found that, in the marshes of Kent, and many other places, the superior hardihood of the native breeds has rendered them more profitable than the Leicester; though, unquestionably, crosses with the latter have much improved their value. Notwithstanding the valuable qualities of the Southdowns, however, they have been found insufficiently hardy to endure the severities of the Grampian hills, or the Welsh mountains. They have been tried, and found wanting. In these bleak situations, vast numbers of them have fallen victims to the inclemency of the weather; and the losses which many speculators have sustained, have been the cause of discouraging others from following their steps.

Where breeding is the object of the farmer, the first rule to act upon is to breed from the best; but this has its limitations and restrictions, as will be seen in the following illustrations of Mr. Milburn:—"A man may easily ruin his flock by adhering to this rule, without attending to its antecedents and adjuncts. There are two modes of effecting it. One man will scour the whole country to obtain the best ram, or to buy a few prize gimmers. From these he will select the most promising, and insure better alliances for his flock. The result will be a set of nondescript mongrels. Some distant impurity of breed manifests itself; some tendencies, far back in the genealogy of the race, break out, which are modified in one case, and fostered in another, until the flock shows signs of indiscriminate and injudicious dabbling. Another man, better acquainted with the rules that regulate vitalism, takes his own flock; and, having selected the best, he takes only those which he knows to be of the same breed; and thus goes on steadily aiming at giving breadth to the animal. He knows that the sheep, in order to thrive, must have a large lymphatic system. It must have a capacious chest and loins, and a frame on which to secrete fat, with lightness of offal. Hence he does not select, at first, that which has the most of these qualifications, but which has, perhaps, the widest form, and most unlike his own flock; he also takes such as show a tendency to pervade, in one uniform direction, not an individual, but the whole of the flock; and this he takes to mend his own. By this means all are a little improved in the direction he requires; and all keeping alike in their general contour, there is a kind of permanency and uniformity in the main features of the improvement. Hence, if we look at the flock of the first-named breeder, we shall have breeds both large and small, 'bony' and 'bloody,' rough and fine, white faces and blue, coarse and tender—in fact, a set of mongrels, none of which are of sufficient value wherewith to form a flock, and none to be depended upon for any future breed. The other breeder, by his cautious and judicious course, has a uniform flock—a mark both of purity and of skill; for no unskilful man ever kept a flock long in a state of anything like similarity to each other. Uniformity is as important to the jobber and the butcher as it is to the grazer. The merit of being 'even' is always appreciated in a market, because it always suits the same class of customers. One butcher buys a large fat animal; it suits his friends: another, a light, thin one (wool being required by one, and mutton by another); one requires fat, and another muscle; and to make an uneven lot of sheep sell for all they are worth in a market, they must be judiciously sorted."

Whatever may be the breed selected, it should be suitable, and, in its management, be tended with the greatest care and attention. Theory and practice have clearly shown that health and thrift are intimately connected in the breeding of sheep; that the influence of cold has such a deteriorating effect upon the body, that it contracts its proportions, and renders a greater supply of food necessary to support it. Therefore, to a certain extent, warmth is a substitute for food. This, then, suggests the great importance of the covering of fleece during the winter. It preserves the temperature of the sheep, and prevents waste; and shows us the reason why animals thrive better in the summer than the winter, except during the very hottest period. The usual
course adopted in breeding is, to take one of the owner's ewes, and buy it, or put it to the ram of another breeder. Before doing this, two selections have usually been made by the breeder; first, those ewes which are so favourable to the object he has in view, are drafted from his flock; after which his best rams are selected from the flock of the preceding year; he next chooses a ram of the same breed, suitable to their condition, and possessed of such characteristics as he wishes to be reproduced in his stock. The ram should be thoroughly bred; and unless it be one of his own, with the qualities of which he is perfectly acquainted, it should have been tried at least one year on a small number of ewes of a good sort, in order to test his excellence. This is commended as safe-breeding; but if uniformity of flock, and purity of blood, are the objects desired to be obtained, the surest way to get them, is by adopting the best means. It must always be borne in mind, that the improvement of a flock, by means of breeding, requires not only very great caution, but long-continued attention and care.

In breeding, the qualities of both parents must be considered, equally with a view of eradicking the bad, as well as perpetuating the good qualities. Speaking on this subject, Professor Spooner, in his treatise on the sheep, remarks, that it must be acknowledged, that in the majority of cases, the influence of the male preponderates over that of the female, and the characteristics of the former are more likely to be impressed on the offspring than those of the latter. This, he says, is shown in most animals; and instances several cases. "The mule," he says, "partakes much more of the nature and size of its sire, the ass, than its dam, the mare. A large Cotswold ram, put to a Down ewe, produces an offspring much more resembling the former than the latter; and a pony mare, put to a full-sized horse, will produce an animal half as large again as the dam. Though this, however, appears to be Nature's rule, it is not without exception; for, occasionally, we see the very opposite results.

In breeding animals of a pure kind, the principal rule to be observed, is to breed from the very best of both sexes, and cull the faulty ones every year, saving only the female lambs for the future flock that are as free from defects as possible. Of course the flock must be kept up to its proper size; but, year by year, the finest animals should be selected, until, in the course of time, the flock will entirely consist of them. When this is nearly accomplished, it will not be prudent for a farmer to employ his own rams for the purpose, as he will probably be able to hire superior rams from others; and it will not do to spare expense in thus raising the character of his sheep." When a difference occurs in the general outline of a flock, it is to be corrected by the breeder acting on the flock itself, by regularly drafting off the failing ewes, and breeding from the common size. This is said to have a very favourable influence on the breed—much greater than that of the dam; for, while she can only influence two animals, the ram exercises his power, in a greater or less degree, over the whole of the produce. The leading features to be attended to in a ram, are, fineness of skin, light offals, broad, deep, and round frame, and the absence of superfluous coarse wool. The back should be broad, especially near the shoulders, and well covered with solid, but yielding, and slightly elastic flesh; though it is sometimes said, that an animal on which it is possible to get a full fat development, is one to be selected, on the ground that, in a bad one, this is impossible. As adipose matter, however, is necessarily laid on muscle, it is obvious that where there is plenty of muscle, there also fat may be expected. A deep chest, broad at the base, is very essential; for this is indicative of weight. For successful feeding this must be thoroughly capacious. The sheep should walk wide on both legs, keeping them at a distance of at least six inches parallel to each other. The head should be fine, not flat, and rather broad. The eyes very full and prominent, exhibiting, on the whole, an expression of quiet liveliness. The ears small; and the bare parts—the face, ears, and legs—must have a clothing of fine hair or wool.

The colour, which varies according to the breeds, is of great consequence. A departure from white in the Cheviot, would be as great a failing as black in the Highland or the Heath sheep; brown in the Southdown, or blue in the Leicester. Mr. Milburn thinks that the colour of the face of a Leicester is of far more consequence, in a fattening point of view, than
is generally imagined. It ought, in his opinion, always to have a tendency to light-blue in the ram, or some Leicestershire or Tweedwater tampering may be suspected. Good legs is another great essential. The tendency is to encourage flesh developments on the back, to the neglect of the legs, especially in the Leicesters. The fine development of the back seems not only to have robbed the leg of its muscle, but, by contrast, to have exaggerated its own deformity. The dread of a long, coarse leg of mutton has diminished the circumference, as well as the length; and, though a short leg of mutton is desirable in a Leicester, we must guard against a loss of its redundancy. Size is also of consequence. The finest specimens of Leicester—the purest and most symmetrical—are now decidedly the smallest. Breeders should earnestly look to this, and be careful, in selecting the ram, to have masculine qualities enough to secure a hardiness in the flock. In reference to the various points sought after by breeders, not because of their own intrinsic value, but because of their being evidence of other valuable qualities, is an aptitude to fatten, and the attainment of an early maturity. In the Southdown breed, for example, small heads, legs, and horns are esteemed, because experience has pronounced them qualities which are found usually associated with fattening properties. Black muzzles and legs are, also, highly valued, because they are indicative of a good constitution, and a certain degree of hardness, which speaks well for the animal. Roughness of the back, roundness of frame, and breadth of loin, are also points in great request, being not only the signs of good qualities, but, in reality, good qualities in themselves. Straightness of the back, although perfect in the Leicester, is not natural to the unimproved Southdown, but rather the contrary. In the improved breeds, however, it appears, and is considered an excellent point, as it gives a greater surface for the accumulation of flesh, and affords larger scope for the abdominal organs. The opposite of this, as witnessed in a round or convex back, is produced, and increased by the effects of longer and cold, and is almost sure to make its appearance, should the breed be exposed to neglect, and the rigours of an inclement season. In summing up some of the profitable requisites of a well-formed animal, it may be stated, that it should have as much flesh, and as little bone and gristle as possible; and this flesh should be found where it is most wanted, and, therefore, most valuable. For example, it is much more profitable on the loins and quarters than about the head, and upper or scrag-end of the neck. Where there is a large development of flesh, a proportional disposition to fatten may be expected; but to be profitable, it is necessary that those qualities should be early developed, or, in other words, should be exhibited by an early maturity.

Having described the points of the ram, we may observe that the ewe should be straight and bread-backed, wide in the loins, and deep-breasted. The angles of her frame will always be sharper than those of the ram; but depth and breadth, with fineness about the throat and legs, ought always to be specially attended to. To secure uniformity in the flock, the ewes ought always to be as much alike as possible, otherwise it will be the next thing to an impossibility to obtain this desirable object. We have already observed that, in breeding for improvement, it is a good rule to breed from the best of the kind; and if a superior ram of the same breed can be obtained from another flock, it ought to be taken, and a preference given to it, should its qualities be equal to any one possessed by ourselves. If our own, however, excel all others within reach, then it should be used, but with the precaution of marking the ewes which are deficient in any of the qualities desired to be perpetuated.

Cross-breeding of sheep has attracted a great deal of attention; and its object is either to increase the size, or to improve the form; to stimulate its fattening tendencies, to give it an earlier maturity, and to extend the length, or enhance the quality of the wool. To practise any of these improvements, it might, at first sight, appear that all that would have to be done, would be to select a ram of any special breed, distinguished for the particular quality desired to be produced. This, however, will not always prove suitable; for, by so doing, a breed will frequently be reared, either weak in constitution, or defective in form, on account of the too great dissimilarity between the parents. Therefore, to render crossing
SHEEP-REARING.

SHEEP.

A successful cross has, also, been made between the Hampshire Down and the improved Cotswold. The Cotswold or Gloucester sheep is of large proportions, and has for centuries been famous for the length and weight of its fleece. As one of the long-wooled races, it is superior to most others; but its carcass could not bear comparison with the Leicester. After being crossed with it, however, it greatly improved in its fattening properties, and attained an earlier maturity, whilst it continued to preserve the quality of its fleece. The Hampshire was originally, in a great measure, derived from the flocks of Essex, and is a larger variety of the Southdown. Either from choice or economy, the largest and coarsest animals were selected and crossed with the native horned sheep, and this breed has been perpetuated on the farms of North Hampshire for years.

A cross between the Leicester and the Black-face is now well established, notwithstanding the wide difference which exists in the character and habits of the two breeds. The excellent mutton qualities of the one, and the fattening tendencies of the other, have caused this race to be extensively cultivated in the north, where large numbers of them are reared, and where they are held in very high estimation, not only on account of their mutton and their hardiness, but for the excellence of the wool which they yield. For this cross, however, it is not the very highest kind of Leicester that is chosen to produce it. It is the good and the useful, rather than the delicate. Therefore, they possess in themselves a certain degree of hardiness, which renders it more easy to acclimatise them to the temperature and hill pastures of Scotland. The cross between the Leicester and the Cheviot is also established, and the produce of this cross is rapidly taking the place of the pure Cheviot. Its size is greater, its fattening tendencies better, and it attains to an earlier maturity. Another cross, in the north, is noticed as being somewhat successful. It is between the Cheviot and the Black-faced—the rams of the latter, and the ewes of the former. This cross, Mr. Milburn says, is calculated for barren pastures, and such exposed situations as cannot be so well borne by any of the other crosses already specified. This cross, as might be expected, produces an extremely

The Cotswold is sometimes crossed with the Leicester, to which size is thereby given, as it is the custom to feed them at one year old.
hardly race, in which the quality of the mutton is not at all deteriorated. To obtain it, however, requires considerable perseverance, as the first is not always successful. When gradually carried back to the pure Cheviot ram, it greatly improves, when good mutton, better wool, and heavier weights are secured. Complications in crossing are considered neither safe nor successful.

Breeding from close affinities, or, in other words, in-and-in breeding, has been much discussed: and, in the estimation of many, is still an unsettled question. Whatever may be its advantages, it certainly has its disadvantages. Sexual intercourse is forbidden by the law, between near relatives in the human subject; and even marriage between relatives of the second degree—such as cousins—is looked upon by many persons as very objectionable, from the liability of entailing disease on the offspring, and especially disease of a mental kind. This opinion is strongly supported by statistical facts bearing upon the subject. “In the animal,” says Professor Spooner, “there is no reluctance to sexual intercourse between the nearest affinities; and the custom of breeding from sheep closely related, has been, for a long time, practised by breeders of considerable eminence. In the human subject, the objections to the practice are at once granted; but let us see whether they likewise obtain with animals. In the former, marriages are generally entered into, with little, if any, regard to the health of the individuals concerned; the consequence of which is, that the diseases of the parents, or, rather, their predispositions, are entailed on the offspring. The result of this is, that most families have predisposition to some particular complaint; and thus, if two members of the same family have sexual intercourse, the probability is, that if both parents had predisposition to a particular disease, in an equal degree, this will be increased in their offspring in a double ratio. But, on the contrary, if a man unites with a woman of a different family, and a different predisposition, the idiosyncrasy of the offspring to the diseases of either parent is likely to be prevented or retarded. With animals, however, the case is very different. If due attention be paid, a principal object will be, to breed from healthy subjects, by which means one fertile cause of hereditary predisposition to disease is prevented. A healthy form and sound constitution are essential to successful breeding, and for the development of the points we seek to obtain. Thus, the principal objection to breeding from near affinities, which exists in the human subject, does not obtain amongst animals; and even if, in the former, mental disease is more apt to occur when this practice is pursued, this, also, is an objection which does not apply to animals; though it has been urged by some, that sheep bred in-and-in, are more subject to diseases of the brain—a conclusion, however, which I am much disposed to doubt.” From this passage, then, it is evident that the effects of in-and-in breeding may be productive either of good or evil; although, in neither case, may this result be attributable to nearness of affinity, but rather to the circumstances with which it is connected. If due care is not taken in culling, or making a selection of the flock, both defect and disease may reasonably be expected to arise; and two animals, having each a predisposition to the same evil, defective, or diseased tendencies, if permitted to have connection, will produce an offspring similarly predisposed, but in a double degree. If proper care is employed, however, in the selection of the flock, the opposite result may be anticipated.

In managing rams and ewes for the purposes of breeding, care should be taken, that about the close of the month of September, the ewes are put upon better keep. Rape is, perhaps, the best thing to give the Leicesters; but if this be not present, aftermath or clover stubble. If a large progeny is the principal aim, such food will be found greatly conducive to the effecting of this object. It is said, that of keeping sheep on rape before the ewes are permitted to receive the ram, fully thirty per cent. of lambs may be obtained. Climate, and the quantity of spring food provided, must, of course, in a great measure, regulate the time when the rams are to be put to the ewes. It is of the utmost importance that the lambs should be dropped as early as possible, in order that they may be well nursed, and have sufficient time to gather strength enough to enable them to provide for themselves before the winter sets in. It is also advantageous to the ewes, that they may arrive at good condition before the
commencement of the rutting season; thus a full crop of lambs may be secured. A proper proportion of tups should be employed—say, three to one hundred ewes, if they are much scattered; but, if they are kept in enclosures, two will be sufficient for a hundred. “A ram, when shearing, or two shear,” Mr. Milburn says, “will serve sixty ewes, or even eighty, if proper care be taken. The too common mode is to allow him to run with the ewes at large. There is a great waste of the animal’s virile powers; and when as many as the last-named number of ewes are given him, another course should be adopted. A shepherd should be left in entire charge; a pen or pair of stocks, as it is indifferently called, provided, and the ram kept confined in the house, or in a very small croft. An active lively ram should be sent with the ewes, and should have an apron tied about the crop, so as entirely to cover the genitalia. If his breast is smeared with red it is no disadvantage, as it more distinctly marks the ewes. When a ewe is observed in full season, she should be brought to the stocks, and served by the ram with whom she is intended to produce, and immediately carried away; but, when eighty ewes are provided, it is indispensable; and when twenty to thirty guineas are given for the loan of a ram for one season, it is not unreasonable to expect him to discharge more duties to the flock than is possible by running at large. When the flock comes in season very rapidly, the ram serves them only once; if not, they are served twice, and then turned away for a fortnight, when they are brought back to the teaser; and he is then smeared with a blue or black colour, to distinguish those who come once. When the ewes are not named, they should all be numbered, and a register kept of the ram and his breeding, and the date of each ewe being served. This is not only an invaluable record in the case of pedigrees, but it is still more useful as being a guide to housing, when near the period of lambing; and, though the dogrel distich is true, that—

"There was never a shepherd, that ever begun,
  Can tell whether they go nineteen, twenty, or twenty-one;"
still, a very important classification is secured by those who have their register, who cannot house the whole flock, especially in a time of severity and difficulty. When the active process of gestation has commenced, care should be taken to prevent the ewes getting too fat. If they do, inflammatory disease, absence of milk, and general risk, are sure to be the consequences.” The apron alluded to in this passage, is believed by Dr. Parry to have been an invention of the celebrated Bakewell. The sexual appetite of the ewes being provoked, and their condition being discovered, by it, they are taken in succession to the proper ram, which is kept in a yard or small enclosure, and permitted to serve each only once. The common practice, on high farms at this season, is to collect the ewes, and drive them to the low ground; but this has frequently the effect of harassing the animals, and spoiling the winter pasture. If they be altogether left at liberty, however, an inconvenient number of rams is requisite. The duties of the shepherd at this season are extremely onerous, as he must be constant in his attendance. If the weather permit, the ewes must rather be kept on the high ground, in separate bodies, scattered here and there, in accordance with the nature of the pasture, and the condition of the ground. Each of these detachments should have a proportion of rams allotted to it; and the shepherd cannot be too careful in not allowing the lambs to quit the ewes to which they have been appropriated. If this be done properly, fewer rams will be required on the ground. When the ewes have become large, they should be run about as little as possible. Nor should they in any way be disturbed, but carefully watched over, and kept away from wet ground, and everything that may be supposed to have an injurious effect upon their health. When very heavy, they are apt to get cast, and unable to rise; and when this is the case, the shepherd should approach them with gentleness, and help to raise them with as much tenderness as he can use. Should ewes miscarry in very cold or severe weather, she should be brought to her cot, and kept there until she has recovered. In mild weather, however, she will be equally safe in the open air. When the yearning time arrives, the ewes should be placed on the most level and driest ground, not only for their own accommodation, but for that of the lambs when dropped.
Having alluded to the onerous duties of the shepherd during the breeding season, we may here observe, that one, whose pastoral care lies among the mountains, must be possessed of certain qualifications to enable him to act upon his trust with pleasure to himself and satisfaction to his employer. He must be active, attentive, careful, honest, and good-tempered withal. This last qualification is as indispensable to make up the character of a good shepherd, as it is to complete the character of a moral philosopher or a sage. Should he suffer himself, at any time, to get into a passion with his sheep, the probability is that he will not only injure them, but act greatly to his own disadvantage in herding and working among them. This observation is not applicable to the shepherd alone. It applies to every man who is in a position to govern, command, or control. He who loses his temper, generally loses a portion of his time, as he certainly does, a portion of his reason, which temper must again restore, before he can do for himself, or get others to act for him satisfactorily. A lad or shepherd, and a close-mouthed dog, will accomplish the object desired in half the time, and with half the trouble which will be given to the quick-tempered, passionate man. It is not by running and hounding his dog after them, that sheep are to be easiest driven to where they are wished; but by quickly directing them, agreeably to the quality of the soil, the nature of the climate, the locality of the farm, where they may obtain in greatest quantity, and with certain safety, a sufficient supply of nutritious food throughout the year. In Little's Practical Observations on Mountain Sheep, it is remarked, that "it is not by walking much or seeming to do much, that a shepherd proves himself to be a good one; but by walking so as to disturb the sheep the least, and by doing, and at the time, whatever is necessary to be done. There is not an experienced shepherd, who does not, as soon as he rises in the morning, and observes the state of the weather, know almost to a certainty where to find nearly every sheep on the hill; and he will, accordingly, take his course to the place where he knows his presence is most wanted. If any of his own or his neighbour's sheep have trespassed, it is foolish to dog or to abuse them; but the more quietly they can be turned back the better. If the boundary should be on the top or ridge of a height, towards which sheep are apt to draw at night, it is better to turn his own a little closer to the boundary in the afternoon, than to drive back his neighbour's; it will better answer the same purpose; and, after the flocks have been a few times gently directed in the morning, without dogs, they will become so well acquainted with their own side, that, at the very sight of the shepherds, they will take to it without trouble. Those shepherds who dog and force their flocks, I take to be bad herdsmen for their masters, and bad herdsmen for the neighbouring farmers. If the boundary be a bourn or brook on low ground, where the sheep graze in the middle of the day, the same plan should be adopted by turning the sheep down tolerably early in the day." These observations, although directed to the mountain shepherd, have yet, more or less, an application to every one who has the care of sheep in any situation.

About a fortnight before the expiration of the period of gestation, the ewes should be separated from the flock, and placed in a grass croft near the house. They should be sheltered by being allowed temporary houses made of hurdles and straw, with smaller houses, in which the newly-dropped lambs may be separated from the rest, and kept free from danger. This is not always practised; but it ought to be done; and for the lambing season, a croft of winter-freed grass, or unceated moss, should be preserved. To save the grass at a time when, from a backward spring, or other reasons, it is scarce, the ewes may be driven daily to the turnip-field, and taken at night elsewhere—a plan which, by giving them exercise, will be found very beneficial. The best food for the ewes, after shelter is no longer necessary to the lambs, is Italian ryegrass, or rye, which, after being eaten down, grows rapidly; and nothing teches the lambs to eat sooner than this. The corn should still be continued along with Swede turnips; while the advent of fine weather, and the diminished wants of the lamb, will be the criteria for deciding when the practice ought to be discontinued. When lambs are observed to drop on a spot where they cannot easily rise, they should be lifted, and placed on their feet; but if everything be favourable, they are better
left to themselves. When a day or two old, they may be docked, which will be the means of saving a great deal of trouble afterwards, when the disease called "pinding" attacks them. About three inches is, perhaps, a length sufficient for the tail; but males, provided pinding does not take place, should not be docked until the season for performing the operation of castration has arrived. When lambs exhibit little signs of sportiveness, in all probability there is something the matter with them, and they should be examined, as well as their dams. By nature they are lively and frisky, full of fun, and much given to play; if, therefore, they exhibit little or no signs of this disposition, it may be taken as a certainty that there is something the matter, either with them or their dams. If they are in any way deformed, they should be slaughtered for home consumption. Should a lamb die, it ought to be slowly dragged home, when the ewe will follow it. After she has been brought into the house, a twin lamb from another ewe may be put to her; and, as soon as she has allowed it to suck, they may be both turned out together.

In the weaning of lambs, the ewes should be taken from the lambs, and not the lambs from the ewes. It is said to be always best to place the ewes and lambs together in a pasture most suitable for the lambs. The ewes should be carried out of hearing of their offspring, and placed in a poor pasture, and milked for a few days, until the lactiferous system ceases to secrete, and then it is best to send them to a cool upland, if possible. Lambs, however, should be allowed to suck during three months and a-half, after which they may be taken up and kept for a fortnight or three weeks, at a distance from their dams. Sale lambs are usually not taken up till their purchaser comes and removes them at once. It is the practice of some to wean their lambs about the middle of July, considering it as important to habituate them to a change of provender before the arrival of the season when braxy is likely to set in. If nature were to be taken for our guide, however, early in August would be sufficient time for the removal of the lambs.

Should lambs become infested with vermin before the time of smearing, the following directions, given by Dr. Parry, will be found serviceable:—The tick, or hippobosca ovis, is extremely injurious to sheep, by making the animal bite and rub itself, so as not only to prove detrimental to the fleece, but to break the skin; in consequence of which, the fly is apt to fix on the wool near the wounded part, and there deposit its eggs. This troublesome animal may be, in a great measure, destroyed by a solution of white arsenic in powder, made in boiling water, in the proportion of an ounce to a gallon, and poured, when cold, on the back of the sheep, and allowing it to diffuse itself down the skin on each side; in this method, however, several of the ticks escape by crawling to the extremities of the filaments. It will be still better to wash the lambs in the autumn, whether shorn or not, in a tub of a similar mixture. For this purpose, three pounds of the same arsenic in powder, may be dissolved in six gallons of boiling water, and the solution mixed with forty gallons of cold water. The whole being, then, well stirred with a stick, the lambs may be plunged into it, great care being taken that they do not dip their heads, or taste the water. The liquor must be squeezed out of their fleeces back into the vessel, in order that it may not be wasted. It is hardly necessary to point out the poisonous quality of this liquid, and how important it is to keep the vessel locked up, and, after the operations are performed, to clean it well; or rather never to use it for any other purpose; and to throw the liquid which remains, where not the smallest quantity of it can be drank by any creature whose life we value. Infusion of tobacco is equally effective, but not so economical.

When the lamb is fairly on its legs, and able to do something for itself, it is frequently the case, that a pasture is chosen for the dam, as uncongenial for the production of milk, as it is unfit for teaching the offspring to feed, which thus prolongs the dependence of the latter on the lacteal supplies which it must draw from the mother. When the vegetable food which the lamb consumes becomes increased, the milk of the dam diminishes; and, either from natural constitution, or from some accident, it frequently happens that she becomes dry, notwithstanding the efforts of the lamb to preserve
the lactiferous stream. When this is the case, the lambs are often depastured on over-caten seed; and as their bowels are tender, and not yet inured to such food, they become affected with purging, and hence the cause of unweaned lambs being afflicted with the scour, when unavailing recourse is had to the shears and medicine, to save lives which too often pass beyond the reach of skill. The discovery is then made that the lambs have been so weaned, and have had improper pasture. Once place weaned lambs on over-caten seeds, and the whole flock takes the scour, followed by flies, maggots, medicine, and death. To prevent such a calamity, Mr. Milburn recommends a hard old grass, or a second crop of mown clover, which he considers perfectly safe. "It is not the excellence of the pasture," he says, "as regards its quantity, which is to be feared, but the quality; for if the land be rich, with grass and newly-grown seeds, the scour is certain to follow. Some flock-masters, who have not red clover, or poor grass land, will send their lambs to a poorer soil to graze, until their bowels have become accustomed to purely vegetable diet. Should scour take place, it is often difficult to stop it. The bowels must be relieved of the dry food, and the system hardened by tonics. A dose of a quarter of an ounce of flower of sulphur, in old milk, will generally succeed in stopping the disease, if it be properly attacked in its early stages."

"It is an excellent plan," the same practical gentleman further remarks, "to have a few wethers, or barren ewes, to put in the field with the lambs after weaning. They teach them to select their food; they draw out the instincts of the young lambs, and materially assist in drawing and training. A pen should be provided in the corner of the field; and to dip as soon as possible after weaning is by no means a bad practice. As soon as the ewes are shorn, and before the weaning, it is very desirable to have the lambs dipped. If deferred till after weaning, there is often much fretting excited in them, and they seem to suffer more by far than when they are subjected to the process during the period when they are remaining with their dams. It is often necessary again to dress the lambs in the autumn, and so keep them from the annoying and irritating effects of insects which seem to grow upon them, despite every care, unless they are subjected to frequent remedial applications. If sale at one year old is intended, the lambs should be kept on artificial food, from the very season of weaning, in order that they may be well brought up."

CHAPTER VI.

THE MANAGEMENT AND FATTENING OF SHEEP.

Before directly considering the methods pursued in the management and fattening of sheep, the construction and power of the digestive organs of the animal, upon which experiments are to be tried, should be well known. These in the sheep, like those of almost all vegetable feeding animals, are extremely complicated; and, in the exercise of their functions, accomplish a much more difficult task than those which are possessed by animals that principally feed upon flesh. The food of these, before it is eaten, is in a great measure ready prepared. The constituent parts of which it is composed have a close resemblance to those of the blood itself, and necessarily have an exact similarity to the very flesh it is intended to nourish. This being the case, a much smaller quantity is required to sustain the body, as there is little of it given off in the way of waste, or ejected in the form of feces. This, however, is very different from what is necessary to sustain the body of the herbivorous quadruped. The food required for it has to be sought in the wilds of nature, in the fields and
the forest, where it is found in the very crudest state, and requires to be consumed in large quantities, in order to yield a sufficiency of nourishment for the sustenance of life. This, as a matter of course, necessitates a difference of construction in those internal organs which have to act upon such a bulky species of nutriment. Accordingly, the digestive organs of the granivorous animals are much more extensive than those of the carnivorous, and proportionally more complicated, that they may be equal to the performance of their work. Both the ox and the sheep have very extensive digestive organs. Their intestines are of great length; and, in place of having only one stomach, like the horse, they have no fewer than four. "The usual course of the food," says Professor Spooner, "is into the rumen, or first stomach, whose entrance is close to the termination of the oesophagus and the entrance of the canal. This stomach is of enormous extent, occupying, indeed, when full, nearly three-fourths of the abdomen. It lies towards the left side, extending to the flank; and, by a sort of muscular band, it is partially divided into two principal compartments. It is lined internally by the peritoneal membrane, in common with the other contents of the abdomen, and, internally, by an insensible membrane, called the cuticular, between which there are two other coats—the mucous, which secretes the fluid found in the stomach; and, external to this, the muscular coat, which is formed of two orders of fibres running in opposite directions. Its interior aspect presents a number of pouches or compartments, which are formed by muscular bands, thrown across from one part to another; and the surface presents an innumerable number of pupillae, or eminences, not sharp, but blunt pointed, which are formed by the mucous coat, and merely covered by the cuticular. These pupillae are coarser in the lower compartment of the viscera than in the upper. We have said the rumen consists of two compartments; but, with greater propriety, it may be stated, that there are three; a smaller one being situated immediately below the termination of the oesophagus, and adjoining the second stomach. The use of these partial divisions is very evident. They relieve one portion of the stomach from sustaining the whole of the weight of the food; and they afford a sort of steps, or

| SHEEP, | [MANAGEMENT.]
<table>
<thead>
<tr>

<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>resting-places for the food that has undergone maceration, the upper, and smaller, compartment being that into which the food is raised just previous to being ruminated. The rumen is partly attached to the second stomach, but only communicates with it through the common opening into the oesophagean canal. The second stomach is called the recticum; its size is considerably less than the rumen, but it possesses much strength in its coats, and its muscular fibres are more developed. It is globular in shape, and somewhat larger than the maniplus, and is familiar to us in tripe, not only from its cellular structure, but from its being thicker than the others. Its internal aspect is very singular, having a vast number—indeed, several hundreds—of shallow cells, somewhat like a honey-comb. The cells are much smaller at the part of the viscera nearest the entrance, and gradually increase in size from this point. The sides of these cells consist of ridges formed by the mucous and cuticular coats, and smaller ridges are also observed, running across within the cells. Most of them are pentagonal, but many have six sides; and, on their surface, we observe an immense number of sharp-pointed pupillae, much smaller in size, though sharper than those of the rumen, and which secrete a mucous fluid. This viscous has the same coats as the rumen, but the muscular coat has two layers of strong fibres, arranged both transversely and longitudinally. The opening into this stomach is of some extent, compared to its size; the duplications, or lips, which form it, are, indeed, the floor of the greater portion of the oesophagean canal. Though, in the ordinary state, the root, or upper part of the reticulum, is the floor of the oesophagean canal, yet if air is pumped into the oesophagus, so as to distend the stomachs, the situation of the reticulum will become reversed, rising up towards the oesophagus; and thus, if this retiplus is distended in the disease of hoove—as, from its free communication with the rumen, it probably is—it must press on the diaphragm with considerable force, greater in proportion, even, than the rumen itself. The contents of this stomach are more liquid than those of the others. Somewhat before the end of the entrance of the second, the canal terminates, as it were, in the third stomach—the maniplus, or manifold;</td>
<td></td>
</tr>
</tbody>
</table>
so called from its curious internal structure, which is formed by a great number of plaits, or folds, arranged longitudinally in a direction from the entrance of the stomach; so that, although it is not large externally—not exceeding the reticulum—its external surface is increased in more than a tenfold degree. These plaits are very curiously arranged, being in the form of seven or eight groups of six leaves, each leaf dissimilar in length, the largest extending almost from the upper to the lower part of the stomach. These leaves are studded with numerous small pupilæ, much harder than those of the reticulum, and some on the edges of the plaits, of the shape of a bent cone, the points directed towards the entrance. It has been found, in certain cows that would never retain their food, but were continually scouring, that these plaits were unusually short. The maniplus has but one opening, but this opening is in direct communication with both the canal and the fourth stomach. The plaits are studded with numerous minute pupilæ, somewhat similar to those found in the reticulum. The maniplus possesses four coats like the others, and its external appearance is globular. Its contents are generally found of a much harder consistence than those of the other stomachs. This stomach, when full, is found above the oesophagean canal, forming, indeed, a portion of its roof; and its longest leaves fall down, as it were, almost into the canal. The _abomasum_, as the fourth stomach is called, is, in fact, the true stomach, being that which secretes the gastric juice, by which the food is converted into chyme. It is this peculiar acid which gives it the power of coagulating milk; and, in calves, it is particularly employed for this purpose in the manufacture of cheese, under the term _senuet_. Externally, this organ is somewhat conical in shape, its apex being the part which joins the intestines. It possesses three coats, like the other stomachs, but its internal surface is very different, being smooth and shining, and of a pale-red colour. Its mucous membrane is, indeed, very vascular, and this secretes the gastric juice. The internal surface is greatly increased, and exceeds the external, by being in the form of plaits, arranged longitudinally, but very different from those found in the maniplus. The entrance to this stomach (its cardiac opening) is close to the entrance of the maniplus; it is arranged in a somewhat crescentic form, and is situated at one extremity of the base; whilst the pyloric opening, backing into the small intestine, is, as before observed, situated at the apex. Such is the situation and appearance of the stomachs; and we deem it unnecessary to follow the course of the food through them.

"To meet the necessity of all these stomachs in the sheep, we all know that a certain quantity of food is required, that the animal may not only be preserved in health, but be kept alive. This quantity is designated its necessary ration of food; and if it is given more after it has consumed this portion, it will grow in flesh, or yield milk, or wool. When an animal is growing, whether of the human or any other species, it should never be stinted in its food. Keep the stomachs of babies and puppies full, and there will be comparatively little crying in the one, or whining in the other. Stint them, however—never let them feel themselves full, and they will necessarily make known their dissatisfaction. It has been found that an ox requires two per cent. of his living weight in hay per day; if he works, he requires one-half per cent. more. A milk cow requires three per cent.; and a fatting ox five per cent.—four-and-a-half when half fat, and only four when fat. Grown sheep take three-and-a-half per cent. of their weight in hay per day, in order to be kept in store condition."

Mr. Richardson, in his treatise on the Sheep, supposes a farmer purchasing a score of the Leicester and Cheviot hogs at the same period, and feeding them for the same length of time on the same food; when the results would be something like the following:

<table>

</tbody>
</table>

As quiet and warmth contribute in a large degree to the fattening of sheep, these should
always be taken into the calculations of the farmer. Their modus operandi is simple, and very easily described. Experience has taught us that, as we accelerate our own motion, we increase respiration, when the excess of oxygen inhaled requires an increased quantity of carbon, which would otherwise be given to the accumulating of fat. So, likewise, cold takes away from the system its animal heat; to renew which, more oxygen and more carbon must be employed in producing extra combustion, in order that the diminution of temperature may be restored. Nature effects this restoration of heat, by causing cold to produce both hunger and the desire for motion; supplying carbon by the gratification of the former, and oxygen by the indulgence of the latter. In proof of these facts, the following experiment may be given:—One hundred sheep were put into a shed, and ate 20 lbs. of Swedes each per day; whilst another hundred, in the open air, ate 25 lbs. At the end of a given period, the former weighed 3 lbs. more than the latter; which proves that, to a certain extent, heat, with animals, is a substitute for food. This was also proved in other experiments into which the effects of exercise on the living animal entered. No. 1.—Five sheep were fed in the open air between the 21st of November and the 1st of December. They consumed 90 lbs. of food per day, at a temperature of about 49°. At the end of this time they weighed 2 lbs. less than when first exposed. No. 2.—Five sheep were put under shelter, and permitted to run at a temperature of 49°. They consumed at first 52 lbs., then 70 lbs. per day, and increased in weight 23 lbs. No. 3.—Five sheep were put in the same shed, but not allowed any exercise. They ate, at first, 61 lbs., then 58 lbs., and increased in weight 30 lbs. No. 4.—Five sheep were kept in the dark, quiet, and covered. They ate 35 lbs. per day, and increased in weight 8 lbs.

Mr. Richardson gives the following experiments bearing closely upon this subject. They were mostly made by Mr. Lawes. That gentleman instituted a series of inquiries as to the abstract food and increase in weight of these sheep in themselves, and also as compared with the Hampshire Downs, assuming the Sussex Down to be the type of the original Southdown sheep. One disadvantage was, that they had to be fed on dry food; they had oil-cake and clover chaff. At first they had food supplied in given quantities, and proportioned to their weight. The quantity given, per day, to the Hampsheires was one pound of each; while to the Sussex Downs it was only three-fourths of a pound of each per day. The former weighed 113 lbs., and the latter only 88 lbs. Swedes were also given ad libitum, but from quantities previously weighed. The sheep were fed for twenty-six weeks. The Hampsheires consumed 1,249 lbs. of oil-cake, 1,120 lbs. of clover hay, and 16,995 lbs. of Swedes; and the increase of live weight was 428 lbs. So much for the large sheep. The smaller, or Sussex Downs, in fact, consumed 96 lbs. of oil-cake, 926 lbs. of clover hay, and 12,445 lbs. of Swedes, and gave an increase, in live weight, of 324 lbs. To put it in a more striking light, it required, to produce 100 lbs. increase in live weight, the following quantities of each kind of food in the Hampsheires:—

<table>
<thead>
<tr>
<th>Food</th>
<th>lbs.</th>
<th>oz.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Oil-cake</td>
<td>291</td>

<tr>
<td>Swedes</td>
<td>394</td>
<td>0</td>
</tr>
<tr>
<td>Or a total of food of all kinds</td>
<td>4704</td>
<td>12</td>
</tr>
</tbody>
</table>

Whereas the Sussex sheep required, to produce 100 lbs. live weight, the following quantities:—

<table>
<thead>
<tr>
<th>Food</th>
<th>lbs.</th>
<th>oz.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Oil-cake</td>
<td>314</td>

<td>4704</td>
<td>7</td>
</tr>
</tbody>
</table>

The Sussex sheep needed, therefore, in twenty-six weeks, 20 lbs. 4 oz. more oil-cake, 44 lbs. 7 oz. more clover hay, and 145 lbs. less Swedes, to produce 100 lbs. live weight; or about 7 per cent. more oil-cake, 17 1/4 per cent. more clover, and 3 1/2 per cent. more Swedish turnips, for the same result. The taste indicated a difference in the animals: the Sussex sold at about 3s. 2d. per stone of 8 lbs.; the Hampshire only 2s. 10s. 2d. per stone; and after paying their way, and allowing for the purchased food—the cake and hay—the forty Hampshire sheep left a profit, as well as the increase, of £6.7 1/2, and the Sussex, of £6.0 3/4 per head. The oil-cake is, however, reckoned at only £6 15s. per ton, and the clover hay at
£4 per ton. Nothing is charged for attendance.

As far, therefore, as this was a paying speculation, neither seemed to answer. The Swedes, the attendance, the washing, shearing, and other et-ceteras, would diminish the profit to less than nil; but this was hardly the object of Mr. Lawes. The forty Hampshires consumed 49½ tons of Swedes, and the Sussex only 36½. The latter were, however, much the smaller, and more would be consumed to the acre. Mr. Lawes himself, however, puts the case in another light. He says—Suppose, then, that in both cases 100 tons of Swedes had been eaten, we should have had consumed with them, and paid for by the increase of the animal—

<table>
<thead>
<tr>

<td>904</td>
<td>1,909</td>
</tr>
</tbody>
</table>

That is to say, in consuming 100 tons of Swedes (and the dry foods), Sussex sheep would, according to our experiments, have given the increase from 904 lbs. more oil-cake, and 1,909 more clover, than the Hampshires. To have consumed the quantities of food supposed above, however, in twenty-six weeks, there would have been required eighty Hampshire, and about one hundred and ten of the Sussex sheep.

Mr. Lawes subjected the Cotswold to the same course. Having, however, originally intended them for a comparative trial with the New Oxfords, but without success, he tried the fifty sheep alone, on different qualities of food, and subjected them to a comparison (as to their fattening tendency) with the two kinds of Downs he had before tried. He commenced with the flock selected by Mr. Garne, on the 24th of October, and fed them on turnips in the field until the 21st of November, when he put them on boards or rafters, and then fed them on oil-cake, clover-chop, and as many Swedes as they could eat. The same proportion of dry food was allotted to the Cotswold in proportion to their weight, which was 113½ lbs. average per animal. The food at first given was 1 lb. per day each of clover chaff, and the same of oil-cake. Near the conclusion of this experiment the oil-cake was increased by one-half. The average weight, on the 1st of December, was 119 lbs. 14 ozs.; but there was a difference between the greatest weighted animal of 146 lbs., and the smallest, 103 lbs., which showed how vast a variation there may be in a lot pretty nearly equal in appearance. Mr. Vernon Harcourt showed that great differences of produce would take place in the same field in various parts similarly treated; and Mr. Lawes' experiments show the same results. In the first month of the experiment, after the weighing alluded to, the increase was in a margin from nil to 22 lbs.; nor could previous weight, or any other element, account for the difference. The weekly average gained, per head, was 3 lbs. 10½ ozs. during the month. In the second month, the extreme variations of increase were 1 lb. against 22 lbs.; but it is very remarkable that it was not the one which had been the greatest gain the preceding month, or increased the most, nor vice versa. Though it eventually happened, that the one which gained the most was that which realised the greatest amount at the end of the experiment. The average gain in this month was less, being on 3 lbs. 3½ ozs. per head per week. In the third month, the greatest increase was again 22 lbs., and the smallest 3 lbs.; and it is again remarkable, that the one which gave the smallest increase in the second month, was that which progressed the most in the next. The average gain fell, however, to 3 lbs. 6½ ozs. per week. In the fourth month, the lowest increase was again 3 lbs., and the highest 28 lbs.; the latter being the one which stood highest in the second month. The average increase was 3 lbs. 5 ozs. per head per week—an increase which shows how much may be gained by judicious management and proper treatment, under the circumstances.

The result of these experiments was, that the final mean weight, without wool, was 174 lbs.; the highest weight, 214 lbs.; and the lowest weight, 147 lbs. The highest average increase, per week, was the one before particularly referred to, which averaged 4 lbs. 7 ozs.; the lowest average being 1 lb. 2 ozs., and the general average 3 lbs. 2½ ozs. The increase in twenty weeks, per 100 lbs. of live weight, took 250 lbs. 11 ozs. of oil-cake, 219 lbs. 1 oz. of clover hay, and 3,683 lbs. of Swedes. Now,
the comparison with the Downs, of the two kinds before referred to, is as follows:—The

<table>
<thead>
<tr>
<th></th>
<th>Covswolds</th>
<th>Hampshire</th>
<th>Sussex</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cotswold gained, per week</td>
<td>3½ lbs.</td>
<td>3 lbs.</td>
<td>2 1½ lbs.</td>
</tr>
<tr>
<td>Hampshire Downs</td>
<td>3 2½ lbs.</td>
<td>3 lbs.</td>
<td>2 1½ lbs.</td>
</tr>
<tr>
<td>Sussex Downs</td>
<td>3 lbs.</td>
<td>2 1½ lbs.</td>
<td>2 1½ lbs.</td>
</tr>
</tbody>
</table>

But there was a difference in the food. The Cotswold consumed more food—more of every kind than the Sussex Downs; and more, though very slightly, of all but the clover hay, than the Hampshires. But then they had a larger frame, and produced greater results. Taking the 100 lbs. increase, for instance, as the test, as it ought to be, the result is, in every way, in favour of the Cotswold; as the following shows:

<table>
<thead>
<tr>
<th></th>
<th>Covswolds</th>
<th>Hampshire</th>
<th>Sussex</th>
</tr>
</thead>
<tbody>
<tr>
<td>Oil-cake</td>
<td>294 lbs.</td>
<td>294 lbs.</td>
<td>314 lbs.</td>
</tr>
<tr>
<td>Clover hay</td>
<td>219 lbs.</td>
<td>259 lbs.</td>
<td>30 lbs.</td>
</tr>
<tr>
<td>Swedes</td>
<td>361 lbs.</td>
<td>394 lbs.</td>
<td>408 lbs.</td>
</tr>
</tbody>
</table>

The increase in weight, per 100 lbs., was about 2 per cent. greater with the Cotswolds.

The "balance-sheet," always so satisfactory, is not here of the same consequence as the experiment. It is not likely, when the animals are so confined and often weighed, that so much can be defined as clearly to make profit a guiding element. The cost of the sheep is given at £66 10s.; the quantity of purchased food consumed by oil-cake and clover hay, £29 6s. 5½d.—a total of £95 16s. 5½d.; while the proceeds of the sale were £20 2s. 7½d.; a small difference of £9 12s. 10d., in the lot, with the manure, for the risk, return for capital, land crop, and Swedish turnips; but they were sold at a "heavy" market, and this may partly account for the loss. There is one curious fact, in this and the preceding experiments, which we cannot help noticing. Mr. Lawes observes, that there is some general uniformity to be seen in the quantities of food in their fresh state, consumed by all the three kinds of animals, per 100 lbs. live weight weekly. "But when the quantities of the respective foods are calculated, each to their contents of dry substances, it is found that the total quantity consumed to a given weight of animal, within a specified time, is all but absolutely the same for the three breeds."

Fattening sheep, at one year old, should begin to lamb; and not only must artificial food be given to the lambs as soon as they will eat it, but they must be supplied with it indirectly before they begin to partake of it in the milk of the mother. Oat, bean, and linseed cake may, and ought to, be given to the parent animal, so that the offspring may always have plenty of the materials wherewith to form bone and muscle, and even fat. The fattest lamb (other things being equal) not only makes the fattest shearing, but will eat the least amount of food to produce any given amount of mutton. Rape cake is said to lay on mutton very cheaply, and is second only to linseed, whilst its price is one-half less.

When the hogs are weaning, they require clipping, and superior food. For this purpose, different combinations of spirits of tar, arsenic, tobacco water, with a mixture of oil or soft soap, are used in various proportions; but Biggs' or Wilson's composition is recommended as being the best. At this time the lambs should not be placed where sheep have been depastured before. The object of this caution is to prevent the probability of an attack of diarrhoea. The second crop of mown red clover, or the fog of inferior grass land, is by far the best food. Should this, however, not be obtainable, a cattle-eaten pasture, but not of the richest kind, will be the most favourable, and the quantity of food given artificially should be slightly increased. Great care must be taken in confining the young sheep on the turnips. The best mode is gradually to accustom them to the watery and succulent, but very valuable sheep-feeding food. With respect to the most advantageous food to be given to sheep, there is a difference of opinion—some preferring oil-cake, some beans or peas, and others oatmeal or barley-meal. Much, of course, will depend upon the nature of the farm, as it must, to a considerable extent, be preferable to make use of the product of the land. Sheep prefer beans to oats; and beans abound in that principle in which turnips are most deficient. Thus they are, in some measure, well adapted to counterbalance the disadvantages of turnip-feeding; and, as the latter abounds more in the elements of fat, it probably prevents the beans from hardening the flesh too much, which they are apt to do. Barley and oats contain less albumen than beans, and are therefore more fattening. Oil-cake does not yield much nourishment, but possesses...
the fattening principle in a concentrated form. Mr. Childers states, that sheep fed with the addition of half a pint of barley per sheep per day, half a pound of linseed cake, a little hay, and with a constant supply of salt, become ready for the butcher in ten weeks; and gain, of flesh and tallow, from thirty-three to forty pounds per head (one sheep gained fifty-five pounds in twelve weeks); and that, with artificial food, thirty tons of turnips will feed sixty sheep; while, on the usual plan of feeding on turnips alone, out of doors, the average of the country is, that twenty tons of turnips will feed, in sixteen weeks, ten sheep, with a gain of only twenty pounds of flesh and tallow.

This gentleman long ago established the fact, that house, or shed-feeding, was a great saving of food. Mr. Richardson was staying with him at Cantley during the experiment, which was most carefully conducted by Mr. Childers in every way. The same food was given to each lot—one exposed, and the other sheltered in a walled and well-littered yard: 27 stones of turnips, 10 lbs. of linseed cake for each lot, and half a pint of barley per sheep per day, with a little hay and salt to go to, were given; but soon the sheltered sheep ate less, by 3 stones of turnips per day, than those exposed, and ultimately 2 stones more, as well as 3 lbs. of cakes per day. The result was, that in three months, two field-fed sheep had increased 36 stones 8 lbs., and the shed-fed, 56 stones 6 lbs.—a difference, in twenty sheep, of just 20 stones live weight! This experiment, Mr. Richardson says, gave the example for general imitation, and has divided sheep-feeders into several classes. The field feeder values the consolation of the animal's kneading, and feeds out of doors. Amateurs, like Mr. Mechi, advocate board-feeding, or houses with hollow floors of boards, set on an edge sufficiently near to prevent the sheep's feet from falling through; and one from his Cotswolds may be fat at one year old. As we disapprove of board-feeding, except under very special circumstances—strong clay land, for instance, or some equally potent physical preventive to the feeding out of doors—we think it fair to give the opinion of a gentleman who warmly advocated it—we mean the Hon. Captain Dudley Pelham.

"The sheep," he says, "should be upon

gratings, made with oak frames and deal tops, three-quarters of an inch between the bars. Beneath the gratings, which should be supported on either side, without cross-supports (which are inconvenient in emptying the pit), should be a tank or pit in brickwork, or rammed with marl, not less than two-and-a-half to three feet deep, so as to contain all the manure dropped by one lot of fattening sheep; thus avoiding the necessity of disturbing the animals for the removal of the manure." This gentleman recommends gypsum to be thrown over the gratings to prevent unpleasant smells, and that the sheds should be even cooler than those intended for oxen, 45° being the point he considers to be aimed at, while those of oxen he thinks should be 50°. The size of the pens he recommends to be eight feet by six, and to contain six Down sheep. The quantity of food eaten by fifty Down sheep, he estimates at two tons; and sheep in these sheds, he conceives, will feed in about twelve weeks. He has had sheep, for three weeks, increase at the rate of 4½ lbs.; and each animal will make, he calculates, 2 cwt. of powerful solid manure.

Stall-feeding sheep is a step still more in advance even of this; and, though inapplicable to young sheep, is, in some parts, practiced with considerable success.

Respecting the comparative economy of feeding sheep at one or two years of age, Mr. Richardson made an estimate, which he published in the Farmers' Magazine. He showed that, during the two years the two-year-old feeding system was in operation, the produce would be, on thirty acres of land, 7,500 lbs. of mutton; and the same area of land would produce 11,000 lbs., in the same period, by the one-year-old system; thus showing a gain, per annum, of 1,500 lbs. of mutton, on thirty acres of land, to the community. He further calculated the comparative advantage to the feeder; and showed that, with mutton at 6d. per lb., the one plan would leave a profit on the two years—out of which the rent was to be paid—of £62 10s.; while that of the one-year-old system would leave a profit of but £50 4s. The figures and calculations are too extended for us to make use of them; but the change, he says, in the demand for small mutton, since the period when these calculations were published, will somewhat modify the calculation,
and give the turn in favour of the one-year-old system—a course, it will be seen, which is only perfectly right, as more capital would be required in the one-year than in the two-year-old system, however it may otherwise be thought.

CHAPTER VII.

DISEASES OF THE SHEEP, AND THEIR REMEDIES.

In the whole range of domesticated animals, there is none so difficult to manage as the sheep, labouring under a state of disease. In acute cases, the use of remedies seems to be utterly in vain; whilst the power of known remedies seems to have literally no effect whatever in effecting the purpose for which they are administered. This is, perhaps, of less consequence now, seeing that the system of management is so well understood, that the animal is always kept fat and ready for the butcher, in order that, on the first symptom of illness, it may be dispatched before the disease has affected its vitals. Let sturdy, or rot, or inflammation, however, take place, and all the medicines in the world may be administered, and no effect will be produced.

The first ailment—for it cannot be called a disease—of which we will take notice, is that of PARTURITION.

In this country, the usual time of lambing with the greater number of sheep, is in the months of March and April; but sometimes an earlier period is obtained, for the purpose of having the lambs sooner fattened for the market. Accordingly, the Somerset and Dorset sheep have their lambs dropped generally before Christmas. At this season great care and attention should be given to the ewes, by way of affording them proper food and shelter from those inclemencies of weather which frequently prevail during the earlier months of the year. They should either be driven nightly into yards or cots properly protected, or a shelter should be supplied to them in the fields, by means of double rows of hurdles lined with straw, with a pound or inclosure, which will afford still greater protection. The care of the shepherd should, at this period, be in constant exercise; whilst the eye of the master should be continually on the watch, as a little assistance, opportunely extended to the labouring ewe, might be the means of rescuing her from the dangerous position of a too much exposed situation in reference to life. Mr. Price, in his work on sheep, observes, that many lambs may be lost without its being possible to change the lamb or shepherd with either ignorance or neglect, although greater attention on his part might have saved many, which otherwise would perish. The practice of lambing is at times very intricate, and is apt to exhaust the patience of a lamb.

Sheep are obstinate; and lambing presents a scene of confusion, disorder, and trouble, which it is the lamber’s business to rectify, and for which he ought always to be prepared. Some of the ewes, perhaps, leave their lambs, or they get intermixed; and the ewes that have lost their lambs run about bleating, while others want assistance. These are only a few of the various circumstances which call for the immediate attention of the lamber, and which render it necessary that the owner of the sheep should be on the spot, and should superintend the whole of the operations. The shepherd, however, must not be led to interfere with the ewe prematurely, if she appear to be labouring under great uneasiness and pain. He must watch her closely; and so long as she rises at his approach, he may be assured that, whatever amount of uneasiness she exhibits, still all is going on well. Much pain is apparent, as she will repeatedly lie down, and rise again with seeming distress.
Should this occur whilst he is driving her to fold, he must give her time, and exercise great caution in urging her too fast. Symptoms of this kind ought to be suffered to continue for two or three hours, or even longer, before he feels himself called upon to interfere, unless the lamb is in such a dangerous position as to excite fears of losing it. Protracted labour often occurs in cold weather. On such occasions, should the ewe seem exhausted, and to be gradually sinking under the prolonged severity of her labour, some oatmeal gruel, with a little linseed, in the proportion of a spoonful of the latter to two of the former, should be given her. When the ewe feels that she cannot of herself expel the lamb, she will quietly submit to the interference of the shepherd, and almost look for his assistance.

Where this assistance is necessary, the first duty will be to ascertain whether the presentation is natural. When this is the case, the muzzle of the lamb is foremost, with a foot on each side of it. Should this be the presentation, his first business will be to disengage the lamb, by gently drawing down the legs, and, with all possible tenderness, smoothing and accelerating the passing of the head with his fingers, rather than forcibly extricating it—the particular attention of the shepherd being given to these points. This is to be done by passing the finger up the rectum until the back of the lamb’s head is felt, which must be urged forward, at the same time that the legs are gently pulled. It sometimes happens that the legs are too backward, whilst the head is sufficiently advanced. In such cases, the head should be gently pushed back, and the hand, being well oiled, that the object may be the more easily effected, must be introduced into the vagina, and applied to the legs, so as to place them in their natural position equal with the head. On the other hand, should the fore feet protrude, they must, in like manner, be returned, and the same assistance given to advance the head. If the hind quarters present themselves first, the hand must be so applied as to get hold of both legs together, and draw them gently, but firmly. In this position the lamb may be often easily removed. It frequently happens that the head of the lamb is much swollen and protruding. Where this is the case, both patience and gentle manipulation will be required to bring it forward by degrees. Nature herself, however, if not unduly interfered with, will, provided the pelvis be not very much deformed, effect her own operation. In case the strength of the mother should be rapidly diminishing, the head may be taken away, and then the operator will be able to push back the lamb and introduce his hand, when, by laying hold of the fore legs, he will effect the delivery. It sometimes happens, however, that the legs are thrust out to the shoulder, when, from the throes of the ewe, it is not possible to replace them so as to raise the head of the lamb; but by partially skimming the legs, they may be separated from the shoulder-joint, when room will be given for the introduction of the hand, and by laying hold of the head the ewe may be delivered. The practice obtained in one season, however, will do more to enable the farmer to act in difficult cases of labour, than all the instructions that can be given in a volume of writing; but, as a general rule, it should be remembered that the fetus should, if possible, be placed in its natural position previously to any attempt to extricate it by force. When this must be employed, it ought to be in as gentle a manner as can be consistent with the tenderness of the object to be delivered. After parturition, it is hardly necessary to observe that the ewe should be nursed with the greatest care and attention until she has completely recovered. After difficult labour, and where much assistance has been given, the labia of the uterus and vagina are sometimes ruptured. In such cases, where there is no other hope, a veterinary surgeon will have to divide the ligatures.

When ruptures of the vagina take place, use the following dressing, rudely known as the "DriFFIELD oil," or black oil:

- Take of Olive oil . . . 1 pint.
- Spirit of turpentine . . 2 ounces.
- Sulphuric acid . . . 6 drachms.

They are safest mixed in a stone jar, as great heat will be generated during and just after the mixture. When cool, it may be put in a bottle for use.

If an appearance of mortification or gangrene occurs, a more decided application will be necessary, when it is best to call in a veterinary surgeon.
GARGET.

This is an inflammation of the udder, and is a very common, painful, and sometimes fatal disease. It is less frequent in the sheep, however, than in the cow, and may be produced by cold and wet hair, and, it is stated, from the hardness and dryness of the ground, or from constitutional derangement. Warm fomentation in the first stage, and rubbing with marshmallow ointment after each fomentation, with a warm, dry towel, is the best local application; while an internal medicine, composed of—

Three drachms of nitre,
Two of cream of tartar,
Dissolved in four ounces of lukewarm water,
may be given with advantage. The black oils may be used, after the first few days, to promote suppuration of the matter formed in the udder, and, after it breaks, a dressing of tincture of myrrh. An ounce or two of Epsom salts is also recommended to be given to the ewe, with a drachm of ginger dissolved in warm water or gruel, and the udder fomented, for some time, with water as hot as she can bear it. The lamb may afterwards be allowed to suck her. The fomentation, if necessary, should be repeated, and the camphor ointment rubbed in twice a day. If the swelling continue, it should at once be opened, and the discharge of the pus assisted by pressure, and renewed fomentation. Should the wound smell disagreeably in the least degree, it should be syringed with a weak solution of chloride of lime for several days. It sometimes happens that, from the effects of garget, some portions of the udder become hard or scirrhous, as it is termed, and, of course, no longer secretes milk. When such is the case, the ewe should invariably be drafted and fattened for the butcher.

PUERPERAL FEVER.

This is not so common in the ewe as it is in the cow. When it does occur, the medicine recommended for acute garget will be found useful, and may in general be given; or the following may be administered:

<table>
<thead>
<tr>
<th>Epsom salts</th>
<th>1/2 oz.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tincture of opium</td>
<td>1 drachm</td>
</tr>
<tr>
<td>Camphor pulv.</td>
<td>1/2 drachm</td>
</tr>
</tbody>
</table>

This is recommended by Professor Spooner after abortion—a complaint which sometimes attends ewes when kept exclusively on turnips.

CASTRATION.

When this operation is performed on lambs about a month old, it is very simple; and, though often executed in a manner somewhat barbarous, it may be more humanely done by a kind of combined knife and forceps, which has been invented for the purpose. In performing the operation, an attendant holds the lamb with a fore and hind leg in each hand, and with the back close to his breast. The operator cuts off the end of the scrotum, presses on the bag till the testicles protrude, and either seizes the testicles with his teeth, one by one, or with the forceps—and no more trouble is necessary than to confine the lamb for a night or two, if the weather be frosty. To accomplish the castration of aged rams, however, is a more difficult operation. After ascertaining that there is no rupture, both the testicles, which are very large, are inclosed and held firmly together by iron clamps, and the testes are divided in a line with these by the cautery. Other methods are adopted, but this is by far the most popular. Some use two sticks united at one end, into which each testicle is inclosed, the inner part of the sticks being smeared with a solution of sulphate of iron. The other ends of the sticks are then tied, and the testicle cut off. In twelve hours the sticks are removed by cutting the string, and all the vessels are thoroughly cauterised. This mode is a great improvement on the cautery.

ROT.

Bad and unwholesome food is generally believed to be the cause of this disease, especially as it appears to be much more prevalent in wet seasons, when plants, at other periods wholesome, become rank and impregnated with poisonous qualities. Drainage is doing much to banish it from the country; for it is found that the disease is very rare when the sheep are fed on dry, heathy pastures. Therefore, when it makes its appearance, the sheep should be removed as early as possible, either to a salt marsh, or to such pastures as are of the driest description. Salt may be given to
the animals in as large quantities as they will take it with their food; and to this the sulphate of iron may be added. Half a drachm daily for each sheep, with the same quantity of ginger, is recommended to be given in nourishing gruel. During the treatment an aperient should be given once or twice, and it may be composed of one or two ounces of sulphate of magnesia, or a large tablespoonful of common salt dissolved in warm gruel or water. Food of the most nourishing kind should be given; and a pint of beans daily is esteemed an excellent diet, with good hay, or sound pasture. The best preventive of the disease, Mr. Milburn thinks, is an allowance of plenty of dry food, with salt ad libitum. He knew a farmer, in Cleveland, who saved his flock of Teeswaters in a rot year, which almost denuded that valley of its sheep, without any other exception than his own flock. They had constant access to the hay-stack, and so were preserved amongst the general ruin. When the rot unhappily sets in, it is by far the best to sell the whole of those which are at all fit for the butcher, for immediate slaughter.

SHEEP-POX.

This disease was introduced into this country by the continental sheep. It is very destructive to the flock, and highly injurious to those animals which recover from it. Professor Simonds, of the Veterinary College, London, recently lectured upon it, as his experience has, unfortunately, lately been very great in the treatment of this disease. We find that, before 1817, the malady had never, during the present generation, been observed among the flocks of this kingdom. It had long, however, been prevalent and well known in several of the great sheep districts of the continent. In some localities, the affection was, so to speak, naturalised; in others it had shown itself, from time to time, in wide and disastrous outbreaks. Within historic periods, the disease had probably never appeared among healthy flocks, unless there had been prior communication, immediately or recently, with animals suffering from the affection. One sheep would infect a flock; a flock would infect a district; and in this way the malady would be spread over the area of a vast country. So it had happened once and again in France, Germany, and Central Europe. But while the communication of sick with healthy animals might be said to be an essential element in the propagation of small-pox, yet it was seen that this could not be the sole element. For now the disease had been observed to break out in one or two scattered instances, and then would appear with a malignity which almost set control at defiance. At one time the flocks showed a higher susceptibility to the disease than at another. This consideration entered largely into the question of prevention. "In the case of human small-pox, Professor Simonds observes, "that we possess a simple, efficacious, and an almost harmless means of prevention in vaccination; but it was not so in the case of small-pox in sheep. Vaccination affords them no protection. Where the separation of the affected animals from the healthy ones proved insufficient to stay the disease, there remained only inoculation to be had recourse to. Nothing was more efficacious than this for securing the ultimate welfare of the flock. He could well understand why so great an authority as Dr. Copeland should, on account of the greater protective power of inoculation, express something like a regret that, in this country, it was prohibited for man. Dr. Copeland apparently doubted the greater value of vaccination as a protection against small-pox. Of the justness of this doubt Professor Simonds expressed no opinion; but he thought it well that it should be alluded to at a time when the recent events in Wiltshire had led to so much discussion on the question, and when the fact of the prohibition of inoculation for man had been used as an argument for prohibiting it in the case of sheep. It had been forgotten by the objectors, that, in the case of sheep, we had no option between vaccination and inoculation. Wide and extended experience had shown that vaccination was valueless as a protection against small-pox in sheep. Wider and more extended experience had, on the other hand, shown the great value of inoculation in mitigating the severity of the disease. Small-pox first appeared among the flocks of England in 1817. It was introduced by foreign sheep sold in Smithfield market. The disease spread rapidly, and committed frightful ravages in several counties during the years 1817, 1818, 1819, and 1850. Since the latter year, the malady had not
been heard of among our flocks until the month of July, 1862, when it broke out at Allington, near Devizes. It soon spread; and neither the shepherds nor the proprietors were satisfied as to its real nature until the aid of Professor Simonds had been sought; and at that time many animals had been lost. The disease quickly spread to neighbouring flocks, and subsequently extended to Berkshire. At the present moment there is good hope—thanks to the preventive measures adopted—that the malady has been stayed in the vicinity where it had first showed itself. As the value of the flocks of this country amounts to many millions sterling, the loss by death, from small-pox, ranges from one-fifth to one-half, or even more, of an infected flock; but this is only one part of the loss which the farmer has to suffer. He has to bear the effects of the disease on the breeding and rearing of lambs, the fattening of stock, &c. In treating for this disease, the advice of an experienced veterinary surgeon should be at once taken.

FOOT-ROT.

This is one of the most obstinate and powerful local diseases to which the sheep is liable, and, if not immediately attended to, is difficult to cure. Should the affected animals not be kept assiduously from the sound, the disease will, for some time, obstinately keep possession of the flock. The infected sheep, therefore, should at first be carefully examined, and all the diseased parts cut completely away. A dressing should then be applied, consisting of—

Corrosive sublimate . . . . 1 oz.
Sulphate of iron . . . . 1 "
Muratic acid . . . . 1 "
Sulphate of copper . . . . 1 "
Coarse turpentine . . . . 1 "
Sulphuric acid . . . . 1 "
Spirit of turpentine . . . . 1 "
Sheep ointment . . . . 4 "

This mixture, simple as it is, is sometimes a necessary application. The sound portions of the flock should have all their four feet dressed with tar, and should be kept all night on a floor smeared with quick-lime. As the diseased sheep approach convalescence, they should be carefully watched, and dressed, if required, daily. In the course of 1862, this disease was rather prevalent in the south-eastern districts.

and the following practical suggestions may be valuable. Mr. F. C. Waide, an experienced farmer, says—"Take 1 lb. of alum, and 2 ozs. of blue vitriol; boil them in one pint of water; when quite cold, add 3 of a pint of aquafortis, and it will be ready for use. It is equally effectual for the foul in beasts feet." Another cure is suggested by a farmer at Malton:— "With a sharp knife cut away the infected part, and then, with a clean wooden skewer, apply once a day some muriate of antimony. This will stop the disease, and effect a cure. A strong solution of sulphate of copper would answer the purpose, applied with a brush; but it is neither so speedy nor so effectual." An "East Suffolk Farmer" suggests the following, which, he believes, is a certain cure:—"Take sixpennyworth of quicksilver dissolved in sixpennyworth of nitric acid; add the same quantity of good vinegar; pare the horn well; shake the bottle, and apply to the parts affected. One or two applications will be sufficient."

THE SCAB

Is a disease of the skin, arising from the presence of minute insects called acari. The German naturalists trace it to the actual fact of the acarus, which buries itself in the skin of the animals, and which must be destroyed; and the sooner the better. The following ointment rubbed in, the wool being first shaved longitudinally, and at about four inches apart, will often be successful:—

Sand . . . . . 2 lbs.
Sulphur . . . . . 1 "
Spirits of turpentine . . . . . 1 "

The application of mercurial ointment is another mode of cure. To make it—take from three to five parts of lard, and mix with it one part of strong mercurial ointment; and after parting the wool, rub it into the furrows from the head to the tail, and about four inches apart.—The following is also an effectual ointment:—

Lard or palm oil . . . . . 2 lbs.
Oil of turpentine . . . . . 3 "
Sulphur . . . . . 1 "

Mix the two latter ingredients gradually together, and then rub down the former with it. Tobacco-water is another remedy, which has been found very effectual.
DIARRHOEA.

This disease is most frequent in hogs or young sheep, and is often caused by improper as well as by rapid changes of food. It has been said that two teaspoonfuls of sulphur will seldom fail of producing the effect, when administered in gruel in time; but if the first stage is over, it will require more vigorous means. A dose of two ounces of linseed oil, with two grains of opium, to allay the irritation of the bowels, will often answer the purpose; but if the disease should still prevail—

Prepared chalk  . .  1 oz.
Opium. . . .  ½ drachm.
Ginger. . . .  3 "
Port wine . . .  2 ozs.

may be given in a gill of gruel with great advantage.

DYSENTERY.

This disease resembles the preceding to some extent, yet is distinguished by other symptoms, which should be well observed. Sir G. Mackenzie thus draws the marks of distinction between them:—

1st. Diarrhoea chiefly attacks hogs and two-year-old sheep; whereas dysentery is frequent among such as are older.

2nd. Diarrhoea almost always occurs in the spring, and ceases about June, when dysentery only commences.

3rd. In diarrhoea there is no fever or pain before the stools, as in dysentery.

4th. In diarrhoea the faeces are loose; but, in other respects, natural, without any blood or slime; whereas, in dysentery, the faeces consist of hard lumps, passed occasionally, the rest being blood or slime.

5th. There is not the degree of bad smell in the excrement, in diarrhoea, which takes place in dysentery.

6th. In dysentery the appetite is totally gone; in diarrhoea it is rather sharper than usual.

7th. Diarrhoea is not contagious; dysentery is highly so.

8th. In dysentery the animal wastes rapidly; but, by diarrhoea, only a temporary stop is put to its thriving, after which it makes rapid advances to strength and vigour.

9th. Dysentery is commonly fatal; diarrhoea rarely, unless the animal has been previously much debilitated. In cases of dysentery, the following treatment is as good as can be advised, provided proper care is bestowed upon the animal, and the food attended to:—

Linseed oil . . . .  2 ozs.
Powdered opium . . . .  2 grains.

This is to be given to each sheep, in an infusion of linseed, the gruel being repeated several times; and, on the following day, the opium to be again administered with half a drachm of powdered ginger, and the same quantity of gentian. This may be given several times, and sometimes combined with linseed oil.

These are the principal diseases of the sheep. Those which refer to inflammations of the chest, bowels, &c., require the treatment of a skilful veterinary practitioner, whose services should be sought as early as possible; for the longer the delay, the greater is the danger of fatal consequences being the result.

This ought always to be borne in mind in such cases.
MEDICINES USED IN THE TREATMENT OF DISEASES IN SHEEP.

**Aloes.** Used as a tincture to stimulate wounds. It should not be given internally to the sheep, because of the danger which attends it.

**Alum.** Used externally, in the form of a lotion; applied to several diseases of the mouth; and, mixed with chalk, it makes an excellent external application to sores. As an astringent, it is inferior to other medicines used as such; but when given, the dose is half a drachm, with gruel.

**Antimony, Butyr, or Chloride of.** This is an admirable caustic for foot-rot and other diseases, and should be applied with a feather.

**Arsenic.** This is sometimes employed as an infusion, in which the sheep are dipped, for the purpose of destroying ticks and other insects. Great caution, however, should be used with it; and all vessels into which it has been put, should be immediately cleaned after using them.

**Camphor.** Used with oil or spirits of wine, camphor is employed as an external stimulant. When used internally it acts as a narcotic, sedative, and anti-spasmodic. The dose is from one scruple to a drachm.

**Cantharides, or Spanish Flies.** This is rarely employed in the diseases of the sheep, except in the form of blisters, in which it makes the chief ingredient.

**Caraway-seeds.** A stomachic, in which the dose is from two to four drachms.

**Catechu.** Given with opium and chalk in case of diarrhoca. The dose is from half a drachm to a drachm.

**Chalk, Prepared.** Used as an external application to wounds and sores; also as a mild astringent in diarrhoca. In such case the dose is from half an ounce to an ounce.

**Copper, Sulphate of, or Blue Vitriol.** Externally, this acts as a mild caustic; internally, as a tonic. The dose is half a drachm.

**Corrosive Sublimate, or Dichloride of Mercury.** This requires to be very cautiously used. It is employed as a strong caustic and poison in cases of sores, and to kill vermin.

**Castor Seeds, or Oil.** A powerful purgative, useful in cases of severe constiveness. The dose is from five to fifteen drops of the oil.

**Digitalis, or Foxglove.** Used as a sedative to diminish the rapidity of action in the heart. The dose is one scruple.

**Epsom Salts, or Sulphate of Magnesia.** An excellent purgative, given in doses of from one to two ounces, or more, dissolved in warm-water gruel.

**Gentian.** A vegetable tonic of great usefulness, administered in doses of from one to three drachms.

**Ginger.** Used as a cordial and stomachic, usually with aperient medicine. Dose, from half a drachm to three drachms.

**Hartshorn, Spirits of.** Used as a stimulant and anti-spasmodic in cases of hoove. The dose is two drachms, in six ounces of water or gruel.

**Iodine.** A powerful stimulant to the absorbent vessels. It is used both internally and externally, and exercises great influence over glandular swellings. As an external application, it is generally used in the form of iodide of mercury, mixed with eight parts of lard. In the form of iodide of potassium, it is used internally, in doses of from four to six grains.

**Lead—Acetate of Sugar of Lead.** A common ingredient in cooling lotions. Used in the form of Goullard's extract.

**Lead, White.** A useful application for the prevention of the fly.

**Lime, Chloride of.** Useful as a preventive of infection, and also an excellent application to foul wounds and ulcers.

**Linseed Oil.** A useful and safe purgative. Dose, two ounces.

**Muriatic Acid, or Spirit of Salt.** Useful in foot-rot, as a powerful caustic.

**Nitrate of Potash, Nitre, or Saltpetre.** A diuretic. Dose, two drachms.

**Olive, or Sweet Oil.** A laxative, but less valuable than linseed oil. As an external application, it is useful in cases of burns and bites from venomous insects.

**Pimento, or Allspice.** A cordial and stomachic. Dose, from one to two drachms.

**Rye, Spurred, or Ergot of Rye.** A strong stimulus to the uterus, given in cases of protracted lambing. The dose is a scruple, infused in hot water; to be repeated, if necessary, in the course of one or two hours.

**Salt, or Muriate of Soda.** In small doses, a stomachic and tonic. In large, a purgative. When given in moderate quantities it is useful to the health of sheep. For counteracting and curing the rot it is very effective. As a purgative, the dose is about an ounce.
Spirit of Nitrous Ether, or Sweet Spirit of Nitre. An anti-spasmodic or stimulant. Dose, two drachms.

Sulphate of Iron, or Green Vitriol. Used as a tonic. Dose, a drachm mixed with ginger.

Sulphate of Copper, or Blue Vitriol. A strong tonic, but rarely given to the sheep. Dose, one scruple. As an astringent lotion it is excellent, infused in hot water.

Sulphur is a well-known substance, sold in the form of a powder or in solid pieces, when it is called brimstone. It is procured in the neighbourhood of volcanoes. In the track of land between Naples and the ancient Baiae, called Solfara—i.e. the smoking plains, the remnant of a half-extinguished volcano—it is found in great abundance; and is also brought in large quantities to this country from Mount Etna in Sicily; but is to be had, in greater or less quantities, near all volcanoes, of which the number throughout the world is very great. It is often found in coal mines; and, indeed, the common coal in our fires, more or less, contains this mineral; which is frequently combined with iron, copper, and other metals, when it is called pyrites.

Sulphurets are combinations of alkalies or metals with sulphur.

Sulphuric Ether. A strong stimulant, and anti-spasmodic. Dose, with warm water, one drachm.

Sulphuric Acid, or Oil of Vitriol, is generally procured by burning a mixture of sulphur and nitre in chambers lined with lead. It is a liquid, somewhat of an oily consistence, transparent, and colourless as water, without any smell, and of a very strong acid taste. When applied to animal or vegetable substances, it very soon destroys their texture. It may be procured by the following process:—Put into a glass retort two parts of sulphuric acid and one part of mercury, and apply the heat of a lamp; the mixture effervesces; and a gas issuing from the neck of the retort, may be received in glass jars filled with mercury, and standing in a mercurial trough. This gas is sulphurous acid. It is a very strong caustic, and is used in cases of foot-rot, either alone, or combined with tar.

Sulphur, Sublimed, or Flower of Sulphur. Given with Epsom salts, as an aperient. Dose, from one to two ounces. In the form of an ointment it is used externally for the scale.

Sulphur Verum. This is cheaper, but not so pure as the yellow sulphur. It is of a grey colour, and is only used as an external application.

Tar. Applied to the feet in cases bordering on foot-rot; it is combined with sulphur, acid, or other caustics.—Oil of Spirit of Tar is used for the same purpose. It is also used for wounds in the skin, and also for the fly.

Turpentine. The common is used in digestive ointments, but is not given to the sheep internally. Venus turpentine is pure, and more expensive.—Oil, or spirit of turpentine, is given as a powerful anti-spasmodic and stimulant, in doses of one drachm.

751
DIVISION VI.

PIGS.

CHAPTER I.

THE ORIGIN OF THE DOMESTICATED PIG.

The hog family is a genus of pachydermatous mammalia, exhibiting strongly-marked differences, in most of their characteristics, from the rest of that very singular class. Like all the ruminating animals, they have cloven feet, or only two fully developed toes; and they are the only pachydermata which do not entirely confine themselves to vegetable food. The others are exclusively vegetarians, principally subsisting on strong and harsh vegetation; though most of them would give the preference to a more delicate food, if they could obtain it. Hogs are omnivorous, but chiefly vegetable in their feeding, and they prefer such as are succulent, especially wild fruits and roots; though, when other food fails, they can subsist upon almost any kind of digestible matter that falls in their way.

All naturalists admit that the wild hog is the origin of our domestic race; but at what period it was reclaimed is very uncertain. The circumstances, indeed, connected with the domestication of every animal subject to the bondage of man, are enveloped in obscurity. The domestication, however, of the wild hog would not involve much difficulty. Young animals, taken in their native forest, soon become reconciled to captivity, and display the same contentment and familiarity which are so conspicuous in our ordinary tame beast. It is this disposition—a characteristic of the pachydermata—which renders the elephant, the rhinoceros, the tapir, and others, so easily subjugated; but, on the other hand, the readiness with which they submit to the restraints of captivity, is counterbalanced by an equal readiness to assume a life of independence. The hog, when left to itself, resumes its original habits—as is the case in America, where wild herds roam the forest; and, as we are told, the elephant often escapes its trammels, and joins its wild brethren; but immediately submits, if retaken, to the voice of authority which it had previously learned to obey. The horse, in a wild state, scours the plains of Tartary and South America, and it requires but a brief struggle to break in the most spirited. It may be laid down as an axiom, that the animals of the services of which man stands most in need, are, each in their way, those whose nature most readily induces them to submit to his dominion—nay, even to court his friendship. Some can be tamed, and only tamed; others can be educated.

The skull of the hog affords an index of the habits of the animal, and is of a conical or wedge-like form. The base, or occipital portion, forms a right angle with the oblique upper surface, and a bold transverse ridge is formed by the union of the occipital and parietal bones. The nasal bones are prolonged nearly to the end of the snout, which, in the living animal, terminates in a movable cartilaginous disc, pierced by the nostrils. The lower jaw is of great strength. The dentition consists of—in ensors, $6$; canines, $1-1$; molars, $7-7$. The canines of the upper jaw are prismatic, and curve downwards, having their anterior surface worn by the action of the huge canines of the lower jaw, which are sharp, sweeping out from the sides of the mouth, and often attaining to the length of eight or ten inches, and sometimes even more. These canines, or
tusks, are terrible weapons; rushing on his antagonist, the boar strikes obliquely upwards, right and left, with prodigious force—a mode of action the best calculated for bringing these weapons into effective play, and in which the muscular powers of the neck and shoulders are the most advantageously and naturally exerted.

The hog is found in both continents; but the American animals are so different from those of the eastern continent, that they require to be separated as a distinct sub-genus. They are much smaller than those of the east, but less useful, and more limited in their distribution, being met with only in the humid woods of the central parts of South America, to the eastward of the Andes. In some parts of these woods, however, they are very numerous. In every part of the globe they delight in humid localities, reposing in the sun by the margins of pools and streams, wandering amongst mud or mire; or, in the absence of anything better, basking by the side of some soft dung-heap. They are much more extensively distributed in the east than in the west—in Asia than in America; but it is in the damp forests of tropical countries where they most abound. In some of the more central parts, and in the south of Europe, they are plentiful, but not so extensively distributed as they once seem to have been. In Britain the wild race is extinct; but tradition has handed down to us records of their having, at one period, abounded. In the remote islands of the Pacific they are still general; whilst, in the more densely wooded portions of Africa, and south-eastern Asia, they are to be found in large herds. In some parts, however, there is considerable difficulty in distinguishing between the wood hog, which is the native, or aboriginal, and such as have been introduced from other countries, and naturalised in their new regions; as these, having been turned loose into the woods, have multiplied, assumed the habits of the wild species, and proportionately lost many of their own original characteristics.

In no essential point does the wild race of Europe differ from our domestic breeds, saving that the snout is more elongated, and, as might be expected, the contour of the frame is more gaunt and bony. The ears are short and erect, the tusks large, and the bristles long and coarse; the general colour is rusty-black, or blackish brown, more or less brindled in patches. After the age of three years the wild boar leads a solitary life in the forest, fearless of every foe, and confident in his weapons, which, added to his great strength, render him a formidable antagonist. It is not, however, until the age of five or six years that he attains to his full dimensions, and the duration of his life is from twenty-five to thirty years. The females, with their young, associate in herds, for the sake of mutual protection. On the approach of an enemy the young are placed in the centre, the old ones forming a circle round them; and should he be hazardous enough to venture on the attack, he meets with a rough reception. It is thus that the young are preserved from wolves, the chief foes to be dreaded by them; to which, in some districts, they often fall a prey, notwithstanding the vigilance of their parent. It is only in defence of their offspring that the females are furious; but the old males are not to be approached without caution, and often rush out upon those who venture near the precincts of their lair. At certain seasons, indeed, the wild boar is very savage; and should he meet a rival, the most sanguinary combat ensues. The wild boar of Europe is now, however, by no means the terrible animal he once was; nor is he hunted in the German forests in the same brave and adventurous spirit which, in former ages, mark the spirit of the Teutons. This is evidenced by the present style of hunting the boar in Germany, where he still roams in freedom, and where he is still hunted, but in a manner which appears to us very unsportsmanlike. As a proof of this, we will describe the manner in which his serene highness of Coburg enjoys the sport.

About four miles from Coburg, and a little to the westward of Rosenau, rise several abrupt hills, clothed to the summits with pine woods, altogether occupying a space of a thousand acres. These are the boar preserves of his highness; and having been honoured by a visit from her most gracious majesty Queen Victoria, they had earned for themselves an extraordinary prestige. The person who describes this scene was directed to be in attendance on the chamberlain of the hogs at five o'clock precisely; and exactly at that hour, as he made across certain fields of flax lying
between the woods and the high road, that functionary appeared, emerging from his pig penetralia. He went about the ceremonial in which he was engaged, quite according to the craft or etiquette of his order. The narrator was requested to approach the preserve with gravity and decorous legility of foot. Onwards he went, treading lightly, till he arrived at a sort of park-paling inclosure, some six feet high, and closely boarded. Entering there by a gate, which closed behind him, he was shown by an ancient forester, with a mortal blunderbuss on his shoulder, and a rapier by his side, into a thing like a cockney summer-house upon stilts. Within this he was shut up among much musty hay, there being a party of ten in a room suitable for two. On each of the four sides of the square box were pepholes, through which these anxiously watched the process of strewing around provisions of corn and potatoes, that savoured very much of the board frugal housewives at home spread for their domestic circle of bacon. Long and fearfully they waited for the guests. Sometimes the master of the ceremonies hinted that perhaps they might not come at all; and when some of the musty hay-dust elicited a sneeze from one of the party, he said he almost despised of an arrival. But they were not destined to be so disappointed. At the end of an hour, spent about as agreeably as it would be in the black hole of Calcutta, a vidette at the peep-holes cautiously gave the words, "Here they come!" And sure enough there they did come, as orderly and well-behaved as if they had been borne in, in rashers, and ornamented with poached eggs. First marched a matron of the sty, accompanied by a very numerous family—quaint little roasters—like nothing in zoology so much as hedgehogs upon a large scale. Anon, through all the loopholes opened for their admission, trooped boars, singly, and in parties; but save an occasional poke in the spare ribs, given by the snake-like snout of some bully to a more gently-disposed sow (the ladies were the most quarrelsome), all went off very tamely. Thus did the feast proceed till the potatoes and corn were consumed, or so much of them as these ravenous creatures were disposed to discuss; for all went to their afternoon meal as gingerly as a Paris elegante.

The wild boars of Germany have, indeed, the characteristics of a race not exactly bred to pass from their nurses into sausages. They give you the idea of a cross between the wolf and domestic swine, but retain, apparently, no trace of their savage origin, except a look of cunning, and an apparent instinct of misanthropy. The least move made by the cooped-up witnesses of this scene, was instantly detected and acknowledged; but that was all. The herd made no manifestation of fight. They are as unpoetic and unvalorous a race as those that frequent the trough of the English farmer—at least, those that were there—and their hunting offers no features of enterprise beyond the slaying of pigeons at the Red House. When a boar is to be shot, the herd is enticed to dinner in the inclosure already spoken of. Then, all but the devoted one being scared away, the trap-door of the loopholes are closed, and the sportsman, ascending a sort of box—like the distance-chair of our English race-courses—quietly administers a leaden pill to his patient. The reigning duke, though keeping up a herd of nearly two thousand, kills a vast number this way every season—such is the degeneracy of European wild hog shooting: no horse-riding, no spear-pointing, no dog-barking; nothing to give the excitement of sport; not even the smallest danger, which we take to be one of the grandest elements that enter into the pleasures of hunting this once formidable animal.

An old French newspaper furnishes an account of an extraordinary boar killed near Cognac, in Angoumois. He had been frequently hunted, but unsuccessfully. His prodigious strength and powers of endurance carried him, on all occasions, safely through the various dangers to which his notoriety had, from time to time, exposed him. He had killed many valuable horses and dogs, and had maimed, as well as destroyed, several men. When at last victimised, several bullets, received during previous conflicts, were found between the skin and the flesh. This animal is described by Sonnini, who does not give his exact measurement, but says that his size was immense. He had a very long head, an elongated and sharp snout, and a terrific mouth, armed with tusks of unusual magnitude and singular shape. The hair on his body was
white; that on the head yellowish; and on
the neck he had a black band; the ears were very
large and straight. Notwithstanding the pro-
digious bulk of this formidable and ferocious
brute, it is stated that he displayed great
swiftness.

Boar-hunting in India still forms a fa-

courteous amusement to those who delight in the
excitement incidental to such diversion. The
animal is usually hunted with Arabian horses;
the swiftness of which, and their well-known
tractability, render them well adapted for this
kind of sport. When the boar is just started,
he sets off at a slow trot at first; but this is
soon quickened into a sort of shambling gallop,
keeping his eyes well behind upon his pursuers.
The pace now becomes exceedingly swift, and
he can only be taken by being run down.
After running three miles he frequently makes
his escape, and will sometimes run even and
even without suffering himself to become a
victim. The usual height of this animal is
about three feet; but some of them reach a
few inches over that. The young of the Indian
boar are of a palish yellow hue, irregularly
marked with yellowish brown. From a remote
period, hunting the wild boar has been a
favourite amusement with those who delight in
manly exercises, and have nerve sufficient
to confront danger even when it glares from the
eyes of a hard-pressed and infuriated animal,
capable, by his strength, of bringing a horse to
the ground, and, with a single rip of his tusks,
depriving it of life.

In the month of December or January, each
male attaches himself to the society of a chosen
female, which he accompanies in the deepest
glens of the forest for about thirty days.
When about to produce her young, the female
seeks some undisturbed retreat, remote from
the haunts of the male, which, it appears,
exhibits a propensity to devour her progeny if
he discovers the litter. To her young the
female is a most attentive mother. She suckles
them for three or four months, and they remain
with her for a long time. An aged female is
sometimes seen followed by several families,
among which are some of the age of two or
three years. These young rovers are called,
by the French hunters, bétes de compagnie.
The wild boar seldom stirs from his lair during
the day, and may, therefore, be regarded as,
in some degree, nocturnal. On the approach
of twilight, he runs to his habitual slumber,
and sets out in quest of food, which con-
sists of acorns, beech-mast, grain, different
vegetables, and roots. In search of the latter,
he ploughs up the ground with his snout.
Corn-fields in the vicinity of forests, where
wild hogs exist, often suffer extensively from
their nightly incursions. The wild boar,
though not truly carnivorous, does not refuse
animal matters which chance may throw in his
way. He does not, however, ordinarily attack
and kill others for the sake of their flesh, but
only devours what he may meet with in his
rambles. In the morning he returns to his
laire, which is generally in the thickest and
most gloomy part of the forest, under a rock,
in a cave, or under the canopy of gnarled and
intertwined branches. When roused by the
hunter and his dogs, the old boar retreats
sullenly and slowly, gnashing his teeth, foaming
with anger, and frequently stopping to receive
his pursuers, on whom he often rushes with
sudden impetuosity, striking with his tusks,
goring dogs and men, and scattering terror
around. When he turns upon a pack, the
foremost dogs are sure to suffer, and several
will fall by as many strokes. An instance is
on record in which a boar turned suddenly
upon a pack of fifty dogs which pursued him,
and instantly dispatched six or seven of them,
wounding all the rest with the exception of
ten. The young boar is less resolute than the
old, and will run to a considerable distance
before he is brought to bay; nor is the
assault attended with any great degree of
danger.

We have said that, from a remote period,
boar-hunting has been a favourite diversion;
and we find the writings of the Greek and Ro-
man classics abounding with allusions to it, and
the great risks which men run in its pursuit.
Ovid gives a spirited account of the chase, in
which the fury and strength of the enraged
beast are admirably depicted. It would seem
that the ancients endeavoured to enclose the
boar by nets, so as to prevent his escaping into
the recesses of the forest. The combat being
close, it was necessarily dangerous. Driven
from his lair by the dogs, and hemmed in, the
infuriated animal turned savagely upon his as-
sailants, and died—after killing and wounding
PIGS,

BOAR-HUNTING.}

Our Saxon forefathers, in the middle ages, deemed the wild boar one of the noble “beastes of venery,” and kept a powerful breed of hounds for the chase. The weapons used by the huntsmen were spears, and a sort of short sword, or *couteau de chasse*. The spears were used when the boar was brought to bay, and the attack gave abundant opportunities to the hunters of showing their skill and courage. The loud blast of the horn, mingled with the shouts of men and the baying of the hounds, proclaimed the vigorous home-thrust which brought the savage lifeless to the ground. The hunters were always mounted on horseback; and, instead of meeting the animal with spears, attacked him with javelins, which were launched at him as he fled, or as he rushed to the charge, which was often so determined that the horses could not be brought to stand the shock, or, if they did, were thrown down and gored. Serious accidents sometimes occurred. Mr. Johnson relates an Indian instance, in which a large and resolute boar, after being driven by the hunters into a plain, stood at bay, and challenged the whole party. He charged every horse that advanced within fifty yards of him, with great ferocity, causing them to rear and plunge, and throw off their riders, whose lives were in jeopardy. Though many of the horses were accustomed to the sport, none would stand his charges, or bring the rider within javelin distance; and at last, he fairly drove the party from the field; and then, gnashing his tusks and foaming, made his way to the jungle, where it was useless to attempt to follow him.

The wild hog was once common in Britain; and it is surprising, considering the passion for the chase, which seems to be part and parcel of our English temperament, that this animal is not re-established in some of its old haunts, the parks and forests of nobility. Englishmen in India are enthusiastically fond of chasing the wild boar; but, as there is greater room in that country than in this, for such a ferocious monster to play his gambols, it may be as well to leave him there. Perhaps the revival of boar-hunting in England would not be attended with that success which some enthusiasts may anticipate. When that animal tenanted our glens and forests, however, he was by no means held in slight estimation. He enjoyed royal protection; and there are in existence various records, which principally consist of edicts or proclamations issued, announcing sundry pains and penalties as the consequence of its illegal destruction. Howel Dha, or Howel the Good, gave permission to his grand huntsman to hunt the boar from the middle of November to the beginning of December; and William the Conqueror inflicted, as a punishment, the loss of sight on those who illegally killed the boar.

In the *History of the Anglo-Saxons*, by Sharon Turner, we are informed, that “among the drawings in the Saxon Calendar, in the Cottonian Library (Table vi. 4), the month of September represents a boar-hunt. A wood appears, containing boars. A man is on foot with a spear; another appears with a horn slung, and applied to his mouth; he also has a spear, and dogs are following.” And in the *Saxon Decalogue*, we have this conversation:—

“Am I a hunter to one of our kings?” “How do you exercise your art?” “I spread my nets, and set them in a fit place, and instruct my hounds to pursue the wild deer till they come to the nets and are entangled, and I slay them in the nets.” “Cannot you hunt without nets?” “Yes; with swift hounds I follow the wild deer.” “What wild deer do you chiefly take?” “Harts, boars, and fallow deer.” “Did you hunt to-day?” “No, because it was Sunday; but yesterday I did. I took two harts and a wild boar.” “How?” “The harts in the nets, and the boar I slew.”

“How dared you slay him?” “The hounds drew him to me, and I, standing opposite to him, slew him. Such was his fate—one of the most handsome animals I ever beheld of his kind, and such as few have ever seen the like. His size was very great; whilst his enormous tusks added a formidable ferociousness to his appearance, which I shall never forget.”

Strutt thus mentions the wild boar in the days of Edward the Second:—

“Master John Gyfford and William Twety, that were with King Edward the Second, composed a book on the craft of hunting, the which book is now preserved in the Cottonian Library.
Part of it is in verse; it runs thus, with no
inapt admonition against a life of idleness:

"All such dysport as voydeth ydlenesse
It sitteth every gentleman to knowe,
For myrth annexed is to gentlenesse.

And for to sette yonge hunters in the way
Of Venery, I cast me fyrste to goe
Of which foure beastes be—that is to say,
The Hare, the Herte, the Wulf, the Boar also.
And thre ben other bestis five of chase
The Buck the first, the seconde the Do,
The Fox the thyrde, which oft hath graçe,
The forthe the Martyn, and the last the Roe.'

"The boor," say the authors of the book
referred to, "is first a pig as long as he is with
his damme; and when the damme leyeth
him, then he is a goryeant; and in the thirde
yeare he is called an hoggaat; and when they
be foure yeares of age, they shall depart from
the sounde for aye; and when he goeth sole,
then he is called a boor.'

At what precise period the wild boar became
extinct in our island cannot be exactly deter-
mined; it is evident, however, that as popula-
tion increased, and the vast woods which
spread over many parts of the country were
cut down and the land cleared, that the range
of the boar would become more and more
limited, and its numbers decrease, till at
length its extirpation would be complete. We
look in vain for the forest which, in the twelfth
century, covered the country to the north of
London; and of which Fitzstephen, in the reign
of Henry II., writes, observing that, "on the
north are corn-fields and delightful meadows,
intermixed with pleasant streams, on which
stands many a mill, whose clack is so grateful
to the ear; beyond them an immense forest
extends itself, beautified with woods and groves,
and full of the lairs and coverts of beast and
game, stags, bucks, boars, and wild bulls."

Banished, however, as the wild boar is from
among our native mammalia, "its name is
immortalised," as Mr. Bell observes, "by
having given origin to the appellation of many
places in different parts of the country, and
by its introduction into the armorial bearings
of many distinguished families of every division
of the kingdom."

The special haunts of the wild boar in ancient
times, are distinguished by such still-existing
names as "Wild Boar's Fell," in Cumberland;

"Barlow," or "Boar's Field," Byro Hills,
formerly "Boar's Hills," near St. Andrew's,
in Scotland; Muskros, near Killarney, in the
county of Kerry, in Ireland; and Mucross, in
Fifeshire, Scotland—meaning literally, "Boar's
Promontory." This last designation origi-
nated in commemoration of the slaughter
of an enormous boar, which had previously
committed terrible ravages throughout the
surrounding country. "The village of Brance-
peth," says Mr. Bell, in his History of British
Quadrupeds, "and the adjoining hill of Bran-
don, in the county of Durham, took their names
from a wild boar or brown, which is recorded
to have been a terrific beast, and the dread
of the whole neighbourhood; his den being
on Brandon (brown's den) hill, and his usual
path or tract leading through the woods of
Brancebeth (brown's path). Tradition states,
that one Roger Hodge, or Hoode, valiantly
slew the monster, and delivered the district
from his ravages. The seal of this illustrious
Roger still remains, and represents a boar
passant."

Fitzstephen, who wrote in the latter part of
the twelfth century, states that boars, wolves,
wolves, and other game, abound in the
great forests surrounding London; and Scot-
tish writers have not failed to mention those
of

"Caledonia, stern and wild."

And it is known, that so recently as the date
of Charles I., that monarch endeavoured to
introduce the wild boar to the New Forest,
Hampshire. They were, however, all destroyed
during the time of the civil wars.

Formerly the boar's head was held as a
trophy of victory won in single combat between
the hunter and the enraged beast. Woe to
the former, if, either from want of skill or
weakness of nerve, he missed his aim. The
attack of the roused animal, like that of the
Spanish bull in the arena, was both sudden
and impetuous, ripping up with its formidable
tasks whatever came in his way, whether man
or horse! Shakspeare's description of an en-
raged boar is as true as it is graphic.

"On his bow-back he hath a battle set,
Of bristly pikes that ever threat his foes;
His eyes like glowworms shine when he doth fret;
His snout digs sepulchres where'er he goes.
Being moved, he strikes whate'er is in his way,
And whom he strikes his cruel tusks stay."
PIGS,

The genus *Sus*, as at present constituted, contains, besides the common wild hog and its domestic relatives, two other species known to naturalists. Of these, one is the Papuan hog, or Bêne of the natives of New Guinea (*Sus Papuensis*), figured and described in the *Zoologie de la Coquille*, by MM. Lesson and Garnot. It is remarkable for its small size, its light and agreeable proportions, and the shortness of the tusks. It is common in the forests of New Guinea, where it is esteemed by the native Papuans as delicate food, and who contrive to catch these animals when young, and rear them in a state of domestication. The other animal is the Wood-swine of Southern and Eastern Africa, and of Madagascar—the Bosch-Vark of the Dutch colonists of the Cape (*Sus livratus*, Cuv.). This savage and formidable brute resembles the wild boar of Europe; but its head is larger in proportion, its snout broader, and an elevated callous protuberance is sent on the cheeks between the tusks and eyes, imparting a revolting aspect to the physiognomy. Prompt and vicious, the Bosch-Vark is much to be dreaded in combat, its strength and the size of its tusks rendering it a match for almost any foe. It dwells in excavations in the ground, where it is dangerous to attack it, as it suddenly rushes out from its retreat, and deals rapid destruction among its assailants. Dr. Smith observes that this species is subject to great variety of colouring, scarcely any two specimens being precisely alike. Some are of a brownish black, variegated with white; and others are of an almost uniform light reddish brown, or rufous without white markings; and it is scarcely possible to say which is the most prevailing style of colouring. The bristles are long, particularly upon the upper parts of the neck and back; the canines are of huge size and strength; the ears are short, and thinly covered, both without and within, with coarse black hair, which is longest at their tips. The tail is thinly covered with black bristles. Average length of body, between four and five feet; of the tail, one foot.

The discovery of the bones of an extinct hog, of huge size, in the cavern of Sundwick in Westphalia, is due to M. Goldfuss. Bones of three distinct species occur in the Epplensheim sand (Miocene division of tertiary deposits, Lyell); and fossil relics of a species have been found in Hutton Cave, in Mendip, and in other places. Several species of an extinct genus (*Charropotamus*), closely allied to the hog, have been discovered in the gypsum of Montmartre, in certain strata in Switzerland, and in the Eocene formation of the Isle of Wight.

---

CHAPTER II.

THE DOMESTIC HOG, AND FOREIGN VARIETIES.

The domestic hog is too well known to require particular description, and its utility too well appreciated to call for comment. It is not, however, valued alike in all countries; and in some it is regarded with abhorrence. In India, both Brahmin and Mussulman reject its flesh as food; yet, in many districts of that country, semi-domesticated hogs wander about the villages, feeding on the refuse which they pick up in the streets. Colonel Sykes states, that in Dukhun, "every village abounds with hogs; but any property in them is equally abjured by individuals and the community." Detestation of the hog was a feeling entertained by certain nations in remote antiquity. The animal was classed by the Jews among the vilest of quadrupeds; and in Egypt the swineherd was numbered among the profane, and forbidden to enter the temples of their gods. Even the lowest dregs of the people refused to bestow their daughter on him in marriage. The Egyptians sacrificed the hog
to Baechus, and also to the moon when full. "In the evening of the festival of Baechus," says Herodotus, "though everyone be obliged to kill a hog before the door of his house, yet he immediately restores the carcass to the swineherd that sold him." - The ancient Sey-
thians, according to the same authority, made no use of swine, nor suffered any to be kept in the country. The Abyssinians and the Copts of Egypt, as well as the Mohammedans, reject the flesh of the hog. Among the ancient Greeks and Romans, though the office of swineherd appears to have been held in contempt, the flesh of the hog was in high estimation, and a sucking pig was as favourite a dish with them as it is with many of our own countrymen at the present day. The Chinese have derived no prejudices against the hog from the Mohammedan nations of the East: on the contrary, they rear these animals in great numbers for the sake of their flesh; and even the numerous population, who tenant the floating town of rafts or barges, contrive to keep and rear them. "One of the most sin-
gular circumstances," says Mr. Wilson, in the Quarterly Journal of Agriculture, "in the domestic history of this animal, is the immense extent of its distribution, more especially in far-removed and insulated spots inhabited by semi-barbarians, where the wild species is entirely unknown. For example, the South Sea Islanders, on their discovery by Europeans, were found to be well stocked with a small black-legged hog; and the traditionary belief of the people, in regard to the original introduction of these animals, showed that they were supposed to be as anciently descended as themselves. Yet the latter had no knowledge of the wild boar, or any other animal of the hog kind, from which the domestic breed might be supposed to be derived."

The domestic hog is by no means destitute of intelligence, and little deserves the character of a stupid filthy brute, as some are pleased to give it. As regards filthiness, this, in a great measure, depends on its keeper. It is true that, like the elephant and hippopotamus, it delights to wallow in the mire; but no animal more luxuriates in clean straw; and when it is styed up in filth, justice is not done to it. The hog is a "huge feeder," but so are the horse and ox; and a fat hog is a more comely-looking beast than one that is lean and ill-fed. With respect to intelligence, it may be ranked far before the ox and horse, though it is less docile. In Minorca it is used to draw the plough, and works well; and Pennant says, that in the district of Murray, between the Spey and Elin, in Scotland, it was formerly employed for the same purpose; and that a credible eye-witness informed him, "that he had seen, in his parish there, a cow, a sow, and two young horses, yoked together, and drawing a plough in light sandy soil, and that the sow was the best drawer of the four.

The senses of taste, smell, and hearing are possessed in great perfection by the hog. It is a saying among a certain class of persons, that pigs can smell the wind; and they are certainly aware of the approach of a storm, as they have often been seen in a state of great agitation during its continuance, screaming, and running about with straw in their mouths, or carrying it to their sty as if to add to their shelter. In Italy, advantage is said to be taken of the sense of smell with which this animal is endowed in searching for truffles; and in our own country, the famous sow Slut, of which we have spoken in a preceding division of this work, was broke-in to the gun, and stood to her game as staunch as the best pointer. But it is now time to speak of some of the continental varieties of this animal, before noticing the British breeds.

Perhaps the most important is——

THE WESTPHALIAN BREED.

The hams of this species have, in this country, become greatly celebrated, from the peculiar excellence of their flavour; and, on this account, large numbers of them are imported from Germany. The animal which supplies these is closely allied to the wild boar of his native country, and, like him, roams the forest in search of food, which principally consists of acorns and beech-malt, to which they are extremely partial, and which gives a favourable development to their flesh. After they have fattened themselves upon this, they are driven home to be slaughtered. In former ages, in Britain, the acorn was the principal food of the hog, as its flesh then formed a large proportion of the diet of the people, who esteemed the increase or multiplication of these animals

750
as a necessity to their comfort and happiness, if not absolutely to their existence. Even at the present day, the hogs of Spanish Extremadura are mostly reared on the acorns of the Ballota oak. In the Westphalian species, the colour of the adult varies. Many are so coloured, that, were it not for their superior condition and less bristly appearance, it would not be an easy matter to point out any striking difference between them and their feral relatives; but in every case, whatever may be the hue of the parents, the young are, at birth, and for some months afterwards, marked with the longitudinal bands so characteristic of their wild blood. In several parts of England, especially in the New Forest, herds of swine are permitted to roam at large during the acorn season, and, when driven home, are said to be in prime condition. From this circumstance it may readily be inferred how valuable were the oak forests of our forefathers to their very subsistence, by enabling them to feed and fatten their swine. Indeed, one of the most oppressive measures of William the Conqueror, was that by which he converted the English forests into hunting-grounds, and thereby deprived the people of the means of rearing their hogs to a good condition. It was felt to be such a grievance, that King John was called upon to remit it at Runnymede, when, on June 19th, 1215, he was, by his assembled subjects, forced to sign Magna Charta. Swine, like some other animals, seem naturally disposed to return to their feral condition, should an opportunity offer, and the circumstances be favourable to their feeding. Mowbray tells us, that two young boars, retiring into a wood between Colchester and Mersey Island, continued, for years, to be the terror of the neighbourhood. The Westphalian swine are seldom over-fat; but they are not on that account to be deemed difficult to fatten. On the contrary, they take on fat with great readiness, and attain to an enormous weight.

THE NEapolitan BREED.

The colour of the Neapolitan breed is black, with little hair on their bodies, and no bristles whatever. Their flesh has a very delicate flavour, the fat being entirely destitute of that rankness which characterises that of some other varieties. Most of the native English breeds may be improved by a cross with the Neapolitan. Indeed, by far the larger portion of the middle breed of pigs, in all the counties of England, manifest some relationship to it by the existence of blue spots on different parts of the body. Mr. Rowlandson, the author of the Prize Essay of the Royal Agricultural Society of England, on the Management of Pigs, endeavours to prove that the Neapolitan is the original breed of pigs; and even urges that the Essex, or rather the improved Essex breed, is due to that race, of which he says it is an improvement; but Mr. Milburn thinks that the Italian climate, operating on the wild bear domesticated, as well as that of China, softened down the asperity of activity and bristles, and made the soft delicate animal we now see, in the shape of the one or the other of these varieties.

"With the true Berkshire breed," he continues, "the Neapolitan produces a cross, to be surpassed by none in every desirable quality that the breeder could look for, more especially if a dash of the white Chinese be added. The inter-mixture of these three breeds—the Neapolitan, Chinese, and Berkshire—may be regarded, if done judiciously, as the ne plus ultra of swine-breeding. Thus was produced that long-celebrated breed kept by Lord Harborough. After having been a short time in this country, the Neapolitan hog begins to lose his naked appearance, and to acquire a coat better suited to the more chilly climate into which he has been introduced."

THE FRENCH BREEDS.

It is believed that the French breeds have some relationship to the Chinese variety of the hog, as the breeders of that nation have been long acquainted with the valuable qualities of the variety which claims the celestial empire for its original habitat. The most distinguished of these breeds are those of Poitou, the Pays d'Auge, Perigord, Champagne, and Bologna. In describing these, it may be observed that the Poitou breed has a long and somewhat large head, with pendulous and rather coarse ears—an elongated body, broad and strong feet, and large bones, with coarse bristles and hair. That of the Pays d'Auge has a sharp muzzle, and a smaller head, narrow and pointed ears, long body,
broad and strong limbs, but small bone. Its hair is also coarse, but scanty in quantity, and of a white colour. The Perigord are generally black, with a very short thick neck, and a broad compact carcass. The swine of Champagne are of considerable size, long-bodied, and flat-sided, with broad pendulous ears, and not favourably looked upon. Those of Bologna are related to the English breeds. They are of a large size, have a large and broad ear, are quick fatteners, and white in colour. It is to these that we are indebted for the celebrated Bologna sausages.

The following extract from the Annales d'Agriculture Francaise, presents us with the unsuccessful trials of a breeder to improve his stock:—"I commenced," he says, "with the large Shropshire pigs. They pleased my eye, and, for some little time, I felt perfectly satisfied. In a short time, however, I began to observe that, although they devoured an immense quantity of food, they fattened but very slowly, and seemed to derive no advantage from the herbage and vegetables which they found in the fields. When killed, the flesh, and especially the fat, was exceedingly coarse. The sows, nevertheless, produced many pigs at each farrow, which, from their size when young, sold well to persons who were tolerably rich, and knew little or nothing about the breeding of pigs. I next tried the small Berkshire pigs, and immediately perceived a very sensible improvement. They fattened quickly, procured most of their nourishment from the fields, and their flesh was very superior to that of the last-named breed. But as they were large, I thought to effect a still greater improvement by exchanging them for the Chinese; but here I fell into the opposite extreme. The Chinese were prolific, fattened speedily, and almost obtained their own subsistence; but they were faulty in form, and their flesh was not firm, but loose in fibre, as if they had died of disease." Jutland swine are long-bodied, curve-backed, long-legged, with large pendulous ears; and they attain a very great size. They, however, are of a coarse make, and heavy-boned. Sweden possesses many different breeds, the favourite being a supposed off-shoot from the wild boar, with erect cars, a turned-up snout, and long, bony legs. The hogs of Russia and Poland are small, but they are hard feeders. Their colour is that of a reddish yellow, and their hair is very rough. The Hungarian pigs are of a grey colour, with straight, pointed ears, short body, and short and firm legs. These are very rough in the coat, and the young are marked with longitudinal bands—two circumstances indicative of a connection, and that by no means remote, with the wild boar. They inhabit Turkey in Europe, Bosnia, Croatia, Hungary, and Austria, and are designated according to the country from which the specimen immediately in question may have been procured. In reference to the Portuguese hog, it is so extremely like the Chinese, that it has, by Mr. Lawrence, been made a question whether these varieties are not identical; the former being but the latter naturalised in that of Portugal.

THE CHINESE BREED.

The Chinese hog is found in the south-eastern countries of Asia, as Siam, Cochinchina, the territories of the Birman empire, the kingdom of Cambodia, Malacca, Sumatra, and in Batavia, and other islands of the Eastern Archipelago. There are also varieties in India and China.

The principal point of difference between the hog of Siam and that of China Proper, is, that the former is usually black, whilst the latter is of a white colour. Neither, however, exhibit a constant uniformity in this respect, the colours of each frequently varying—the blacks coming from China, and the whites from Siam. Even in the same litter, pigs of different colours frequently appear; and instances are not uncommon in which even pied individuals have occurred. On account of these differences of colour, some have gone so far as to assert that there are no fewer than seven varieties of the Chinese pig; but, as the distinctions are referred only to colour, these varieties can hardly be said to have more than a hypothetical existence. The small white breed is almost perfect in make and quality. Parkinson says—"These are certainly pigs in miniature; their legs about two or two-and-a-half inches long; their ears, the size of a large leaf on an apple-tree; the length of the jaw, from the snout end to the crown, about six inches; from the crown to where the tail is set on, about two feet; with height proportionate;
weight, when full-grown and fat, six stones, at two years old." The black variety is of similar shape and beauty, and, when fat, is of a heavier weight. Both the Chinese and Siamese pigs feed well, and attain to an early maturity. They require less food, and, within a given time, become fatter and heavier than any of the European varieties. To the flesh of the pig the Chinese are remarkably partial, and they fatten it to an enormous extent, taking great care that the animals which yield it are thoroughly attended to, and fed regularly. Those which are kept in temples become perfect monsters, and are viewed by the Chinese with an eye of great tenderness and partiality. They are not even permitted to distress themselves with walking, but are often carried from one place to another, to which may be attributed the admirable qualities of their pork. The animals are kept especially dry and clean, which, no doubt, has a corresponding effect upon their health; and the very knowledge of which has a tendency to impart a greater relish to their flesh when it is brought to the table. Those which are generally seen in this country, principally come from the neighbourhood of Canton, and have been brought thence as part of sea-stock. They have greatly improved the larger kinds of our English pigs, having been advantageously crossed with our own coarser domestic breeds. The offspring of this cross have shown a vast improvement even in their Chinese progenitor; and, on the whole, proved a most profitable breed.

The Chinese pigs are less known in Ireland than in England or Scotland; although the climate of the last-named country would appear unsuitable to their Asiatic temperament and constitution, probably from the variableness of its temperature.

CHAPTER III.

BRITISH BREEDS OF THE DOMESTIC HOG.

We have, in a previous chapter, alluded to the fact of the hog being of great importance to our Saxon ancestors. Its flesh was a staple article of consumption in every household; and a great portion of the wealth of the farmers and landed proprietors consisted of droves of swine, which were attended by swineherds, thralls, or bond-servants, and which were driven into the woods of oak and beech, in order to feed on acorns and mast, and all the while guarded from the attacks of the wolf. The domestic hog of that period, appears to have closely resembled, in form and colour, the wild species; and the old unimproved breed, now seldom seen, may be regarded as its modern representative. There are now, in our island, several breeds of this useful animal, of acknowledged excellence, the result of judicious crossings. The test of excellence is productibility, a readiness to become fat, small bone, and the quality of the whole animal when converted into bacon. Size is of minor importance. The introduction of the small Chinese breed is one great source of improvement. This breed, we have said, is short in the head, with neat ears, low on the limbs, and high in the chine. It is very prolific, and fattens readily. The prevailing colours are black, or half black and half white. Another, closely allied to it, extends from China throughout various groups of islands in the Pacific. The breed nearest to the Chinese, in this country, is the Suffolk, which is generally white, compactly made, and deep in the chest.

Another source of improvement is the Neapolitan hog. This, as already described, is a plump animal of a black colour, without any hair, and with a singular predisposition to become fat. It is, however, of a tender constitution. The pure black breed of Essex, which has very little hair, is closely allied to it; and when crossed with the Neapolitan,
produces a most valuable stock. A cross between the Neapolitan and Berkshire breed is also in high esteem. A breed between the Berkshire, Chinese, and Neapolitan, now, by careful selection, produce every quality which can be desired—great fecundity, an early acquisition of fat, and moderate size, with admirable form and proportions. Mr. Cully asserts, that there are, in this country, only three true varieties of the domesticated hog—the Berkshire, the Chinese, and the Highland, or Irish; and that all other breeds, although they have a separate description, are nothing more than off-shoots from one or other of these three main stocks. In some degree this may be true; but these themselves, must, at the same time, be regarded as only off-shoots from the great original wild stock. To distinguish these, therefore, as the primitive breeds to which we are indebted for all the other breeds now grown in Britain, is to give them a distinction which can hardly be said to belong to them. Indeed, the fact of the matter is, that we are not only indebted to these breeds for the numerous varieties amongst us, but to the Spanish, Portuguese, Italian, and African hogs, as well as to the wild boar of the large forests of Europe.

THE BERKSHIRE HOG.

Berkshire was the first county to avail itself of the opportunity of improvement afforded by the introduction of foreign stock; and among the black breeds, the improved Berkshire stands at the top of the list, either for breeding pure, or crossing with other breeds of inferior qualities. The old breed is said to be now extinct; but, for a long period, it had a high reputation, and held a prominent place among breeders or reapers of swine. The improved Berkshires are almost all traced back to the herd of Lord Barrington, who died in 1829. In Mr. Youatt's treatise on the pig, we find it remarked, that the improved race is now considered, by the Berkshire farmers, to have deviated into a middle-sized and a small-sized breed. To rank in the first class, they should be well covered with long, black, silky hair; whilst the white should have only four white feet, a white spot between the eyes, and a few white hairs behind each shoulder.

The old race of Berkshires had a long and crooked snout, with the muzzle taking an upward turn; the ears were large and heavy, with a slight inclination to be pendulous; the body was not deep, but long and thick; whilst the legs were short, the bone large, and the size enormous. The modern improved Berkshire is an animal of large size, which, to be fully developed, should not be allowed to breed until it is over a year old. Mr. Sadler, one of the most successful improvers of Berkshires, considers the improved breed superior to any other black breed for size, quality, hardness of constitution, fruitfulness, early maturity, and aptitude to fatten. The Rev. T. C. James, one of the judges of pigs at the Royal Agricultural Society's show at Warwick, in 1850, says, that "the improved Berkshire is a good big animal, well calculated to produce a profitable fitch. A good little pig is very well, but a good big pig is better, if with aptitude to fatten. Two exhibited at Chelmsford, in 1856 (of Sadler's breed), weighed each twelve score at seven months old; and, with that weight, were of such good constitution, that they were well upon their legs. They had walking exercise in an orchard every day while fattening." The Mr. Sadler alluded to in this passage, resides at Bentham, near Crickdale, and is one of the most successful improvers of Berkshires: his original stock all came from the herd of Lord Barrington. Speaking of the Berkshire breed, Mr. Loudon says, "that they are, in general, of a tawny, white, or reddish colour, spotted with black; large ears hanging over the eyes; thick, close, and well-made in the body; short legs; small in the bone, with a disposition quickly to fatten, and, when well fed, producing fine flesh. This county has long been famous for its breed of swine, which are excellent in all respects, but particularly so as a cross for heavy, slow-feeding sorts. It has extended itself from the district from which it takes its name, over most parts of the island; is the sort mostly fattened at the distilleries; feeds to a great weight; is good either for pork or bacon; and is supposed by many to be the most hardy, both in respect to its nature and the food on which it is fed." Mr. Bakewell, the founder of the new Leicester sheep, was a great improver of domestic swine.

"Before his time," says Mr. Martin, "the
Leicestershire hogs were of the same coarse, ungainly kind, which prevailed generally throughout the midland counties. He commenced, as he had done with the sheep, by a judicious selection of stock destined for breeding; and, by persevering in this course, he greatly modified the characters of the old races. This was imitated in Yorkshire. The old breed, by crossings with the new Leicester stock, was much improved. The cross breed lost in size, but gained in every other good quality. It became deep-chested, short-limbed, small-boned, and fattened readily. The coarse ugly bristles were exchanged for fine thin hair, and the whole aspect of the animal underwent a transformation. The hogs, at about two years old, averaged from thirty to fifty, and even sixty stones, of 14 lbs.; the younger animals weighing in proportion."

Some of the Yorkshire breeders still rear the pure new Leicesters, and consider them more profitable than the larger kinds. These breeds have also found friends in Yorkshire; and among these, are the Berkshire crosses with the old Yorkshire, and with Lord Western's improved Essex breed. The improved Berkshires are classed among large swine; but the effect of crossing with various smaller breeds, has been to reduce the size and improve the shape; so that the present Berkshires are short of limb, roundly made, arched in the neck, with heavy cheeks, sharp ears, and abruptly rising forehead, short snout, broad back, and clean limbs. In colour they are usually a mixture of half white, half black. The average weight of an improved Berkshire hog, fit to kill, is about 400 lbs.; but ham-curers purchasing them from the farmers, give a preference to the smaller breed, which averages from nine to fourteen score.

**The Hampshire Hog**

This hog is about the same size as the Berkshire; but as less attention has been paid to its improvement, it possesses a degree of coarseness to which the other is a stranger. It is generally black, or spotted with red; but there are, also, a considerable number of white pigs in this county. Within the last twenty years a great improvement has been produced in their make, which may be considered to have been forced upon the breeder, on account of his being so near a good market where improved animals could meet with ready disposal. No Hampshire farmer, however, has distinguished himself as a pig-breeder; and we do not remember an instance of Hampshire pigs carrying away any of the prizes at the Smithfield show. From these facts we may draw the conclusion, that although the county is productive of excellent hogs, still these are not such as would be chosen to establish a new, or improve an old breed. The New Forest of Hampshire was long notable for the numbers of swine which fed upon the acorns that fell from its oaks. Even so recently as the time of the Rev. Mr. Gilpin, we find him describing, in his Remarks on Forest Scenery, the manner in which the swine were suffered to range themselves as they wandered beneath the umbrageous trees, which were the means of both sheltering and nourishing them:—"These woods afford excellent feeding for hogs, which are led in the autumn season into many parts of the forest, but especially among the oaks and beeches of Boldre-wood, to fatten on mast. It is one of the rights of the forest borderers to feed their hogs in the forest during the pawning month, as it is termed, which commences about the end of September, and lasts six weeks. For this privilege they pay a trifling acknowledgment at the steward's court at Lyndhurst. The word pawnage was the old term for the money thus collected. The method of treating hogs at this season of migration, and of reducing a large herd of those unmanageable brutes to perfect obedience and good government, is curious. The first step the swineherd takes is to investigate some close-sheltered part of the forest, where there is a conveniency of water, and plenty of oak or beech mast, the former of which he prefers, when he can have it in abundance. He fixes next on some spreading tree, round the bowl of which he wattles a slight circular fence of the dimensions he wants; and covering it roughiy with boughs and sods, he fills it plentifully with straw or fern. Having made this preparation, he collects his colony among the farmers, with whom he commonly agrees for a shilling a-head, and will get together perhaps a herd of five or six hundred hogs. Having driven them to their destined habitation, he gives them a plentiful supper of
acorns or beech-mast, which he had already provided; sounding his horn during the repast. He then turns them into the litter, where, after a long journey and a hearty meal, they sleep comfortably. The next morning he lets them look a little around, and shows them the pool or stream where they may occasionally drink; then leaves them to pick the offal of the last night's meal; and, as evening draws on, gives another plentiful repast, scattering acorns among them for an hour together, to the sound of his horn. He now sends them again to sleep. The following day he is perhaps at the pains of procuring them another meal, with music playing as usual; and then leaves them a little more to themselves, having an eye, however, to their evening hours. But as their stomachs are full, they seldom wander far from home, retiring generally very early to bed. After this he throws the sty open, and leaves them to cat for themselves; and from henceforward has little more trouble with them during the whole time of their migration. Now and then, in calm weather, when acorns fall sparingly, he calls them perhaps together, by the music of his horn, to a gratuitous meal; but in general they need little attention, returning regularly home at night, though they often wander, in the day, two or three miles from their sty. There are experienced leaders in all herds, which have spent the roving life before, and can instruct their juniors in the method of it. By this management the herd is carried home to their respective owners in such condition that a little dry meal will soon fatten them. The hog is commonly supposed to be an obstinate, headstrong, unmanageable brute. He may, perhaps, have a degree of positiveness in his temper; in general, however, if properly managed, he is an orderly, docile animal. The only difficulty is to make your wishes, when they are fair and friendly, intelligible to him. Effect this, and you may lead him with a straw.

"Nor is he without his social feelings, when he is at liberty to indulge them. In these forest migrations, it is commonly observed, that of whatever number the herd consists, they generally separate, in their daily excursions, into such little knots and societies as have formerly had habits of intimacy together; and in these friendly groups they range the forest, returning home at night in different parties, some earlier and some later, as they have been more or less fortunate in the pursuits of the day. It sounds oddly to affix the life of a hog to be enviable; and yet there is something uncommonly pleasing in the lives of these emigrants—something at least more desirable than is to be found in a hog Epicerus de grege. They seem themselves, also, to enjoy their moro of life. The hog has a greater variety of language than, perhaps, any other quadruped. He signifies his want of food with great energy; when affronted, his note is very significant; and his cries of distress are truly lamentable. But here you see him perfectly happy, going about at his ease, and conversing with his friends in short, pithy, interrupted sentences, which are, no doubt, expressive of his enjoy-ments and of his social feelings. Besides the hogs thus led out in the mast season to fatten, there are others, the property of forest-keepers, which spend the whole year in such societies. After the mast season is over, the indigenous forest-hog depends chiefly for his livelihood on the roots of fern; and he would find this food very nourishing if he could have it in abundance. But he is obliged to procure it by so laborious an operation, that his meals are rarely accompanied with satiety. He continues, how-ever, by great industry, to obtain a tolerable subsistence through the winter, except in frosty weather, when the ground resists his delving snout; he must then perish if he do not, in some degree, experience his master's care. As spring advances, fresh grasses, and salads of different kinds, add a variety to his bill of fare; and, as summer comes on, he finds juicy berries and grateful seeds, on which he lives plentifully, till autumn returns and brings with it the extreme of abundance. Besides these stationary hogs, there are others, which, in some of the more desolate parts of the forest, are bred wild, and left to themselves without any settled habitation; and, as their owners are at no expense, either in feeding or attending them, they are content with the precarious profit of such as they are able to reclaim."

This kind of feeding has brought the Hampshire bacon much into demand; and it brings even a higher price than the Westphalian. This is, in some measure, to be attributed to the manner in which it is cured, and which
has been greatly the means of preserving its high reputation.

THE SUFFOLK HOG.

Mr. Richardson, with some other writers, thinks that the Suffolk hog is the most nearly allied to the Chinese; and Mr. London describes it as a small, delicate, white pig, which, for many years, has enjoyed a great reputation. It is shorter, he says, and more pugnacious than the Norfolks; and, by its dish-face and pendent belly, it may be supposed that the variety proceeded originally from the white Chinese. Some of them are extremely handsome, and very regularly shaped. Others have observed, that the Suffolk is the best bred race in England; but whether such be the case or not, is a matter of opinion. "The present breed of Suffolk," says Mr. Richardson, "or, at least, that which existed in that county within the last few years, is a long, straight-backed pig, with a broad forehead, and short, bristly hair; appearing large and heavy from its extreme length." Prince Albert was very successful with a cross of the Suffolk and Bedford.

The improvement in the Suffolk breed consists in small and light offals, with greater length being obtained. It is a white pig, and, on several occasions, has figured popularly in the Smithfield Club Show; but the most celebrated pigs are quite black. Mr. Crisp, of Butly Abbey, a distinguished Suffolk breeder, reared both black and white pigs. The best Suffolks now, however, are Yorkshire-Cumbrians, which have settled in the county, and have found their way to Windsor.

THE YORKSHIRE HOG.

The old Yorkshire pig was a large, narrow animal, having a strong coat of white hair, and a few pale-blue spots on the skin, the hair on these being white. It was long-headed, great-eared, long-legged, and strong in the bone. A long period elapsed before it attained its full growth, when it could be fattened up to 600 lbs.; but it is doubtful if this could be done with profit. The first step taken for the improvement of this breed, was the introduction of the white Leicesters to Yorkshire. These were a large species; but their heads were smaller than the old sort; their ears erect; their hair finer; their bone smaller, but with a carcase less deep, and not so full in flesh. The white Leicesters were the great improvers of the Yorkshire large breed, which is now principally confined to the northern part of the county. On the introduction of the Leicesters, in the early part of the present century, they were carefully bred from until several admirable qualities were obtained—viz., early maturity, beautiful proportion, and a constant fatness, even from the time of their birth. The difficulty with this breed is, how to keep them poor, as the sows have enough to breed and suckle their offspring. This species is denominated the small breed; and the spinners and artisans of the large towns, more particularly those of Bradford and Leeds, discover great skill in breeding them. In a new edition of Mr. Youatt's work, we find it stated, that in the West Riding, the competition in pigs is keener than in any other part of England. There is scarcely a town which has not its pig and poultry show, where prizes are presented for pigs reared by working-men, with rules that entirely exclude shopkeepers and small tradesmen. The breed of these competitors is usually of the large or middle-size; and the prizes contended for are—for the first, £4; second, £3; third, £2; fourth, £1. The Keighley Agricultural Association keep a van for conveying the pigs of the exhibitors to their shows; and the following details from Mr. Youatt's work, edited by Mr. Samuel Sydney, places, in a graphic point of view, the enthusiasm which pervades the minds of some of the small pig-breeding fanciers of Yorkshire. "One evening in August, 1858, a stout labouring woman left her home in Airedale, accompanied by her only sow and her litter of pigs, on a journey (by rail) of sixty-five miles, to the city of York, where the Yorkshire Agricultural Society held its show that year. She bore with her the white rosettes of several previous victories of her treasure, 'Lady Kate'; but on this occasion fortune did not smile on her, and 'Lady Kate' suffered her first defeat. Although, however, she did not win the prize, she carried the public pig-breeding opinion so far with her, that she was able to sell all 'Lady Kate's' suckers at £5 a-head. When, next month, the Keighley and Shipton shows arrived, 'Lady
Kate' retrieved her first and only defeat, and stood at the top of her class. Thirty-eight sovereigns had been counted down on the table for ‘Lady Kate.’ She afterwards reared a litter of sixteen, and enabled her owner to maintain an aged father and invalid sister in comparative comfort. She was, indeed, the prop of the house; and by the side of many a sty in Airedale, for years after her flesh had been consumed in bacon, were her merit and victories discussed in the long summer evenings consecrated to pig-gossip. ‘Lady Kate’ was of the middle breed; a cross between a small boar and a sow of the modern improved large breed.

At Northallerton, in 1859, the finest lot of large sows ever seen in one place were collected together. There were at least a dozen, the live weight of each of which would not be much less than half a ton. The Royal Agricultural prize-winner at Norwich only got second honours. When the two famous sows, ‘Lady Havelock’ and the ‘Duchess,’ went for the Chester prize, the partisans of each were confident of success, and the betting was hot and heavy. ‘Lady Havelock’ was in splendid condition, having been bought at a long price, and ‘bottled up’ specially for this event; while the ‘Duchess,’ from having weaned her little ones so lately, was not quite up to the mark, but was again in a breeding state, and it was thought that would have weight with the judges. It was, however, universally agreed that one of the two must win, for Yorkshire had never sent anything like them before. On Wednesday night it oozed out that the ‘Lady’ was the prize-winner. The telegraph was set in motion, and the morning trains brought in a motley crowd of the Leeds pig-fancy, with wives, aunts, and sisters, all bound to the Rhuodee, to celebrate the triumph. There the ‘missus’ of the ‘Lady,’ excited by the congratulations of her friends, gave her native Yorkshire eloquence full swing, and astonished the assembly with a speech, in which she complimented the judges; vowed that ‘Lady Havelock’ should lick all the world; whispered her Tom would never have bought the sow but for her, and announced that the prize money should be spent on the spot.” In Yorkshire, the prejudice against black pigs is now greatly modified.

THE CHESHIRE HOG.

The size of the Cheshire hog is very great; his proportions having been pronounced gigantic; but is now, however, almost extinct. He was long-legged, long-eared, and had a loose kind of unsightly skin. His colour was either white, patched black and white, or blue and white. The prevailing pigs, now mostly used in Cheshire, are what are termed “Manchester boars,” which is only another name for the Yorkshire-Cumberland breed.

THE WILTS HOG.

This hog is a long-bodied, low animal, hollow about the shoulder, and high on the rump, round in the bone, with middling-sized pointed ears, and of a light colour. It is supposed to have come originally from Wales, and was of comparatively little value; but since it has been crossed with the improved Berkshire breed, its worth has increased. Wiltshire bacon is celebrated, the reason of which may partly be attributed to the judicious crossing which has, from time to time, been practised with the Neapolitan, Chinese, and other improved breeds. These are not so large as the former breed; while they are more compact, and fatten quicker, without any deterioration to the quality of the meat.

THE BEDFORDSHIRE HOG.

Bedfordshire cannot boast of an original pig stock; but one bred at Woburn, and described by Mr. Youatt, was a good animal, although it had no specially-marked character worthy of notice. It was a bad smeller, but a good feeder. It has, however, been allowed to die out; and a race sprung from Berkshire sows crossed with Suffolks boars, has taken its place. At present a white breed is looked upon with the most favour in Bedfordshire. The late Duke of Bedford introduced the improved breed, and was the means of introducing them also to East Lothian in Scotland, where they carried off all the agricultural prizes. They have the peculiarity of growing very rapidly, and, at the same time, when mature, feeding very fast in proportion to the food given. The former breed was so little distinguished, that the tenant of a large farmer in the shire, said he was not aware that such a race had an
PIGS, [NORFOLK HOG, ETC.

existence, until he saw it notified over one of the pens of the late Prince Albert, about ten years ago, at the Smithfield Show.

THE LEICESTERSHIRE HOG.

The original hog of Leicestershire was a large, deep, flat-seated, light-spotted animal, possessed of rather a handsome head, with well-formed ears. Mr. Bakewell, however, by skilful crossing, not only improved the breeds of sheep and cattle, but also those of pigs. Accordingly, his Dishley pigs evinced consummate skill, as did his Leicester sheep. "With symmetrical form," says Mr. Richardson, "as far as rotundity, depth, and thickness could constitute it, he combined such great aptitude to fatten, that it has, with the Chinese and Neapolitan, been the source of almost all the improvements of our breeds of pigs; and a pig is just good 'blood' or bad in proportion as it is allied nearly or remotely to the Dishley breed. There was a little tenderness of constitution, but so much flesh and fat in proportion to time and offal, that it looked more like one great cylinder of flesh than a living animal—the feet, neck, and face being lost in the exuberance of fat. Owing to its lethargic disposition, and thoracic temperament, it is not a vigorous breeder, and much less prolific than many other kinds; neither will it grow so rapidly as some varieties, being more calculated to lay on fat than to make bone and muscle. Still it is a physiological wonder—a triumph of skill." The Leicesters have been crossed into middle, or small Yorkshires, and have been the grand improvers of the large York breed. Mr. J. V. Williams, of Haygrove, Bridgewater, Somerset, in 1854, exhibited a pair of white Leicesters, and received the gold medal of the Smithfield Club. Writing to Mr. Sydney, he says—"I first exhibited in 1852, and have since won, besides the Smithfield Club gold medal, two gold medals of the Paris Universal Exhibition in 1855, five silver medals and cross, and upwards of one hundred prizes." His fat pigs usually average the following weights:—

5 to 6 months old, from 7 to 9 score lbs.
8 " 10 " 12 " 13 "
10 " 12 " 15 "
12 " 15 " 18 "
The three pigs exhibited in 1854, at eighteen weeks, old, weighed, sinking the offal, nine score each.

THE HEREFORDSHIRE HOG.

Of this animal there is little to say; but it is commonly believed to be the result of a cross with the Shropshire. Mr. Richardson says it is little inferior to the Berkshire breed; and that it is to the adoption of crosses from the boars of Herefordshire and Berkshire, that we are to attribute the major part of the improvement which has, of late years, appeared among the Irish breeds. To the present white breed of this county no attention has been paid, although the sow is acknowledged to be a useful animal.

THE NORFOLK HOG.

The Norfolk breed is small, with pricked, erect ears; and variously coloured, but generally white. They are well-formed, fatten quickly, and produce good meat. Those that are white are said to be the best; but in the vicinity of Lynn, and generally on the Lincoln side of the county, there is a larger spotted variety, of good form and quality. We believe, however, that little or no attention has been paid to this variety.

THE GLOUCESTERSHIRE HOG.

The hog of Gloucester is less in size than the Hampshire breed; still it is of sufficient proportions to be ranked among the larger breeds. It is round in form, somewhat short for its depth in the belly, and altogether presenting a very compact appearance. It is generally white, and has—what may be either an ornament or a disfiguration—wattles hanging from each jaw. Its constitution is hardy; the sows are prolific, and the pigs are very profitable, more particularly for pork. As store pigs they are excellent.

THE NORTHAMPTONSHIRE HOG.

This animal is considered handsome, being very compactly formed, steep-sided, and having little bone. It feeds well, attains early to maturity, and fattens rapidly. For storing or pork it is excellent. It is of a light colour.

THE LINCOLNSHIRE HOG.

The old Lincolnshire breed was a light-
coloured, long-legged, ungainly-looking animal, with a narrow back and a thick skin, covered with close, coarse hair. The head was large, and the forehead being ample, the ears were necessarily placed far apart. It was an enormous eater, and a very indifferent fatterer. The true Lincolnshire is now a very different animal from this, having a straight body, round carcass, fine skin, and few bristles. It is generally white, and is easily fattened. At a year and a-half old it will often weigh twenty-five and even thirty stones, giving 15 lbs. to the stone.

THE SHROPSHIRE HOG.

The original breed of this county has been improved by a cross with the Berkshire, Chinese, and other favourite breeds. The former breed was not very well adapted for farm stock; but by brewers and distillers, who have large quantities of refuse grains and mash, they were held in some degree of estimation.

THE CUMBERLAND HOG.

Little has been done towards the improvement of the large Cumberland breed; but the small breed of this county has risen into considerable favour. It is larger than the small Yorkshire, and is the offspring of a cross between the Cumberland and the Yorkshire; the former giving quality and proportion, and the latter affording size. The bacon of this county has attained great celebrity in the north of England. The breed is described as being short in the legs, with a straight and broad back, well-developed ribs, full neck and breast, and good hams. The snout is short; the ears clean, fine, and of moderate size; whilst the body is evenly covered with short, fine hair.

THE SUSSEX HOG.

The hogs of this county are of moderate size, well-formed, thin-skinned, and black and white. The hair upon them is both long and fine. They rarely feed over twenty stones; but they attain an early maturity, fatten quickly, and produce excellent flesh. In this county there was formerly a breed called the Rudgwick swine, among which were some of the largest hogs ever seen in England. Although they yielded capital meat, they were considered very unprofitable, from the time which they took to fatten. They are now extinct.

THE ORIGINAL OLD ENGLISH HOG.

The primitive breeds of England have now almost lost all traces of their individuality, from the different systems of crossing to which they have been subjected, by the spirit of improvement which has possessed many of the breeders of agricultural stock. It may be a question, however, whether this has not been already carried too far. Mr. Low observes—"While we should improve the larger breeds that are left us, by every means in our power, we ought to take care that we do not sacrifice them altogether. We should remember that an ample supply of pork is of immense importance to the support of the inhabitants of this country. England may, one day, have cause to regret that this over-refinement has been practised, and future improvers vainly exert themselves to recover those fine old races which the present breeders seem aiming to efface." The original English breed had a heavy head, a large ear, long legs, and ragged coat, and had by far too much bone to be a profitable animal.

THE ESSEX HOG.

Essex, like other counties, has improved its breed of pigs, by crossing with the Berkshire and Neapolitan races. The original animal, however, possessed some good points; but as improvement seemed necessary, a new breed appeared, and now takes a high place among the different species of Great Britain. The present race has erect ears, a long, sharp head, a short flat back, with small bone. The colour almost invariably is white. It is a rapid feeder, and makes fat so quickly, that before it has obtained its due proportions it usually attains an inconvenient state of obesity. So great, indeed, are its fattening properties, that it sometimes becomes the victim of them.

"One of the finest specimens of the improved Essex breed," says Mr. Richardson, "was reared by C. L. Clare, Esq., of Hindley House, near Liverpool. She won eight first prizes, two seconds, and one third; and several of her litters have been sold for £120. The peculiarities of Mr. Clare's improved breed, are small bone, great aptitude to fatten, early

5 F
arrive at maturity, and a small proportion of loss between live weight and dead. A very favourable specimen of the whole, weighed alive, 688 lbs.; and dead, as much as 653 lbs. — a most unprecedented fact — her offal being but 30 lbs. She was shown at the Yorkshire Agricultural Society's meeting at York, with twenty-nine competitors; and though she did not receive a prize, was highly commended. This, against all the best pig-breeders in the kingdom, showed her to be of a very prime sort.

There is another improved breed in this county, called Half-blacks, supposed descendants of the Berkshire race. Lord Western originally introduced it into the county, and it rose to great celebrity. They are black and white, fine-skinned, short-haired, with smaller heads and ears than the Berkshire, having short snubby noses, and a very fine bone. They are broad and deep in the belly, full in the hind quarters, but light in the offal. They feed remarkably quick, grow fast, and are of an excellent quality of meat. The sows are capital breeders, and bring litters of from eight to twelve; but they have the character of being bad nurses.

THE ORKNEY BREED.

In the Orkney Islands, the Hebrides, and the Shetland Islands, there exists a small breed of swine, characterised by Dr. Hibbert, in his Account of the Shetland Isles, as a little, ugly, brindled monster — an epitome of the wild boar, yet scarcely larger than an English terrier. "This lordling of the Shetland scatholds and arable lands," says he, "ranges undisturbed over his free demesnes; and, in quest of the roots of plants, or of earthworms, hollows out deep furrows and trenches in the best pastures; destroys, in his progress, all the nests which he can find, of plovers, curlews, or chalderons; bivouacs in some potato field, which he rarely quits until he has excavated a ditch large enough to bury within it a dozen fellow-commoners of his own size and weight. Nor is the reign of this petty tyrant altogether bloodless. When a young lamb is just dropped, it is then that he foams, and, as Blackmore has pompously sung, 'flourishes his ivory war,' never quitting his ground till the grass is stained with the red slaughter of his victim."

These small animals give their owners little care, as they are mostly left to shift for themselves in the best way they can. They are wholly unprovided with shelter; and although they must, during some part of the year, undergo great privations, still they are healthy, and produce good and agreeable flesh. In autumn they are in best condition; and if then put up to fatten, very inexpensive provender will suffice for this purpose, as they lard themselves with considerable rapidity, growing quickly in size, and presenting a short, diminutive, aldermanic appearance, capable of raising astonishment in the minds of those who, before the commencement of the bringling up process, had seen them.

The Rev. George Low, in his Fauna Caledonia, describes them as very diminutive creatures, but exhibiting a great variety of colour. They are bristly in the back, stand erect on their legs, and have short, pointed ears. Their snouts are singularly strong, produced, no doubt, by the constant exercise of their grubbing propensities in the inhospitable region to which they are confined. They travel far and near in search of food, wandering over distant hills, and feeding on such roots and earth-worms as they can find. With such roving habits, it need be no matter of wonder that this little animal, notwithstanding his dwarfish size, should perpetrate greater ravages in corn-fields than the most gigantic of our English porcine breeds. This small breed is usually converted into pork, and forms an article of considerable commerce between the natives and the coast, for shipping stores. In Mr. Low's time, the butchers used to purchase the breed from their owners at from four to five shillings a-piece; and after being cleaned and cured, they were disposed of to the shipping contractors at the rate of two-pence per pound. The average weight of these pigs is from sixty to seventy pounds. Ropes are made of their hair, and used in the Orkneys by those adventurers who suspend themselves from the summit of the cliffs, in search of the eggs and young of the sea-lowl. They are preferable to those made of hemp, on account of their not being so apt to cut from the effects of friction against the sharp edges of the rocks. The Highland pig of Mr. Cully, is the same as that of the Orkney Isles.
THE OLD IRISH HOG.

In Ireland the pig is truly a domesticated animal, often having the snuggest part of the labourer's cabin allotted to him, where he sleeps at his ease, feeds with comfort, grumples to the children, and fattens for the rent. The old, high-legged, flat-sided race, has for many years been gradually dying out, and is now to be met with perhaps only in Galway, and the western part of the country. An improved breed is taking their place; and as they exhibit all or most of the characteristics of the English races, it has become difficult to discriminate between them. The small cost at which pigs can be kept and fattened, coupled with their extraordinary fecundity, make them a real substantial blessing to many a poor cottier, who, with his small savings, may purchase a young and poor-conditioned animal, fatten it on all the refuse he can spare or collect, and sell it at a very remunerative profit. Nay, he may kill it with advantage to his own family, who will thereby obtain a large supply of a cheap, nutritious, and strengthening diet. Were it not for this animal, numberless individuals of the labouring poor would hardly be able to preserve a roof over their heads; and, on this account, the pig is not inaptly called "the poor man's friend." The improvement effected in Ireland upon her old stock, has been done by the introduction of Berkshire and Chinese boars and sows, with which the old breed has been extensively intermingled. Accordingly, the great size and large bone have been reduced, whilst the fattening qualities have been very much increased. It is well known that England imports a large proportion of the bacon, pork, and live pigs, whether fat or as stores, necessary to her consumption, from Ireland, which has a great tendency to keep up the price of bacon in that country. Notwithstanding the rather unpromising exterior presented by the original old Irish pig, there was one shown, some years ago, at the cattle-show of the Royal Dublin Society, which is said to have been the offspring of a cross with the Hampshire. Whether this was or was not the case, the animal weighed over forty-one stone, and was the property of an humble cottier. It attained that weight with a very small proportion of feeding. Irish swine possess flesh of a peculiarly good flavour, which the principle of improvement does not deteriorate; whilst the hams closely resemble, in form and quality, those of Westphalia.

EXTINCT RACE.

The skull of a variety of pig found in an excavation in an island on Loch Gür—a lake in the neighbourhood of Limerick—is, by Mr. Richardson, supposed to indicate sufficient evidence of having been the great ancestor of our well-known long-faced pig, once so plentiful in Galway, and usually designated, from its long limbs and gaunt appearance, by the name of the "Greyhound Pig." Several of these skulls were found at Loch Gür, with those of oxen, goats, sheep, red deer, reindeer, and the extinct gigantic deer, sometimes erroneously styled the "Irish Elk." They were found several feet below the surface, resting on layers of a calcareous tuft, and covered with black bogstuff, the result of the decomposition of vegetable substances. All the skulls, apparently, belonged to animals which had been slaughtered; as their frontals were all broken in, as if by the blow of a pole-axe, or other heavy instrument. It would be difficult to assign the precise period when these animals were thus slaughtered; but, from the circumstance of their being cotemporary with the gigantic deer, it has been suggested as possible that they lived in the times of the Druids, and that Loch Gür was the scene of one of their vast assemblages, and these osseous fragments the long-buried remnants of a stupendous sacrifice to their sanguinary gods.

Having thus described the principal breeds of swine, several of which present really such very slightly-marked differences from others, that it was almost unnecessary to introduce them to our pages—but, in order to give this work all the fulness possible, we deemed it unavoidable—we may observe, that there are certain fancy breeds, which require no specific description, as being less adapted to the practical, than to the gentleman farmer and breeder. Prominent among these is the Windsor breed, greatly cultivated by his late royal highness Prince Albert; the Coleshill and the Bushy breeds. These are all white, and much sought after by gentlemen pig-breeders, who hold them in high estimation.
POINTS OF A PIG.

In describing the *points* which are to be looked to in making the purchase of what is called a good pig, it may be as well to remark, at the outset, that care must be taken not to be influenced by a mere name. There is nothing easier in the world for an eager and unscrupulous salesman to do, than to say that his pig is a true Suffolk, when it is, in reality, no more allied to the Suffolk, than the buyer might be himself if he were a Hebridean. The only certain plan to go upon, is to make oneself thoroughly acquainted with the approved points of the animal, and rely upon that knowledge rather than upon the declarations of the seller. "If you find a pig," says Mr. Richardson, "possessed of such points of form as are indicative or productive of early maturity and facility of forming flesh, you need care little what it has seemed good to the seller to call him; and remember that no name can bestow value upon an animal deficient in the qualities to which I have alluded. The true Berkshire—that possessing a dash of the Chinese and Neapolitan varieties—comes, perhaps, nearer to the desired standard than any other." The chief points which characterise such a pig, are sufficient depth of carcase, and such an elongation of body as will insure a wide lateral expansion. The loin and breast should be broad; the breadth of the former denoting room for the play of the lungs, and a consequent free and healthy circulation, essential to the thriving or fattening of the animal. The bone should be small, and the joints fine. Nothing is more indicative of high breeding than this; and the legs should be no longer than, when fully fat, would just prevent the animal's belly from trailing upon the ground. The leg being the least profitable portion of the hog, no more of it is required than is absolutely necessary for the support of the rest. The feet should be firm and round; the toes lie well together, and press straightly upon the ground; and the claws even, upright, and healthy. "Many say that the form of the head is of little or no consequence, and that a good pig may have an ugly head; but the head of all animals is regarded as one of the principal points in which pure or impure breeding will be the most obviously indicated. A high-bred animal will invariably be found to arrive more speedily at maturity, to take flesh earlier, and with greater facility, and altogether to turn out more profitable than one of questionable or impure stock; and, such being the case, the head of the hog is by no means a point to be overlooked by the intending purchaser." It should, therefore, be rather light in bone; not too flat in the fore part, or too long in the snout. "Indeed, the snout should, on the other hand, be short, and the forehead rather convex, recuring upwards; the ear, while pendulous, should be inclining somewhat forward, and, at the same time, be light and thin." Nor should the *carriage* of the pig be overlooked as an indication of the health and spirit of the animal. Of course, if you are purchasing a fat hog for slaughter, or a sow heavy with young, you are scarcely to look for much sprightliness of deportment; but, in young stores, sprightliness is a consideration.

The points of each breed, though generally similar, have still a difference. In the small breeds the hair should be soft and delicate, and short, light, and silky in its texture; nor ought there to be any indications of bristles, or any increased thickness of hair on the top of the neck. The skin should be soft and elastic to the touch; whilst the cuticle should be thin, and almost transparent. A thick cutis is an almost invariable symptom of hardness, and of difficulty in fattening. In the side-view, the frame should have a resemblance to a rectangle. The back should be long, and show nearly a straight line from the rising behind the ears to the setting-on of the tail, with only a slight elevation over the shoulder and ham, to the line, or even above it. This, however, must be so slight as not to present a slack back. When the back is so raised as to be nearly as high as the shoulder-blade and hip-bones, it is a good sign, for there must be room for the active and full play of the vital viscera. The elevation at the back of the ears is, perhaps, the surest indication, as regards form, of the power of the animal to accumulate fat. When there is a fattening tendency in this part of the animal, it may be taken as an almost certain indication that the animal will deposit it elsewhere with facility. The same will take place with the shoulders and the hams, which are the best portions of the animal.
Hence they should have depth enough to give the two ends of the rectangle, which is the desideratum in a well-formed pig. The same remark applies to the throat. It is not naturally fat; but if it descends so as to fill that corner of the rectangle, it is also indicative of the thriving propensity. The chest should be deep and long; and as the belly carries with it a deposit of internal fat, it may be expected nearly to fill that corner also of the rectangle. Such may be considered the principal features of a perfectly formed pig.

It must be further stated, that whether viewed from behind or before, the animal should still present the rectangular view. Looking at it in either of these directions, the back will exhibit a broad and flat appearance, and form the top; the sides will be full, and the hams and shoulders will fill up the angles, and give the base of the rectangle. In conjunction with these marks, the head should be fine and small; while the chaps and upper part of the face should show a full development of muscle and fat, not only because the snout is useless and the chaps valuable, but because the smallness of the former is highly characteristic of a fine quality in the pig, while the latter indicates a power to feed well. The neck should be short and deep; for if flabby and loose, coarseness and grossness must be expected in the animal. The ears should be small, pricked upwards, thin and fine, and either destitute altogether, or very slightly sprinkled with fine soft hairs. The bones should be small; the legs short and fine; and the tail small and curled, as being indicative of a strong back. The eyes should have a bright and mild expression, and all the extremities should be as small, light, and delicate as possible.

In the large breed of pigs, there is much that is the converse of this. Here the skin is thicker, the hair stronger and coarser; and though the large animal can grow and thicken, and increase in size, it is not fat only that is accumulated. It is divided with muscle; and hence the bacon is the streaked, marketable article, which is sought after much more than that of the prick- eared animal. This sort of pig is also harder and constitutionally stronger, and much more able to resist the influences of a cold climate than the smaller animal. Accordingly, in the valleys which intersect the hills, especially of the “backbone of England,” this breed is highly esteemed. It is fed on the skim-milk of dairies where butter is made, and on the whey where cheese is the product, and is, therefore, altogether more profitable to the dairy farmer than the small-bred pig. Many efforts have been made to combine the qualities of the two; but, to a certain extent, they have been found incompatible. More rapid feeding and earlier maturity may be gained, at the expense of size, constitutional power, and mottled or streaked bacon.

As types of the smaller and larger breeds, the Leicester pig, or the Essex, will be the most perfect for the former, and the Yorkshire and the Berkshire for the latter. In the purchase of a pig, Mr. Richardson says, that even colour is not altogether to be neglected. “In the case of pigs,” he says, “I would, as in reference to any other description of live stock, prefer those colours which are characteristic of our most esteemed breeds. If the hair be scanty, I would look for black, as denoting connection with the delicate Neapolitan; but if too bare of hair, I would be disposed to apprehend too intimate alliance with that variety, and a consequent want of hardihood, which, however unimportant if pork be the object, renders such animals hazardous speculations as stores, from their extreme susceptibility of cold, and consequent liability to disease. If white, and not too small, I should like them, as exhibiting connection with the Chinese. If light or sandy, or red with black marks, I should recognise our favourite Berkshire; and so on, with reference to every possible variety of hue. Some judges are much influenced by the colour of an animal. They disregard his make and qualities, and pass him by if he is not black. It is true that the black nose in cattle is generally indicative of a want of pure blood, as the white back is in any ox, not a Hereford or an Irish. To so ridiculous an extent was this notion at one time carried, that the best pigs were passed by, at the Show of the Royal Agricultural Society of England, and the prizes given to those which were of the black breed; this being considered an indispensable qualification for a winner. As indicative of breed, therefore, it may be useful to attend to colour; and it may be taken as one point indicative of
PIGS, [PIGGERIES.]

PIGGERIES.

quality: the blue spots of Neapolitan; the white, if small, of Chinese; if large, of the old English; if black, of Berkshire, &c. but beyond this, it is neither politic nor reasonable to go."

For general purposes, an inclosure which allows sufficient space for the number of swine to be kept, with the means of extending it, if necessary, will be found the best; for there are few things which conduce more to the health of the pig family, than spacious, airy, well-constructed, cleanly kept accommodation. At one time, swine were imagined to be far happier when kept in a continual state of filthiness; any place was then deemed good enough for them; and the consequence was, that the poor despised animals were housed in dirty, damp, close sheds or sties, without the smallest attention to comfort or cleanliness being bestowed upon them. In such places who could expect the blood of any animal to be preserved for any length of time in a healthy state?

"The blood, the fountain whence the spirits flow;
The generous stream that waters every part,
And motion, vigour, and warm life conveys
To every moving, breathing particle."

A proper piggery should have a range of sheds, so situated as to be quite sheltered from the north and east winds; from snow and rain; and it should be paved or flagged at the bottom, with an outward slope. To insure cleanliness and dryness, very efficient drainage is absolutely necessary; and it will be advantageous if the bottom be of concrete, as well as drained. "The whole pig-cote should slope towards one corner, and be intersected by channels in the flagstone or pavement: the former is by far the best; and to this a common metal stench-trap should be placed. This is, in every respect, the best. Connected with this drain should be a tank; or it might communicate with the drainage of the rest of the buildings. The interior, or covered shed, should be kept constantly littered; and so, indeed, should the court-yard, if the object of the pig-keeper be to convert his straw into manure. If not, it should be swept and washed clean, and occasionally sprinkled with fresh sawdust. There is no better absorbent—no cleaner material than this—and it is cheaper than straw, when both have to be purchased; much more por-
table, easier obtained, carried, or stowed away, and should be the sheet-anchor of the amateur pig-keeper."

Mr. Henderson recommends a house on an entirely different plan. "Have a house," he says, "thirty feet by fifteen, with four doors, all opening outwards, and three partition-walls through the house, by a wall between each of the doors, dividing the house into four compartments—the two middle ones for eating, and the others for sleeping apartments, having an inner door between each eating and sleeping apartment. By this plan, the keeper is enabled to get the eating chambers swept out, and troughs cleaned, and the food put into them, without disturbing the swine, or being disturbed by them. There should be a division-wall through each sleeping apartment. In the hinder part should be the litters; and the front and smaller compartments, through which the animals pass to their food, may be used by them as a kind of necessary; for these animals will never defile their beds, if they can avoid it.

"The manger should be as long as the house is wide, and fixed against the middle wall; in form similar to a horse manger—wide at the top, narrow at the bottom, but not so deep. It must be divided into compartments by partition-boards four feet in length or height, and a little broader than the manger is wide. At such a trough a number of pigs will feed as quietly, and as well, as two or three. Before every meal the trough should be well washed, and the place swept; and once every day a little fresh litter should be placed in the sleeping chambers. Each of the eating and sleeping rooms should be divided into two. The sleeping rooms should be dark, as animals fatten more rapidly when they can quietly lie down and sleep after each meal."—Mr. Parkinson suggests, that in the yard, or inclosure before every piggery, there should be "a rubbing-post, or, what is still more beneficial, two posts, having a hole between them, similar to a horse's leaping-bar, but not revolving; this pole should be raised or let down to the height of the pigs, as the rubbing of the animals against it causes a freer circulation of blood, the same as the flesh-brush does to human bodies." All these plans, however, are suitable only for large farm-yards. For
cottages, therefore, some mode less aspiring should be adopted.

In this case, a well-built stand, and water-proof shed for a sleeping-place, with an inclosure for air and exercise, as large as convenient, will be sufficient. It should not open to northerly or easterly winds; nor should it be exposed to the full heat of the mid-day sun. Its dimensions should be about eight feet square, and the court about ten. The second, or supplemental sty, need not be more than six feet square; and it does not necessarily require a court. Of course, if the three mud walls can be built, and a little gate appended for the ingress and egress of the tenant, it will be so much the better; but here cottier management only is spoken of. In constructing cottier pig-cotes, it is hardly necessary to say that the roof should always slope from the court and behind the sty, or be spouted in such a manner as to allow the water to be carried off by a system of drains entirely separate from those conveying the liquid from the sties.

CHAPTER IV.

BREEDING, Rearing, Fattening, AND FEEDING THE HOG.

It is now a fact admitted in the principles of breeding, that the progeny usually inherit the physical and constitutional qualities of one or both of the progenitors; and in the case of the hog, it is the qualities of the boar which principally predominate in the offspring. Hence the male animal, in swine, should always be selected with the utmost care. "In the breeding of swine," says Thaer, "as much as in that of any other live stock, it is important to pay great attention, not only to the breed, but also to the choice of individuals. The sow should produce a great number of young ones, and she must be well fed to support them. Some sows bring forth ten, twelve, or even fifteen pigs at a birth; but eight or nine is the usual number; and sows which produce fewer than this must be rejected. It is, however, probable that fecundity depends also on the boar. He should, therefore, be chosen from a ram that multiplies quickly. As good one-year bacon-hogs are much in request, we must do all we can to obtain a breed well adapted for producing them. Swine of such a breed may be known by their long bodies, low bellies, and short legs. Long pendulous ears are usually coupled with these qualities, and attract purchasers. If, however, as is often advisable in large dairies and cheese factories, hogs are to be sold at all seasons to the butchers, great attention must be paid to quickness of growth and facility of gaining flesh, so that the animals may attain their full growth, and be ready for killing before they are a year old. This quality is particularly prominent in the Chinese and African breeds; but among our ordinary varieties, hogs are often met with which are better adapted for this purpose, than for producing large quantities of bacon and lard. The boar should be selected from a breed well suited to these several purposes. He must be sound, and free from hereditary blemishes. He should be kept separate from the sows till he is about a year old, and has finished his growth, or he will begin to leap too early. He is usually castrated before completing his third year, otherwise his flesh becomes unetable. If, however, he is of a peculiarly excellent breed, one which cannot be easily replaced, his flesh may be sacrificed for the sake of preserving him for breeding from, a few years longer. A boar left to pasture at liberty with the sows, might suffice for thirty or forty of them; but as he is generally shut up, and allowed to leap at stated times only, so that the young ones may be born nearly at the same time, it is usual to keep one boar for ten or twelve sows. Full-
grown boars being often savage, and difficult to tame, and attacking men and animals, must be deprived of their tasks. The sow must be chosen from a breed of proper size and shape, sound, and free from blemishes and defects. She should at least have twelve teats; for it is observed that each pig selects a teat for himself, and keeps to it; so that a pig not having one belonging to him would be starved. A good sow should produce a great number of pigs, all of equal vigour. She must be very careful of them, and not crush them by her weight; above all, she must not be addicted to eating the after-birth, and what may often follow, her own young ones. If a sow is tainted with these bad habits, or if she has difficult labours, or brings forth dead pigs, she must be castrated forthwith. It is, therefore, proper to bring up several young sows at once, so as to keep those only which are free from defects. Breeding-sows and boars should never be raised from defective animals."

These observations comprise much that is excellent in connection with the principles of breeding; and they might be greatly extended, although it would be a work of repetition. It may be observed, however, that, in every case, whether bacon or pork be the object of the breeder, a spirited-looking head, a deep and broad chest, ample ribs and barrel, a haunch almost as low down as the hough, broad loins, wide hips and long body, in proportion to the height, are the qualifying points of a good animal. The back should also be broad, and the flesh abundant, round, and behind the ears. Smallness of bone is also one of the first considerations, and should be taken into calculation with the proportion of flesh, fineness of the best parts, and the lightness of the offal.

Breeders are not altogether agreed as to the exact age for the boar and the sow to commence breeding at. In speaking upon this point, Mr. Richardson advises that the sow should be at least one year old, and the boar at least eighteen months; but, if the former have attained her second year, and the latter his third, a vigorous and numerous offspring are more likely to result. The boar and sow continue to breed for about five years; or until the former is upwards of eight years old, and the latter seven. A boar should not be used after he has passed his fifth year, nor a sow after she has passed her fourth, unless she has proved a peculiarly valuable breeder. In such a case she might be suffered to produce two or three more litters. When the services of the boar are no longer required, he should be emasculated—an operation that can be performed with safety at any age—fattened, killed, and sold. When it is no longer desirable to breed from the sow, she should be killed also. Perhaps the most saving plan, where the breeding and fattening of pigs are carried on simultaneously, is to take no more than three litters from a sow before she is killed. If less are taken, she will not have attained her full maturity; if more, she will prove injurious for bacon. A sow that has had only three litters, will be as fine bacon as an emasculated hog; but, if she has had more, the flavour of her flesh will be coarse and strong. Should a sow exhibit a more than ordinary tendency to take on fat, she should be bred from at an early age—say at about nine months—as the rapid accumulation of fat in the animal is attended with danger at the period of parturition. She should be allowed the boar a couple of months after pigging, and permitted to breed as frequently as she is capable of doing. This will effectually check her fattening tendency. After having taken a few litters from her, the rapidity with which she will consume her food, will soon bring her into condition for the butcher. The boar should be well fed, in order that he be kept in high condition without being fat. On the other hand, till after conception has taken place, the sow should be kept rather low; but after that, she should be gradually brought up to good condition.

For successful breeding of swine, the best times are in the month of April and the beginning of August. After this period, the litters being farrowed late, they have a good deal to contend with regarding the inclemency of the weather; consequently they do not always turn out profitable. Indeed, some assert that the litter, either from accident or some other cause, is not worth keeping. Should, however, a late litter be brought into the world, the best plan is to trust them entirely to the care of the sow; and both her and them should be well fed on warm stimulating food. This will secure good pork at a period when that
commodity is both scarce and high-priced, and when a paying profit may be obtained upon it. This is the only plan to realise some benefit by a late litter. The time which the sow carries her young is about 113 days, or sixteen weeks. This is our observation; but a French gentleman, of the name of M. Tessier, allurs, that from his having carefully observed the period of gestation in twenty-five sows, he concluded that it varied from 109 to 143 days. Be this as it may, however, the young produced average from eight to thirteen, and sometimes even more at a litter. We have heard of one sow producing, in thirteen litters, no fewer than 301 pigs; and of others exhibiting an extraordinary degree of fecundity; but it is questionable if this is desirable, as the pigs are generally much smaller than those that form the aggregate of litters less abundant. When giving suck, the sow should be well fed, as she has then a craving appetite for both meat and drink; and which, if properly satisfied, will keep both her and her pigs in good condition. This is an important point; for, if the mother is allowed to become lean, it will require double the quantity of food to enable her to get into condition again; and the young ones, if suffered to degenerate, will not only require extra feeding and time before they can be brought to market, but will never make such good swine as they would have done had they always been kept up to a proper standard. “To guard against such evils,” says Mr. Henderson, in his Practical Grazier, “let the sow and her progeny be fed three times a-day with milk and wheat-bran, or something similar. Water, a little warm, may be substituted for milk, when it is scarce or too valuable. The mixture, of whatever kind, ought never to be thick, but should be more of the nature of a drink than anything else. After the pigs are about ten days old, if the weather is mild, they ought to be allowed to stretch their legs a little, once a day, in an open court attached to their house; during which period the sow may be turned out from them, which will contribute very materially to the supply of milk; but care must be taken to avoid the sow’s remaining out from them all night. Feeding as above will be found very beneficial almost in every case; but more especially when a sow brings forth more than she is able to support, which is not un-

frequently the case. It is likewise of great importance to accustom pigs to food when suckling, as such will prevent their taking the ‘weaning brash.’ When the pigs are about a month old, such as are not intended for breeding should be castrated or spayed.”

As some sows are apt to lie upon, and thereby destroy their young, it is better to keep such from getting too fat, and to have the straw of her bed short, and not too much in quantity. It has been suggested by some, to put an inclining or projecting rail to the lower part of the interior wall of the sty, that the pigs might run through between the rails, and make their escape if the mother attempted to lie upon them; but whether this plan would be successful we cannot say, as we have never seen it tried, although we believe such has been the case. Before weaning the pigs they should be gradually fed; and should they and their dam have been kept warm and dry, and well supplied with drinks moderately warm, mixed with a little meal or wheat-bran, the young ones may in general be weaned when they are six weeks old. Should they, however, have been neglected, they will require to be left with their mother two weeks longer, and even then will not be in such good condition as they otherwise would have been, had they received a sufficiency of food for six weeks. If the pigs are intended for sale, this is the time that they should be driven to market, as they have then a better appearance than they would have for many weeks after being weaned. After they have been taken from the sow, it is necessary that she should be well fed for ten days with boiled potatoes, meal, oats, &c., which, in a short time, will stimulate cition, and the proper season for bringing forth her young will not be lost. After weaning, the pigs must be regularly fed three times a day, with similar food to that recommended to them while sucking, and in a few weeks they will begin to eat raw potatoes or grain. The author of The Pig says, that young pigs should be gradually fed before they are perfectly weaned; and recommends milk for their first food; which, he says, “may be succeeded by ordinary dairy wash, thickened with oat or barley meal, or fine pollard; and this is better scalded; or, better still, boiled. To the sow some dry food should be given
once daily, which might consist of peas or beans. Swedish turnips, carrots, parsnips, or the like, either well boiled or raw, may be given; but a preference should be shown for the food always boiled, or, what is better, steamed. Some wean the pigs within a few hours after birth. It can hardly be conceived under what circumstance this may be found advantageous. The best mode of management is clearly to turn the boar into the hog-yard a month or two after parturition, at which time it is proper to remove the sows for a few hours daily from their young, and let them accept his overtures when they please. It does not injure either the sow or her young if she take the boar while suckling; but some sows will not do so until the cessation of their milk; and this is much more natural. At weaning-time the young pigs may be rung. After about five weeks' high and careful feeding, subsequent to weaning, the young pigs may be put up for stores, porkers, &c., according to the owner's views respecting them. Very young pigs, indeed, immediately after being weaned, if fed on the refuse of a dairy, can be brought up for delicious pork in five or six weeks; for the last week, prior to killing, the addition of beans, peas, or bruised corn, will impart a degree of firmness to the flesh, which is considered an improvement. This is called "dairy-fed pork," and it never fails to fetch an enhanced price, thereby amply remunerating the producer."

When pigs are intended for pork, they should not be so highly fattened as those which are destined for bacon. This should especially be the case with such animals as are designed for home consumption, or, in other words, domestic purposes. To the feeder whose object is to sell, however, a different line must be pursued. What he wants is fat, because fat produces weight, and weight yields profit. It is questionable, however, even whether he should feed the animals till they attain the enormous state of obesity to which we see them brought and exhibited for sale. "There is," says Hurtlel D'Arboval, "no animal so liable to become over-fat as the pig, and especially the Chinese and Siamese swine. Naturally inclined to corpulence and gluttony, they easily acquire an enormous bulk; and when fat has once begun to accumulate, the animal eats little, breathes with difficulty, becomes inert, unable to sustain its own weight, and deficient in sensation. We have seen wretched pigs so fat that they were obliged to be lifted or dragged out of the sty whenever it was necessary to move them. We have, also, made incisions in their buttocks, and even taken off portions of skin from their backs, without their betraying any sense of pain. We saw a hog that had lain for a considerable period on one side, too powerless or too inert to shift its position; and when it was raised, a large hole was perceived in that part of the back which had been undermined. This had been made by rats feeding and gnawing into the fat of the beast, evidently without its being in the least conscious of their proceedings." When fattening pigs for bacon, they should be kept by themselves, as they require no liberty. Their sties, however, should be kept nice and dry, and clean; whilst, in order to bring them into the condition required for the knife, they should be abundantly fed. It seems almost ridiculous to talk of the cleanly comforts which ought to be extended to the pig; but if its accommodation be not attended to in every way to make it feel comfortable, it will not thrive so fast or so well as it would otherwise do. Whilst speaking of pigs being fattened for bacon, Parkinson says, that when he lived with his father, acorns were so plentiful in the woods one year, that they made the pigs sufficiently fat for bacon without any other food. The flesh was equally good, and as well flavoured as that of other animals which had been fed on beans and peas. In the United States, when apples and pumpkins are abundant, the swine are fed on these fruits, which are considered excellent for them. A breeder says on this subject, that on the 10th of October, twenty swine were put up to fatten, all of which were only in middling store order, in consequence of the scarcity of food. The cows producing very little wash from the dairy, and the crops of apples being scanty this season, they had only, during summer, the free range of a small orchard containing an acre and a-half of land—with the premature apples which fell—in which was a pond of water; a very essential requisite to hogs, and one to which, under the powerful influence of the sun, they will resort for their chief

778
comfort. These twenty swine were divided into three lots, and closely confined; we proceeded to fatten them, by steaming four bushels of small potatoes, twelve bushels of apple pomace, four bushels of pumpkins, and one hundredweight of buck-wheat corn, adding a little salt; the whole being well incorporated together, while hot from the steamer, with a wooden pounder, and suffered to undergo fermentation before it was used as food. They were, at the same time, supplied with plenty of charcoal and pure water. While feeding them with the first steamer, or the compound, a more than ordinary moisture was observed on their litter, which was occasioned by urine; a knowledge of animal nature convinced the owner, that any more than an ordinary flow would weaken the system, and retard the progress of fattening; and he attributed this evil to the steamed pumpkins acting as a diuretic, stimulating the kidneys, and increasing the evacuation of urine. In the next steamer, therefore, four bushels of ruta-baga were substituted for the pumpkins, and this had the desired effect. The experiment afforded proof that a mixture thus compounded, contains a larger mass of nutritive material ready prepared for the action of the stomach, and therefore producing flesh more rapidly, than any other combination of food made use of.

Professor Johnston furnishes a table of the comparative nutritive elements of different kinds of food; and from which we take the following materials used in the feeding of the pig:

A food, formed of the combination of roots—say potatoes and grain, as oats—is generally chosen by the best pig-feeders for fattening large pigs. The Rev. Arthur Young, in his work on fattening cattle and swine, gives the following directions in reference to the best method of using grain as a meal for this purpose:—"The most profitable method of converting corn, of any kind, into food for hogs, is to grind it into meal, and mix this with water in cisterns, in the proportion of five bushels of meal to one hundred gallons of water; stir it well several times a-day, for three weeks, in cold weather, or for a fortnight in a warmer season—by which it will have fermented well, and become acid; till which time it is not ready to give. It should be stirred immediately before feeding. Two or three cisterns should be kept fermenting in succession, that no necessity may occur for giving it not duly prepared. The difference in profit between feeding in this manner, and giving the grain whole, is very great—so great, that whoever tries it once, will not be apt to change it for the common method." In another portion of his work, the same author observes—"Some persons appear to be exceedingly successful in fattening their pigs on bread made of coarse rye or barley-meal. They cut this bread in pieces; dry it in an oven; then soak it in water, mash it, and give it to the animals in the form of porridge. Where sour milk or whey can be substituted for water, this food is said to surpass all others for quickness and efficacy in fattening, and for the goodness of the flesh and the fat it produces."

Wheat-meal is not so well relished as oatmeal, because, from its glutinous character, it sticks to the teeth of the animals, and thus annoys them; and all annoyances do harm to fattening animals. For store pigs, nothing more is necessary than the pickings of the fold-yard (especially where cattle are fed on linseed cake; for they will carefully collect all the dung in this case, and feed upon it), with a few chopped turnips and a little sour wash in winter. In summer they may be given a run in the grass fields, with a little wash, in which almost any refuse may be thrown. As the pastures fail, and before the stubbles are ready, a handful of old dry beans in the morning, per animal, will exercise a very wonderful influence for the better; the binding character of the beans will counteract the too-relaxing wash and grass; and, when the harvest
is over, the stubbles are a very valuable auxiliary. When these are finished, the pigs should at once be put up to feed; and at first a large quantity of roots may be given. It is a great satisfaction, then, that diseased potatoes will not only have no injurious tendency on either the live animal or its bacon, but will be almost, if not altogether, as fattening as when they are sound. Hence the value of a stock of pigs. As the feeding progresses, barley or oatmeal should be given in increasing proportions; and, as the process becomes more nearly completed, the whole of the roots may be abstracted with advantage.

When the pig gets too heavy to stand, in the west of Yorkshire they give him oatmeal balls, made just dry enough to hold together; and the display by the porcine tumbelained mammoth, as he lies, eats, and sleeps, with the evident satisfaction he evinces, shows that they are no bad judges of his appetite. Boiling and steaming the food is absolutely essential to pigs. Their digestive powers being by no means strong, they partake of the sluggishness of their general organism. Hence they must have their roots broken down by steam or boiling, and their grain not merely crushed, but absolutely made into flour.

Position, circumstances, and price, will often decide the kind of food given to pigs; and those who make pig-feeding a business, and consequently keep a number of them, should so manage as to be enabled to provide for their maintenance and fattening from the produce of their crops. "They should therefore cultivate, for pig-feeding, beans, peas, barley, buckwheat, potatoes, flax, parsnips, carrots, lettuce, lucerne, rape-grass, Italian clover, rape, chicory, and vetches; they should also sow thistle—which is a most nutritious article of diet for pigs; but so much neglected, that it is, as yet, scarcely ever to be met with in a state of cultivation, or in any condition but that of a weed. Nor ought we to forget a most important article of porcine dietary—namely, mangel and Swedish turnips."

"Until this last year," says an anonymous writer in the *Farmer's Gazette*, "I was in the habit of giving them steamed potatoes, with a portion of broken corn, and now and then bean-meal. The latter article I have used very little, as beans are seldom grown in my district, except by the landed proprietors, and a few extensive farmers. I resolved this year to try, for experiment, if pigs could be fattened on Swedish turnips; and am happy to say, at present, my herd are fattening as well as they were this time last year, when they were consuming a great quantity of potatoes. Hay being so scarce this year on my small farm, I should have been obliged to buy a considerable quantity, had I not changed my mode of feeding. The potatoes my pigs ate last year, I am able to give to my horses and cows, thereby saving my hay; and I have no doubt but pigs can be fattened as well, though not, perhaps, as quickly, on steamed Swedish turnips. I give them as much as they can eat of the turnips, mixed with a little broken corn and wheat chaff, with about a pint of buttermilk to every three pigs; and I have every reason to expect, judging from their present improvement, that they will be ready for market about a fortnight later than I had them last year, and at, at most, one-half the expense. I bought them in the beginning of December, for about £2 a-head; and, if they continue to improve as they are doing, I have no doubt but they will average from 4 to 4½ cwt. at Christmas," &c.

Rice is, also, an important article used in porcine dietary. An amateur pig-breeder says—"We purchased from the government stores several tons of damaged rice at a very cheap rate; with this we fattened our pigs; and such pork I never saw before or since. The fat was as firm and solid as the lean, and the flavour of the meat very superior. The way in which the rice was prepared as food was as follows:—My copper held forty gallons; in the afternoon it was filled, or nearly so, with water; as soon as the water boiled, the fire was raked out, two pails of rice immersed in the water, and the whole covered close down, and left to stand until the morning. On the following day the copper was emptied of its contents, which consisted of a thick jelly, so firm as only to be taken out with a shovel; and on those contents the pigs were fed. The effect was perfect. As to the economy of the plan, that, of course, must be a matter dependent upon circumstances; we found it more profitable than almost any other kind of food we could have given, from the price at which
AND THEIR VARIOUS BREEDS.

Feeding.

We were able to purchase the rice, and its goodness. From slight experiments, I am induced to think that equal parts of rice-jelly and mashed potatoes would constitute an excellent food." Hay-tea is another advantageous kind of feeding, of which we have an account given by Mr. Richardson. The article was first publicly announced by Mr. Saunders, of Stroud, in Gloucestershire. This gentleman was induced to try it with pigs, from having observed its efficacy in weaning calves; and the result was laid before the public in the columns of the Agricultural Magazine. In the manufacture of his tea, he employed various sorts of qualities of hay. The most suitable were found to be clover, sainfoin, and lucerne. The tea produced from an infusion of these plants was thickened with grains, pollard, bran, any kind of meal most abundant at the time, boiled cabbages, or potatoes; but he had no carrots, or he would have used them. Mr. Saunders generally compounded several of these ingredients into a mess, and found that one sack of potatoes, thus used, went as far in feeding as four or five bags given in an unmixed state; the expense being also greatly reduced. He gradually increased his stock of swine to the number of 400, and, in the course of his experiments, used upwards of 1,500 hogsheads of wash, or about five hogsheads daily. His swine were thus maintained at a rate somewhat under one penny per day for each—were in excellent condition, and many, indeed, ripe and ready for the butcher. He had previously been feeding them on potatoes alone; and after he resorted to this new method of feeding, he, within a week or fortnight, found his stock not only improved in coat and skin, but in general health and condition. Mr. Saunders used to store his potatoes, after having them steamed, in casks carefully closed; and found that, thus stored, they were preserved sweet for twelve months, and fermenting, generally, a sort of spirit, which, as it promoted sleepiness in the swine, conduced to their acquiring fat with more than ordinary rapidity, as well as giving to the pork a peculiarly rich and delicate flavour. One sack of meal was thus found to go as far as two under the old system; and he found also, that thickening the wash gradually with meal, formed the best introduc-
should be given, except in combination with a large proportion of other substances, as they are of a very greasy nature, and are apt to impart a rank flavour to the flesh, if given in an unmixed state; and are, besides, actually more efficacious in combination. If there is plenty of meal, the addition of a little to one of the daily feeds will be found to tell well, especially towards the close of fattening; a few weeks previous to transferring your stock to the butcher. The refuse of mills also forms a very valuable item in swine-food, when mixed with such boiled roots as have been enumerated; or as what are called starch-sounds, the refuse from the manufacture of that article; and also the fibrous refuse remaining from the manufacture of potato starch." In treating of this subject, we must not forget to notice the important experiments made by B. Lawes, Esq., on the chemistry of pig-feeding; and published in the fourteenth volume of the Royal Agricultural Society. This Essay is of the greatest value to the scientific agriculturist; but for general perusal, is, perhaps, too elaborate. The food employed in the experiments made by this gentleman, comprised—

1. Equal weights of beans and lentils.—

2. Indian corn.—3. Bran.

The food was accurately weighed, and the animals were, every fourteen days, put into the scales. For the first series of experiments, thirty-six animals, of the same character and age—about ten months—were bought and separated into lots of three each. They were then inclosed in twelve pens, and, for twelve days, fed alike; but afterwards changed from pen to pen, and the evil-disposed, or quarrelsome ones, whipped, so that they might all be brought into a sufficiently agreeable state, to start fair in the feeding experiment for weight. When this had fairly commenced, twelve dietaries were prepared from three standard food-stuffs, and arranged in the following order:—

Pen 1.—Of bean and lentil mixture, an unlimited quantity allowed.

Pen 2.—Two pounds of Indian corn to each pig per day; of beans and lentils, unlimited.

Pen 3.—Two pounds of bran per pig per day, and beans and lentils unrestricted.

Pen 4.—Two pounds of Indian corn, two pounds of bran, and the beans and lentils unrestricted.

Pen 5.—Indian corn alone, in unlimited quantity.

Pen 6.—Two pounds of beans and lentils, and an unlimited quantity of Indian corn.

Pen 7.—Two pounds of bran per day, and an unrestricted quantity of Indian corn.

Pen 8.—Two pounds of bean and lentil mixture, two pounds of bran, and unlimited Indian corn.

Pen 9.—Two pounds of bean and lentil mixture, with bran unlimited.

Pen 10.—Two pounds of Indian corn-meal, and bran unlimited.

Pen 11.—Two pounds of bean and lentil mixture; two pounds of Indian corn, with an unlimited quantity of bran.

Pen 12.—Bean and lentil mixture; Indian corn-meal and bran; each separately and unlimited.

To render this food more palatable it was mixed with water, and the animals were fed with it three times a-day—early in the morning, at noon, and at five in the evening. In the first two feeds, a small quantity of the food which was to be given ad libitum, was mixed with that which was limited, and care was taken that the pigs should always have a liberal allowance within their reach. The troughs were also carefully cleaned out before a fresh supply of food was put into them.

Three sets of pigs having been portioned off, and put into twelve pens, containing three each, they were subjected to three series of experiments, with the various proportions of the food mentioned. In one series, barley-meal took the place of Indian corn; and the third series was devoted to the trial of dried Newfoundland cod-fish, in connection with the other food named. The quantity given varied from one to two pounds of cod-fish per day. In all cases it was boiled, and a portion of other food mixed with the soup thus obtained. The more simple conclusions at which Mr. Lawes arrived are as follow:—"Indian corn, or barley-meal, given with a liberal supply of bran, is good; the bran contributing to the value of the manure. When the animals had unrestricted access to three kinds of food—namely, to the highly nitrogenous false mixture, the non-nitrogenous Indian meal, and the moderately nitrogenous bran—the proportion of their first week's consumption was gradually discon-
continued as they approached maturity; and, throughout, consumed only five per cent. of bran. The average consumption of corn, per pig, per week, was sixty pounds, or about nine pounds per day, which yielded from ten to twelve pounds of meat per week, or about one-and-a-half pounds per day. As the animal fattened, a considerable reduction took place in the consumption of food. The nearer it approached to maturity, the greater was the proportion of fat in the gross increase obtained. On the whole, it was found—"That the larger the proportion of nitrogenous compounds in the food, the greater was the tendency to increase in frame and flesh; but that the maturing or ripening of the animal—in fact, its fattening—depended very much more on the amount of certain digestible non-nitrogenous constituents in the food. It also appeared that some of the cheaper, highly nitrogenous foods, would produce a given amount of gross increase more economically than the expensive ones (peas, beans, &c.), which are usually preferred by pork-feeders. If the amount of gross produce of meat, in return for a given amount of food of a given money value, is alone to be taken into consideration, then, in addition to roots, wash, &c., it would be most advantageous to rely for fattening upon highly nitrogenous foods, such as dried fish or animal refuse, or leguminous seeds, beans, lentils, and the like; because, not only would the weight be obtained at less cost than by the use of cereal grains, but the manure, the value of which must never be lost sight of in calculating the economy of the feeding process, would be much richer than if the latter were employed. But it is not a large amount of gross increase that makes the farmer's profit upon his sties. When pigs are fed freely upon highly succulent food, such as cooked roots, the refuse of starch, herbs, and the like, they are frequently found to give a very rapid increase. But pork so fed is found to sink rapidly in the salting process, and to waste considerably when boiled. And, although the first batch of pigs so fed may fetch a good price, their character is at once detected, and the market closed against a second sale. On the other hand, when pigs are fattened upon the highly nitrogenised leguminous seeds—peas being, however, much less objectionable than some others—the bone is hard, and the fat wastes in cooking. Fish, flesh, and strong oily matters, give the pork a rank flavour. Finally, it is the interest of the farmer to use highly nitrogenous leguminous seeds, and even refuse flesh, if at command, during the earlier and growing stages of his bacon hogs. But if a constant market is to be secured for pork, barley-meal, or other cereal grain, must supersede everything else as fattening proceeds."

Such were the general conclusions arrived at by Mr. Lawes, after he had made a series of the most elaborate experiments which were ever entered upon by any scientific pig-breeder whatever; and we are all aware that swine are often kept and maintained by butchers, mostly upon such garbage as entrails, the paunches, lights, and the viscera of sheep and cattle, as well as the blood. The pig being omnivorous, hardly any kind of food comes amiss to him; but, when the animal is not fed upon choice or selected food, his flesh becomes both rank in smell and taste, and is easily recognised as not having been nourished by a vegetable dietary. Pork-butchers, resident in large towns, usually feed their pigs with their garbage, and not unfrequently help greatly to support one pig by the offal of another. This practice is very disgusting; and, if it were generally known, we believe that there would be much fewer purchasers of pork than there really are. Mr. Richardson says that there is yet another kind of pig-feeding, which has a great tendency to produce revolting sensations. It is that of feeding swine in knackers' yards. "The animals are kept by these persons in considerable numbers, and are fed wholly upon the refuse of the dead horses—chiefly the entrails, the carcass being in too great demand among those who keep dogs to permit of its being unnecessarily wasted. I have frequently been disgusted by the sight, in one of these yards, of three or four fierce, wolfish-looking hogs, their muzzles plunged to the eyes in the abdomen of a slaughtered horse, and their savage jaws dripping with gore. Nor are these horses always fresh. I have witnessed the swine, on more than one occasion, revelling in corruption, and disputing with the maggot and the worm the possession of a mass of liquid putrefaction. In Paris this shocking practice has been long known; but where the knackers
themselves are in the habit of regaling on the choicest morsels, can we wonder that they should fancy the less dainty portions of the same old carrion good enough for hogs? In the yards attached to many of the continental schools of veterinary science, a similar, but, if possible, more disgusting spectacle is constantly to be witnessed. While such a practice is tolerated, with what caution should we not purchase bacon or pork, lest we should thus eat, at second-hand, of substances so revolting to the feelings, so dangerous to individual and public health! Whether knackers should be permitted to keep swine at all, is, indeed, a question; for, without an express prohibition to that effect, issued by the higher powers, I do not see how the evils of which I have spoken could possibly be removed. Chandler's greaves are likewise objectionable as food for swine, unless given in comparatively small quantities, and mixed with bran-meal and boiled roots. If fed wholly on either greaves or oil-cake, or flax-seed, the flesh becomes loose, unsatisfactory, and carriony, and gives out a flavour resembling that of rancid oil."

Pigs that have been fed chiefly on corn, alternately with the vegetable diet, yield pork nearly equal in delicacy of flavour, whiteness of colour, and consequent value, to that well-known delicious article, dairy pork. When swine are not of very large size, and it is desirable to raise pork rather than bacon, a very economical mode of feeding may be advantageously adopted. It consists of equal parts of boiled Swedish turnips and bran. If it be desirable to render the accumulation of fat a little more rapid, let oatmeal be substituted for bran.

We have more than once spoken of the great requisite of cleanliness to the well-being of pigs. A hog washed weekly with soap and a brush, will be found to thrive, and take on flesh in a ratio of at least five to three, in comparison with one not so treated. This has been proved. There can be no possible question about its correctness; and, as it is not a very difficult operation, neither involving a great deal of time or much cost, it should be attended to. Surfeiting hogs is an evil as well as starving them. Illustrative of this, the following anecdote is adduced by Mr. Monbray:—"Four or five-and-twenty years ago, the late Mr. Tattersall requested of me to choose him a store-pig, to put up for fattening. I applied to Mr. Wyat, the then salesman, and we chose one at Finehley, out of a fine drove of Herefords, not then out of fashion. After the hog had been at Mr. Tattersall's two or three days, I received a letter from him, to tell me it was taken very bad—in fact, dying. On inspection, I found the animal sleepy and torpid, refusing food, but occasionally throwing up the contents of its stomach, which consisted of half-digested meal. I immediately perceived the cause of the patient's malady. The feeder, determined to lose no time, had been assiduously filling the trough with food. The hog being empty, after a long journey, voraciously devoured it, until its stomach was filled, and its digestive organs totally overpowered. My prescription was, abstinence from corn, a moderate quantity of sweet grains, thin wash, and sulphur with it: in a few hours the hog was perfectly recovered. In the sequel, the feeder held up his hands with astonishment at the possibility of a hog being gorged with food."

Many examples might be given of the great weight attained by pigs, when they have been skilfully fed and properly attended to. A Mrs. Snarbrich, of Naseby, is instanced as having fed a pig, which, eight weeks before she was publicly noticed, farrowed nine fine young pigs, which were sold in Garstang market for £7, being five weeks old, and this her second litter. The former litter realised the same sum; and, when slaughtered, the sow weighed thirty-four score, which realised, at 8s. per score, £13 12s.; which, by adding the £14 for the two litters of pigs, makes the value of this pig amount to £27 12s. This was a profit of more value than could be made from a fat cow in the same neighbourhood.

The following was the mode of feeding adopted:—"Profit was the great object of the feeder of the pig slaughtered by Mr. Eccleston, of Garstang; and it would have well repaid keeping for a few weeks longer; but Lent being at hand was the reason why it was not kept. Here, in this experiment, is a clear proof that it is better to keep pigs more than one year for profit; and it is well known that there is little gained by feeding an old sow. The food of this pig had been principally whey, as in this neighbourhood there are large quantities of cheese made, and the whey is excellent both for pigs.
and calves; and if it was not for them it would not be consumed. To this whey were merely added what waste and leavings were made in the house, or what is called the swill. When she had the young pigs, she had about 12 lbs. of oatmeal allowed for the first week, which was made into porridge. The mode of feeding for fattening was on oatmeal and potatoes. The latter were boiled by themselves; to 21 lbs. of meal were added 7 lbs. of potatoes, they being boiled to a complete jelly, and then mixed with the meal, and made into balls. It consumed 90 lbs. of meal, and 30 lbs. of potatoes per week, with whey and water to drink; so that in eight weeks it consumed 720 lbs. of meal, the price being 1/4d. per lb., and which, therefore, amounts to £3 15s.; and the 30 lbs. of potatoes per week, amounts to 210 lbs., which, at 1d. per pound, amounts to 5s.; and there were also 20 lbs. of wheat bran, given to it at different times, to keep its bowels open; the price of this bran was 1s. 2d.; and for 24 lbs. of meal, given to it when it had the young pigs, 2s. 6d. The price of the pig, at first, was 12s.: which makes the total amount laid out on this pig, to be £1 15s. 6d.; and, therefore, by deducting this sum from the £22 12s., the produce, it leaves a clear profit of £22 16s. 1d., besides the valuable manure it must have made in the course of the two years."

The following cautions, which we have slightly altered, in conjunction with the directions already given relative to feeding, are suggested by Mr. Richardson:

Avoid foul feeding. No food fit for the table can proceed from unclean feeding. Add salt, in moderate quantities, to the mess given. It is advantageous to do this. Feed at regular intervals. Nothing is more essential to a healthy animal. Without this precaution, all other attempts at cleanliness will be in vain. Cleanse the troughs previous to feeding, by washing out carefully. Do not overfeed. Give only as much as will be consumed at the meal. Never allow any to remain in the trough; clean it out for the store pigs. Vary the bill of fare. Variety will create, or, at all events, increase appetite; and it is, farther, most conducive to health. These variations should be guided by the state of the dung cast: this should be of medium consistence, and of a greyish-brown colour. If hard, increase the quantity of bran and succulent roots. If too liquid, diminish or suspend with bran, and give beans or acorns, and let the mess be firmer. If a portion of corn can be added, such as may have been spoiled, and rendered unfit for other purposes, it will be found to answer perfectly well. Feed stock separately, in classes, according to their relative conditions; keep sows in young by themselves; stores by themselves; and bacon pigs and porkers by themselves. It is not advisable to keep stores too high in flesh; for high feeding, however strange it may seem, is calculated to retard development of form and bulk. It is better to feed pigs intended to be put up for bacon, loosely, and not too abundantly, until they have attained their full stature. They can be brought into the highest possible condition in an inconceivably short space of time. It is by such a system of management as this, that the monstrous swine are raised—their weight frequently exceeding 1,200 lbs., or, at all events, half a ton. Do not regret the loss or scarcity of potatoes, so far as swine-feeding is concerned. The potato is capable of being replaced; and its loss has been the means of stimulating inquiry, and producing experiment, which has resulted in the discovery that many other useful vegetables have been hitherto neglected, and thoughtlessly passed aside. Do not neglect to keep swine clean, dry, and warm. These are essentials, and not less imperative than feeding; for an inferior description of food will, by their aid, succeed far better than the highest feeding without them; and, while speaking of cleanliness, we may reiterate the benefit derivable from washing pigs; this will amply repay the trouble. They are always washed for agricultural shows, where they must be exhibited fat. Watch the markets. Sell when a reasonable profit is to be got. Many a man has swamped himself by his cupidity, and by desiring to realise an unusual amount of gain. Recollect how very fluctuating are the markets, and that a certain gain is far better than the risk of loss. Even great capitalists have fallen from over-avidity.

Before leaving this subject, it may be beneficial, as well as interesting, to give a few instances of pigs which, by different kinds of feeding, have, in a given time, arrived at a proportionate increase of weight. Mr. Laurence
PIGS, for if and but [ATTENiya, being about per forty-six and barley-meal, every stone, with house-wash, for A Shropshire hog, three years old, was kept in high condition as a store—being nearly 80 stone, or 610 lbs. weight—on three bushels of barley-meal, with house-wash as usual, for every seventeen days: about eleven pints per day. The Earl of Winchelsea’s celebrated prize hog, so much admired when exhibited, consumed, of corn and meal, one quarter, one bushel, and one peck, in fourteen weeks and three days. This animal was of the Suffolk breed, and consequently small. A Kentish hog, being six months old, and weighing 20 stone 1 lb., or 161 lbs., having been put up to fatten, consumed, during a period of forty-two weeks, forty-six bushels of peas and barley. It was then killed; and when stripped of its head, feet, flare, or internal fat, all loose fat, skirts, and kidneys, it was found to weigh 53 stone 3 lbs. A Tonquin pig—an epithet then given to the black and white, or improved Essex breed—weighed, at four months old, 101½ lbs. It was put up for forty-seven weeks; when, during that period, it consumed eleven bushels two pecks of hog peas, and eighteen sacks of meal, at 85 lbs. to the sack. When killed, its weight was 30 stone 2 lbs., at 8 lbs. to the stone; and it had, as usual, been dressed London fashion; that is, deprived of head, legs, flare, loose fat, &c.

Mr. French Burke gives the following details:

"The time requisite for fattening, depends, of course, on the condition of the animal when put up, as well as upon its age. If a young store, five or six weeks may be sufficient; if older, six or eight; and if the mature age intended for a perfect bacon hog, of that moderate degree of size and fatness which is preferred for the general consumption of the middle classes, from twelve to fourteen. A bacon hog, if intended to be thoroughly fattened for farm use, should, however, be of a large breed, and brought to such a state as not to be able to rise without difficulty; but may, perhaps, require five or six months, or even more, to bring him to that condition. This, however, supposes him to be completely fat; to ascertain which with perfect accuracy, he ought to be weighed every week during the latter part of the process; for although his appetite will gradually fall off as he increases in fat, yet the flesh which he will acquire will also diminish, until, at last, it will not pay for his food, and he should then be immediately slaughtered. Thus the increase of flesh in a pig put up to be fattened, and regularly weighed, was, on the following dates:—

"Respecting the quality of food, vast numbers of bacon hogs are imported from Ireland, where they are almost invariably fed upon potatoes; but however apparently satisfactory may be their weight and condition, yet, when slaughtered immediately, or before having several weeks of substantial food, to harden their flesh, they are always found inferior to the corn-fed pork and bacon of this country, the fat having a tallowy appearance, of an insipid taste, and shrinking for want of firmness; whereas, when boiled, it should be transparently hard, with a tinge of pink in its colour; the flavour should be good, and the meat should swell in the pot. Potatoes, therefore, though fine food for stores, should never be used alone as sustenance in the fattening of bacon hogs; for, in proportion to the quantity employed, they will render the flesh, and consequently the price, inferior to that of hogs which have been properly fed. They are, however, frequently employed, when steamed, in conjunction with either tail or stained barley, coarsely ground; and farmers who grow potatoes for the market, may thus profitably dispose of the chats along with their unmarketable corn: but those persons who wish to acquire a reputation for producing fine bacon, should never use anything for fattening but hard meat, together with skim-milk, if it can be procured." The rapidity with which flesh can be laid on by pigs,
AND THEIR VARIOUS BREEDS.

(says Mr. Richardson), when all the resources of human skill are brought to bear upon the point, is further illustrated by an experiment made by a very intelligent agriculturist, Mr. John Outhwaite, of Bainesee, related at the Thirsk meeting of the Yorkshire Agricultural Society. He laid a wager of £10, that one of his pigs would lay on 10 stones in a month, in place of one in a week, which is the usual average of a well-fed pig. He estimated the weight of the animal at 22 stones; and it increased nearly a stone over the gain of 10 stones in twenty-eight days. The eye can, perhaps, detect the increase in pigs' flesh more readily than either in cattle or in sheep—the touch being called to the aid in both these, to assist the eye, which is scarcely ever done in the fat pig of any age whatever.

CHAPTER V.

SLAUGHTERING; CURING BACON AND HAMS.

The ordinary way of slaughtering a pig in the country, is to tie a rope round the upper jaw, and throw it across a joist or beam. This, by an assistant, is pulled just sufficiently tight to force the animal to support himself upon the extremities of his toes, whilst his snout is raised in the air. The butcher then kneels in front of him, and taking a knife, first shaves away the hair from a small portion of the front of the throat; then gently passing the blade through the superficial fat, he gives it a forward thrust, a turn, and then draws it out. This operation is followed by a gush of blood, which is caught in various vessels, for the purpose of being manufactured into black-puddings. The rope is next a little slackened, and life speedily becomes extinct. The next process is to put the pig into a scalding-tub, whence he is soon withdrawn, placed upon a table, and the hair and bristles carefully removed by scraping with a knife. He is next disembowelled. The more humane practice of stupefying the animal with a knock on the head before his throat is submitted to the knife, is often done; but we have heard it asserted, that a pig does not scald so well unless he has some remains of life in him. The ordinary way of ascertaining the death of the animal, is by passing a sharp knife between the claws, where the part is extremely sensitive; and the scalding process, if he quivers or exhibits some lingering signs of life, is not allowed to begin until this ceases. When this no longer appears, it is taken for granted that sensation has fled. An important element in the production of good bacon is, that the pig should be slaughtered as quickly, and with as little excitement, as possible. The animal, for at least a day, ought not to be allowed any kind of nutriment; and in killing the greatest care should be taken thoroughly to divide the jugular vein, so that he may bleed both rapidly and completely. After this comes the cutting-up.

“The hog,” says Mr. Henderson, “should be left fasting for full twenty-four hours before being killed; and, after the carcass has hung all night, it should be laid upon its back upon a strong table. The head should then be cut off close to the ears, and the hinder feet so far below the houghs as not to disfigure the hams, and leave room sufficient to hang them up by; after which the carcass is divided into equal halves, up the middle of the back-bone, with a cleaving knife, and, if necessary, a hand-mallet. Then cut the ham from the side by the second joint of the back-bone, which will appear on dividing the carcass, and dress the ham by paring a little off the flank, or skinny part, so as to shape it with a half-round point, clearing off any top fat that may appear. The curer will next cut off the sharp edge along the back-bone with a knife and mallet, and
slice off the first rib next the shoulder, where he will find a bloody vein, which must be taken out; for if left in that part it is apt to spoil. The corners should be squared off when the ham is cut out.

For curing bacon, there is, literally, no end of recipes; and in Yorkshire, Westmorland, and Cumberland, no sugar is made use of. Mr. Rowlandson's plan for salting is thus described:—"Having cut up a well-fed hog, which absorbs much less salt than an ill-fed animal, and runs very little risk of having been over-fed, salt and salt petre, in the proportions of about one pound and a-half of salt, and one of salt petre, to 41 lbs. of meat, must be sprinkled over the fitches, &c.; and then they must be laid, one over the other, in a slate trough, or a wooden trough lined with lead, to the number of half-a-dozen. In the course of twenty-four or forty-eight hours, according as the salt is converted into brine, and this will depend on the atmosphere; in frosty weather the meat will not take the salt, and in moist weather it is apt to spoil, the sides are removed, rubbed, replaced in inverse order, the top at the bottom, with a little fresh salt sprinkled between each course, and the brine thrown over the whole. In favourable weather for curing, once turning and replacing will be found enough, and will not occupy more than a week. Packed dry with layers of salt, and covered with canvas, bacon is thus prepared 'green' for the London markets, and thence drawn to be smoked as required for consumption." To this Mr Rowlandson adds, "that nothing makes better hams or bacon than a well-bred sow, spayed after producing four or five litters."

The most approved method of curing bacon, as practised by a majority of extensive curers, is thus given by Mr. Richardson:—"If the swine you design killing have been a recent purchase, and have been driven from a distance, so as to have become winded or jaded, it is right that they should be kept up for a week, or perhaps more, until the effects of the journey have been entirely removed, and the animals restored to their original tranquillity and primeness of condition. During this interval they should be fed upon meal and water. A difference of opinion exists, as to whether this food should be given in a raw state or boiled. I have taken some pains to ascertain the truth, and have no hesitation in pronouncing in favour of the latter. At the same time, however, the mess should be given in a perfectly cold state, and not of too thick consistency. Some recommend that a small dose of nitre should be given daily in the food for a fortnight previous to killing. Others pronounce this to be unnecessary; but all unite in recommending a very considerable reduction in the animal's food for two days before killing, and a total deprivation of food for at least the last twenty hours of life."

For domestic purposes, bacon is cured by well rubbing into the fitches a sufficient quantity of salt with a little nitre, either with the salting-glove or the bare hand. The fitches are then placed on the floor of an outhouse, and covered with straw, with the rind downwards—straw being laid above this; then another fitch, and so on. Over the whole is placed a board; and, above all, heavy stones or weights. In three weeks, or a month, the meat is sufficiently salted, and is hung upon hooks in the kitchen rafters. The general practice of burning wood and turf, in some kitchens, imparts a sweetness to the bacon not to be met with in any which can be purchased. Another mode is to prepare a pickle, by boiling common salt and nitre in water. Mix, for a single pig of tolerable size, 1 lb. of coarse brown sugar with half a pound of nitre; rub this well in with the salting-glove; then put the meat into the pickle, and let it lie there for two days; afterwards take it out, and rub it with salt alone; then put it back into the pickle. A sweet pickle may be formed by boiling molasses with salt and water. In using this, rub the meat with sugar and nitre; add a small portion of strong pickle to the meat; put the meat into this, and let it lie in it for three weeks. If there be any spare room in the eask, fill it up with molasses. Eight pounds of salt, one pound of nitre, and six pints of molasses, will about suffice for each hundredweight of meat, and will take about five gallons of water. In about three weeks—less or more time being required, according to size—take the meat out of pickle, and hang it in the drying-house. While kept there, the fitches should be hung neck downwards. The ham and the fitch may be cut out and trimmed, according to fancy.
"Nearly every county has, in this respect, a fashion of its own. If you possess the means, remove your hams and bacon to the smoking-house. They should not be suffered to touch each other. With this precaution you may hang them as closely as you please. Smoke-houses are of every dimension; but the smallest answer as well as the most extensive. Before suspending the meat in the smoke-house, it should be previously well rubbed over with bran. The fire is made of sawdust, which burns with a low smouldering glow, giving out far more smoke than if actually flaming. In the process of smoking, your meat will lose from about 15 to 20 lbs. per hundredweight—a fact necessary to be borne in mind."

Sometimes the pigs are killed before they arrive at full size, and their hair removed by singeing; the bacon and hams of these are said to possess peculiar delicacy of flavour. The best sawdust for smoking hams or bacon, is that made from oak, and it should be thoroughly dry. The sawdust of common deal imparts a flavour of a disagreeable character, not unlike that of red herrings.

WESTPHALIAN HAMS.

The genuine Westphalian bacon is particularly good, and the fine quality depends on several causes; as the healthy and semi-wild life the swine are permitted to enjoy; their relationship to the wild boar; and their not being fattened to the fullest extent previous to killing. A large portion of sugar and juniper-berries is used in curing, the proportion being usually 1 1/2 lb. of sugar to 3 lbs. of salt, and 2 ozs. of nitre. The smoke is also applied in a cold state. This is, perhaps, the principal secret. The hams are hung at the top of a very lofty building, and by the time the smoke reaches them it is perfectly cold. These hams are the most famous in Europe, and are principally cured at, and exported from, Hamburg. The smoking process which they undergo, is performed in extensive chambers in the upper storeys of high buildings. Some are four or five storeys high; and the smoke is conveyed to these rooms from fires in the cellar, through tubes, on which the vapour is condensed, and the heat absorbed; so that the smoke is both dry and cool when it comes in contact with the meat. They are thus kept perfectly dry, and acquire a colour and flavour unknown to those smoked by the common method. Hams, after being smoked, may be kept for any length of time, by being packed in dry ashes or powdered charcoal, or by being left in the smoke-house, if that is secure against theft; or a smoke being made under them once a week. When meat is fully smoked or dried, it may be kept hung up in any dry room, by slipping over it a cotton bag, the neck of which is closely tied around the string that supports the meat, and thus preserving the bacon from bug, fly, &c. The small part of a ham or shoulder should always be hung downward in the process of smoking, or when suspended for preservation.

YORKSHIRE BACON.

The mode of curing, in Yorkshire, consists of hanging the pig for twenty-four hours, until it has become perfectly stiff. It is then cut up in the common way. The large veins which proceed from the jugular are carefully extracted with a fork. The bacon is then removed to leaden bowls—the salt wiped over the smooth side, and the shanks carefully stopped with salt and saltpetre, from four to six inches deep. The skin side is then laid downwards, and the whole flesh side covered with salt, and sprinkled with saltpetre. The same is done to the hams and the other sides; and the proportion of coarse salt—which is always used for the purpose, in preference to the more finely pounded—allowed for a 20 stone pig, is 1 stone of salt, and 1 lb. of saltpetre; and so on in proportion. Two or three pigs may be laid in a leaden bowl, exposed to a northern aspect, with plenty of air, and in a place especially free from all putrefying matter. In three days all the sides are removed, the bottom ones placed uppermost, and the whole of the bare places, in the flesh side, again covered with salt. In this way the bacon is removed three or four times in a month, during which period it is said to be in pickle. It is then taken out of the leaden bowls, set on an edge, and the extraneous salt wiped off. It is hung for three weeks more in the kitchen, and is then fit for storing away. This is generally done in sacks, strewed with bran, where it remains until taken out for use, when it is much esteemed.
HAMPShIRE BACON.

This bacon is held in very high estimation. With both Hampshire and Berkshire bacon, the proper time is to choose a dry day, when the wind is blowing from the north; and kill the hog early in the morning, if having fasted the day before. "When dressed," says Mr. Youatt, "hang him up in some airy place for twenty-four hours; then proceed to cut him up. This being done, lay the flitches on the ground, and sprinkle them with salt lightly; so let them remain for six or eight hours; then turn them up edgeways, and let the brine run off. In the meantime, take two or three gallons of the best salt, and two ounces of saltpetre, pounded very fine, and well mixed together; and the salting-bench being made of the best seasoned oak, proceed to salt the flitches by rubbing in the salt on the back side of the flitch. This being done, turn the inside upwards, and lay on the salt about a quarter of an inch in thickness. In like manner treat every flitch. On the third day afterwards, change the flitches—namely, take off the uppermost, and reverse them at the same time, laying the salt a quarter of an inch in thickness. There will be no need of rubbing as before mentioned, neither should the saltpetre be repeated, otherwise the lean of the bacon will be hard. The changing and salting should be done every third day for six successive times, when the bacon will be sufficiently salt. Then proceed to rub off all the stale briny salt, and lay on each flitch a covering of clean fresh bran or sawdust, and take it to the drying-loft. It should be there hung, by means of crooks fastened in the neck of the flitch, and remain for fourteen or sixteen days. Clean oak or ash is the best wood for drying bacon." In both this county and in Berkshire, singeing is adopted more generally than scalding; and this process is considered superior to scalding, the latter being supposed to soften the rind and render the fat less firm. The Wiltshire bacon is of a peculiarly delicious quality; but the cause is obvious, and is not to be referred to any of the details of the curing process. It is prepared from dairy-fed pork. This is the true secret. The same remark applies to the Cumberland bacon. In several counties the hog is skinned prior to curing. Some amount of additional profit is, of course, derivable from this practice; but the bacon is inferior, being liable to become rusty, as well as to waste in the boiling. Hams and flitches should always be hung up in a dry place. Indeed, it will be found useful to sew up the former in pieces of canvas or sacking, as is the practice with the Westphalian.

THE SCOTCH MODE OF CURING HAMS AND BACON.

In Mr. Henderson's treatise on swine, we find the following account of the method of curing hams and bacon in Scotland:—"In killing a number of swine, what sides you may have dressed the first day, lay upon some flags or boards, piling them across each other, and giving each flitch a powdering of saltpetre, and then covering it with salt. Proceed in the same manner with the hams themselves, and do not omit giving them a little saltpetre, as it opens the pores of the flesh to receive salt, and gives the ham, besides, a pleasant flavour, and makes it more juicy. Let them lie in this state about a week; then turn those on the top undermost, giving them a fresh salting. After lying two or three weeks longer, they may be hung up to dry in some chimney or smoke-house; or, if the curer chooses, he may turn them over again, without giving them any more salt; in which state they may lie for a month or two, without taking any harm, until he has convenience for drying them. I practised, for many years, the custom of carting my flitches and hams through the country to farm-houses, and used to hang them in their chimneys, and other parts of the house to dry—some seasons to the amount of 500 carcasses. This plan, however, was found to be attended with a number of inconveniences. About twenty years ago I contrived a small smoke-house of very simple construction. It is about twelve feet square, and the walls about seven feet high. One of these huts requires six joists across—one close to each wall, the other four placed at proper distances. To receive five rows of flitches, they must be laid on the top of the wall. A piece of wood, strong enough to bear the weight of one flitch of bacon, must be fixed across the belly end of the flitch by two strings, as the neck end must be hung downwards. The pieces of
wood must be longer than the fitch is wide, so that their ends may rest upon a beam. They may be put so near to each other as not to touch. The width of each will hold twenty-four flitches in a row, and there will be five rows, which will contain 120 flitches. As many hams may be hung at the same time above the flitches, arranged in the best manner you can. The lower end of the flitches will be within two-and-a-half or three feet of the floor, which must be covered five or six inches thick with sawdust; this should be kindled at two different sides. It will burn, but not cause any flame to injure the bacon. The door must be kept close, and the hut must have a small hole in the roof, so that part of the smoke may ascend. This lot of bacon and hams will be ready to be packed up in a hogshead, and sent off in eight or ten days, or a little longer, if required, with very little loss of weight. After the bacon is salted, it may lie in the salt-house until an order is received."

THE IRISH MODE OF CURING HAMS AND BACON.

In Limerick, hams have long had celebrity; and their excellence is supposed to arise principally from the sparing use of salt, and the substitution for it, to a large extent, of coarse sugar, accompanied with a judicious plan of smoking. Some of the rooms in which this process is carried on, have a height of upwards of thirty feet. To extract the superabundant salt from the meat, Mr. Richardson recommends the following:—"Put your meat to steep in tepid water; and after it has lain in it for some hours, add a small quantity of sulphuric acid. In three or four hours take it out, and wash it two or three times in water; to the third water add a small portion of carbonate of soda. Take your meat out, wash it again, and boil it for dinner. You will find the salt nearly, if not wholly discharged; but you need not be surprised, should the colour of the meat be somewhat darkened; the deterioration does not extend further; the flavour remains the same as when first corned, and the article becomes as wholesome as fresh meat. It is possible that this simple process may be found useful in long voyages; for a long-continued diet of salted animal food, without a free use of vegetables, is found to contribute to the production of many diseases. A much more simple process is the steeping of the bacon over-night in cold water. So great is the affinity of salt for water, that a twenty-four, or even eighteen hours' steep, will generally remove any degree of superabundance of salt. It interferes less with the flavour than any other chemical mixture whatever; and is, on this account, and its easy mode of being effected, by far the preferable plan."

The following communication was sent by Mr. J. Hawkins, Dublin, to Mr. Richardson, and explains the Irish mode of curing hams and bacon:

"The hog is usually kept fasting for twenty-four hours previous to being killed. He is then brought to the slaughter-house, and dispatched in the following manner:—The butcher takes a maul (a hammer with a long handle, like those used for breaking stones on a road), and with it strikes the pig on the forehead. If he be an expert hand, a single blow will suffice to knock the hog down, and render him quite senseless. A knife is then taken, and the butcher sticks the animal in the lower part of the throat, just between the fore legs. A boiler, or tub, full of very hot, or boiling water, is in readiness, in which the hog is immersed until the hair becomes so loose that it can be scraped off with a knife quite clean. When there is no convenience of this kind, the same effect may be produced by pouring boiling water over the pig. The hog is then hung up by the hind legs, cut up the middle, and the entrails taken out; after this, the carcass is left there for about twelve hours, to cool and become firm, when it is fit for boning or cutting up. Sometimes, instead of scalding, the pig is swaled by fire: burnt straw is generally used for this purpose; and this is called 'singed pork.'

"The following is the mode of boning or cutting:—The pig is placed on a strong tabio or bench; the head is then cut off close to the ears, and the body opened down the back. A cleaver or saw is used for the purpose, and both back-bone and hip-bones are taken out, except in one or two places, yet to be spoken of, where a different system is pursued. The hind feet are then cut off, so as to leave a shank to the ham. The fore legs are next cut
PIGS, [IRISH BACON.]

round at the hough, the flesh scraped upwards off the bone, and off the shoulder-blade, which is taken out quite bare under the side. The saw is then run along the ribs, so as to crack them, when they will lie quite flat. The pig is then divided straight up the back, and the sides are ready for salting; the ham still remaining in. This is the method usually practised in the county of Wicklow. When the sides are ready for salting, they are well rubbed on the rind side, and the space from which the shoulder-blade was taken out is filled with salt. The sides are then laid singly upon a flagged floor, and salt is shaken over them. In a day, or two days, if the weather is cold, they must be again salted in the same manner; but now two sides may be put together, and powdered salt-petre shaken over them, in the proportion of about two ounces to each side, if of average bacon size. After three or four days, the sides are to be again changed, the shanks of the ham rubbed, the salt stirred, a little fresh salt shaken over them, and five or six sides may now be placed over each other. The sides may then be left thus for a week, when they may be piled one above the other, to the number of ten or twenty, if there have been so many pigs killed. Leave them so for above three weeks, until they get firm. They may then be considered cured, and will keep for six or eight months, or according to pleasure.

When required for use, or for market, the sides are taken out of the salt, and well swept and cleaned; the ham taken out, hung up, and dried with turf. If a brown colour is desired, a little sawdust of hard wood may be thrown over the turf. If hung up in a kitchen where turf is burned, and suffered to remain, not too near the fire, the same effect will be produced; and if the bacon has been well cured in salt, it will be excellent. The Belfast and Limerick methods of cutting differ from what I have described, inasmuch as the hip-bones are left in, and the hams are cut out while the pig is fresh, and cured separately. In some cases, also, the ribs are taken out of the sides; and, in Belfast, the shoulder-blade is taken out over the side. Both the Belfast and Limerick hams are cured in the same mild manner; they are, as I have stated, cut out of the pig when fresh, cured separately, and only left a sufficient time to be cured, and no more. They are not suffered to become too salty—a fault sometimes perceptible in the Wicklow hams. The Limerick and Belfast curers also make up different other portions of the pig separately, as long sides, middles, and rolls, for the English market. Sometimes the ribs are taken out, and sometimes not, according to the market for which they are intended. Limerick, Belfast, Wicklow, and Waterford, are the principal curing districts of Ireland. The Wicklow method, first described, is that in use in all counties of Ireland which prepare their bacon for the Dublin markets. The bacon, when cured, is then consigned to factors in Spitalfields, and sold on commission to the provision-dealers of Dublin. Limerick and Belfast hams are cured in the following manner. They are, as I have said, cut fresh from the pig, with the hip-bones left in them, and are placed on a flagged floor, the front of the second ham resting upon the shank of the first, and so on until all are placed; they are then sprinkled with strong pickle from a watering-pot, and a small quantity of salt is shaken over them. Next day the hams are taken up, well rubbed with salt, and laid down as before, when salt-petre is shaken over them in quantities proportionate to their size; they are left so for two days, and then taken up and rubbed as before, when they are laid down again, according to the space they have to fill—from three to six hams in height, with layers of salt between. After six days, the hams are reversed in the piles; that is, those that were packed on the top are put at the bottom. They then remain for six days longer in the pile, when they are considered cured. After this, they are taken up and washed, and hung up to dry in the air. When it is intended to smoke them, they are placed in a house made for that purpose, and smoked—in Belfast, with wheaten straw and sawdust; in Limerick, with peat or turf."

**Curing bacon for the navy** is differently performed from ordinary salting. A little more skill is exercised in cutting up the pig into pieces of as nearly equal size as possible; when a combination of salt and salt-petre dissolved in water, and almost in a saturated solution, is placed in the curing-tub, and there allowed to remain from three to four weeks.
A barrel is provided, and the bottom covered with a layer of hay and salt; then alternate layers of pork and salt up to the top, when it is covered and coopered up, so as to exclude the air as completely as possible. A hole is then made in the head of the cask, and the saturated pickle is poured in till the cask is full, when it is plugged up, and ready for use. Salt pork, as it is called, is generally a much more useful and genuine article than either of the preserved meats, or the salted beef supplied to the navy.

The principal injuries to which bacon, after curing, is liable, is that of becoming rusty, and being infested with the larvae of a small fly known as jumpers. The first often takes place if it is dried too near the fire, or is exposed unnecessarily to the air. In drying, it should be so near the fire as to be within its influence—so far from it as to prevent its drying, and so turning rancid, known provincially as "rusty" or "reastye" bacon. Some parties recommend whitewashing the bacon with lime-wash after it is dried; and this is certainly a decided preventive; but it may be equally prevented by being cured with plain bran, or any wholesome material which will keep it from the air.

CHAPTER VI.

DISEASES OF THE PIG.

It is observed by Mr. Youatt, that swine, from having been, until recently, considered as a subordinate species of stock, have not yet, to any extent, become sharers in the benefits which the present advancing state of veterinary science has conferred upon other domesticated animals. "When anything goes amiss in the piggery, the farmer, too often, instead of exercising that shrewd sense which he turns to so good an account in almost every other instance, either sends for the butcher, or consigns the sick tenants of the sty to the care of an ignorant pig-doctor, whose whole pretensions to leech-craft rest on the possession of some antiquated recipe, which he uses, indiscriminately, as a grand panacea for 'all the ills that swine's flesh is heir to,' or on the traditionary lore he inherits from some ancestor, famous in his day for certain real or supposed wondrous cures." That this is still, in a great measure, the case in many parts of the country, cannot be doubted; but if proper care were taken of the pig, disease would much more rarely attack him, and his owner would reap far more advantage from it than he otherwise does.

"Cleanliness," says Mr. Richardson, "is the great point to be insisted upon in swine management. If this, and warmth, be duly attended to, the animal will not, in one case in a hundred, become affected with any ailment. The pig-feeder will find that, in most cases, his pigs will never ail from their birth to their slaughter. There may be a few attacked with disease; but the feeder will generally find that the first symptoms of it will give way before a dose of flour of sulphur—say half an ounce for a large animal, combined with new milk, which he will generally drink—with warmth and confinement. As it is almost impossible to administer medicine by force, it is better thus to take the disease in its first stage, and give it to them by enticement."

The following are a selection of some of the principle diseases to which the pig is liable; and the treatment recommended in them is such as has been found effectual.

APOPLEXY.

This disease is chiefly brought on by highfeeding, want of exercise, and laziness, all of which beget a plethoric habit, inducing apoplexy, which in swine is often fatal. When it
appears, the treatment must be very prompt, and blood should be immediately taken from the palate. As purgatives, Epsom salts and sulphur should be given, or emetic tartar, dissolved in sufficient water to cause the animal to vomit. Should these prove effectual, there must be no stimulating food given for some time afterwards, and the animal should be bled, at least, every three months. There should also be some nitre infused with the water he drinks.

**CATARRH, OR COLD.**

This disease springs from the same causes as those which affect other animals with it. It consists of an inflammation of the mucous membrane of the nose, &c.; and, if taken in time, is easily cured by opening medecine, succeeded by a warm bran mash, abstinence from rich grains, and careful, comfortable housing. Where the cases are very severe, it is well to administer medicine; and the following is recommended by a writer in Morton's *Cyclopædia*:

- Antimonial powder... 2 to 6 grains.
- Nitre...
- Digitalis...

This to be given daily. Should the disease extend to the lungs and become bronchitis, in addition to the above medicine, the animal should be bled, and a stimulant rubbed on the brisket.

**COLIC.**

Colic frequently attacks the hog, and is indicated by the animal rolling on the ground, murmuring sounds that betray suffering, and exhibiting great restlessness. The following is recommended to be administered:

- Peppermint water...
- Tincture of opium...

The animal must be kept warm, and supplied with new and warm milk, until well. Some recommend a dose of Epsom or Glauber salts; but for colic, oleaginous medicines are the best; therefore, castor-oil, given in a dose proportioned to the size of the pig, may be safely administered.

**CASTRATION.**

As this can be no more called a disease than parturition or spaying, it might have been introduced in another part of the Division of this work; still, as it is a surgical operation, we consider this the most appropriate place to speak of it. There is no great difficulty in the performance of this operation, consequently, in country towns, there is always one sufficiently skilled in the art to gain a livelihood by it. In castrating hogs, which should not be older than three weeks, they are grasped by an assistant by the hind legs, with their faces towards his person, so that the testes may be kept on a level with the hands of the operators. As the skin of the testes is loose, a longitudinal cut is made in the serotum, over each of them, when the finger and thumb are pressed gently on each side of the incision, so as to cause the testes to protrude. This being done, it is gently taken hold of by the other hand, and the spermatic cord separated by the knife. The whole of the operation is soon over; but, after it, the pig should be suffered to fast for a few hours, although the little animals seem to be so slightly affected by any pain which they may have endured, that, by the following morning, they are as active as ever. Beyond three weeks, and in proportion to the age of the animal, the operation becomes proportionally difficult. "With the aged boar, especially, it is a very tedious affair, as he cannot be held up in the way the young pigs can under a month old. It is thus necessary to lay him on his side, and have him well secured before the operation is performed. He should also fast a little before it is done, as well as through the following night, and be supplied only with bran and milk after. Sows in season should be kept from him till the wound is healed. There is more difficulty, however, in performing the operation, either on the old or young, when there is a rupture, which is not unfrequently the case. Greater care must be taken in making a perfectly clean cut. The pigs should fast a day before, and a night, at least, after the operation; and the serotum should be carefully stitched up after its performance, otherwise inflammation will ensue."

**CRACKINGS.**

The cause of crackings is exposure to the extremes of temperature; and, when they do
appear on a pig, it is usually upon the flanks, and at the roots of the ears and tail. In the heat of summer the disease is especially troublesome, should the hog be exposed, for any length of time, to the direct influence of a hot sun, and no pool or marsh near in which he might recline himself, and cool his body with a bath. To cure the disease, after neglect has brought it on, the affected parts should be anointed two or three times a day with tarp and lard, well melted together.

DIARRHEA.

Among all our domesticated animals this disease is very common, and is produced by scanty and unwholesome food, as well as by over-feeding. It arises from inflammation or congestion of the mucus lining of the intestines, and consists of a thin discharge of the fecal matter. Before trying to stop this discharge, a change of diet, from that which the animal has been feeding on, will often be effectual in producing a cure. If, however, it continue for any considerable length of time, medicinal remedies should be resorted to. The best for it is—

| Prepared chalk | 1 oz. |
| Powedered catechu | \( \frac{1}{2} \) dr. |
| ginger | 2 drachms. |
| opium | \( \frac{1}{2} \) |

These should be mixed and dissolved in half a pint of water, and from half an ounce to an ounce of the mixture, according to the size of the animal, given twice a day. The diet should, as far as possible, be composed of dry farinaceous food.

EPILEPSY.

This disease is common, and often arises from the ringing of the mother during the period of gestation. The indications are restlessness, constant grunting, and a greater quickness in the breath, accompanied with an unsteady, staggering gait. Bleeding, strong purgatives, and cold infusions applied to the head, followed by low diet and cooling medicines, are the remedies.

FEVER.

The symptoms of this disease are, redness of the eyes, dryness and heat of the nostrils, the lips, and the skin generally. The appetite is entirely gone, or very indifferent; whilst the thirst is usually violent. The animal should, as soon as possible, be bleed at the back of the ears; and if this is not sufficient, a portion of the tail should be excised. Good and comfortable housing must be attended to; whilst, at the same time, there must be a free admission of fresh air. The bleeding will, perhaps, in an hour or two be followed by such a return of appetite as to induce the animal to eat sufficiently to enable it to support the administration of some internal remedies. For giving it these, the best vehicle is bread, steeped in broth. The fever, however, will usually be found to yield to the bleeding; and the only object to be kept in view is, to endeavour to support the strength of the animal by small portions of nourishing food frequently administered. It must, however, be borne in mind, that, as the hog surpasses every other animal in the rapidity with which it accumulates fat, so does it in the facility with which its strength becomes prostrated when once it loses its appetite. The French veterinarian practice recommends the addition of peppermint to the bread and broth; and if the bowels are confined, the addition of castor and (unboiled) linseed oil, in equal quantities, and in the proportion of two to six ounces, according to the size of the pig, should not be omitted. Mr. Moubray relates the following instructive case, which may serve as an example to be taken in others:—“One of my sows, four years old, a good mother, remarkably good-tempered, a cross between the Oxford and China breeds, with eleven fine pigs by her side, which had been farrowed three weeks, was suddenly seized with fever and inflammation. In twelve hours she became unable to stand; was very restless, and apparently in great agony; no evacuation having taken place during two days. In consequence, I called in the aid of a noted cow-leech in the vicinity, who gravely promised he would do what he could for her, but that all would be of no use. The operations of bleeding, anointing, and medicine, were carried on for three days, at a charge of thirty-five shillings, when the sage doctor dismissed the case, with the consolation to me that he could do no more for the patient, and that it was impossible that she could live. I then took her in
hand myself, bled her, and gave her a strong dose of salts and jalap, which I succeeded in delivering, her jaws being held open by a rope attached to each. In about an hour thereafter she had three pints of warm gruel; and in less than three hours I had the satisfaction of observing symptoms of great tranquility and improvement in my patient. After leaving her at night on a clean and comfortable bed, I was gratified by finding her on her legs the next morning, and in a fair way of recovering. I then repeated the above dose, somewhat reduced in strength, and still keeping her on warm gruel, when, in two days, my satisfaction was complete, on finding her quite restored to her former health, saving a little inconvenience from the obstruction of her milk. Of the young pigs, previously removed, nine did well; and the sow became freed from all relics of her disease in ten or twelve days. I did not, however, choose to risk another farrow with her, therefore put her to the boar in October, and fed her for the knife. She was killed at Christmas, and made excellent bacon. Thus, I saved a fine hog by Dr. Common Sense, to atone for the insufficiency of the most skilful leech then and there going; and if my brethren pig-breeders would follow my example, in most cases, in my opinion, it would be to the benefit both of their pockets and their pigs."

There is a description of fever that frequently occurs as an epizootic, which is described by M. Roche Lubin, in The Veterinarian, and from which we make some detached extracts bearing upon this subject.

"The Charbonneuse typhus of pigs does not always assume the same character. It often attacks the male pigs, and generally the most vigorous and the best looking, without any distinction of age, and with a force and promptitude absolutely astonishing; for in the space of twelve hours I have seen a whole piggery succumb. At other times its progress is much slower; the symptoms are less intense and less alarming; and the veterinary surgeon, employed at the commencement of the attack, may promise himself some success. It will be advisable to divide the whole into different classes.

"First Class.—Symptoms.—The pigs that are ranged in this class often die without there being the slightest precursory symptoms. I have been able to collect only the following:—Sudden loss of appetite, and a general prostration of strength; small and frequent pulse; the ears drooping, of a dark colour, and tender to the touch; the eyes projecting and haggard; the conjunctiva of a deep red; the mouth half open, red, and charged with foam; a leaden tint stealing over the part; frequent and laborious perspiration; anxiety; plaintive cries; frequent convulsions; the appearance of red spots, and becoming more and more deep at the ears, the belly, and the inner surface of the thighs; palsy of the hind limbs; involuntary and fetid discharge. In less than an hour this animal died.

"Second Class.—Symptoms.—In this class I range the pigs in which charbonneuse typhus follows a somewhat rapid march, and offers some sufficiently distinct periods. The symptoms that are the least alarming, and the malady the least rebellious, are the following:—The animal is dispirited, continually lying down, and not getting up without evident pain; the ear is hot and painful; the pulse quick, but regular; the conjunctiva red; the eye fixed; the respiration a little agitated; the flank distended and painful; the tail hanging down; the animal drinking with difficulty, and eating, without appetite, even the most delicious food; he is likewise constipated. This state sometimes remains two days without any sensible change; but, on the third or fourth day, if the medicine that we have employed is without effect, the symptoms redouble their intensity. The pig grinds his teeth, trembles, and is convulsed in every part; the pulse becomes intermittent, and, by degrees, is almost perfectly lost; the pupil is dilated; the red spots become more and more deep in colour, and death is near at hand. The pathological lesions are nearly the same as those already described, except those of the tissues. I have sometimes found the nasal and buccal membranes quite decomposed, and the interior of the mouth presenting numerous black and charbonneuse spots. One mark should be regarded. The sows with young ones always resist the attack of the disease; but, as soon as the little ones are produced, the malady does not spare either the one or the other. The causes of the disease are, in the majority of cases, the bad sties
in which the pigs are lodged, and the noisome victuals which they often contain. The food which the pigs meet with and devour, is the remains of mouldy bread and fruit, more especially peas and lentils—the fermentation and decomposition of which farinaceous substances, with the quantity of bran which is too frequently given to them, occasion the most serious ills in the animal economy. In addition to this, is the constant lying on the dung-heap, whence is exhaled a vast volume of deleterious gas; and also, when they remain too long on muddy or arid ground, or are exposed to the rigour of the season for any length of time. Such are the causes which effect a functional derangement that cannot fail of being dangerous or fatal, especially when brought back to the farm. The pigs are then exposed to an alarming degree of humidity; they lay themselves down on a poisonous and disgusting dung-heap, which is certainly destructive. I could also cite many villages and farms which, for two months of the year, have the houses of their pigs destitute of almost everything that is comfortable and useful. Although, during the whole course of the year, this typhoid disease never suspends its ravages, yet there are certain times in which it rages with great intensity—in the course of the summer, and the commencement of autumn. There are farms and communes where it is enzootic. It is a highly contagious disease. I could cite many facts confirmatory of this; and need only speak of the inoculation in different parts of the body, and the ichorous matter which is contained in the spots that affect every part. The consequence to the pigs at first brought home, apparently sound, is, that when a little time has passed away, the disease spreads through the whole of the piggery. As to the transmission of the malady, by ordinary means, to different kinds of animals, I am unable to give any opinion. The flesh of infected pork has been given to dogs. No evil has resulted from this experiment; and the inoculation of blood and of ichorous matter has not occasioned any morbid affection to the last of these animals; but it was not the same with regard to some sheep that were submitted to a similar experiment. They died two days after the operation, presenting all the symptoms and pathological lesions of charbonneuse fever.

"Preservative Treatment.—The experience of every day proves that it is more easy to prevent a malady than to cure or combat it. In consequence, I have always said to the farmers who suffer the accumulation of typhoid maladies, that they will never banish these from their piggeries whilst the system of carelessness and ignorance, touching the rearing of the pig, continues to be so negligently overlooked. I have always said to them, that, in despite of their singular remedies, the scourge under which they labour will not disappear until they place the animals in proper situations—not humid, but well aired, and where the litter is often renewed; until, also, they give them sound nourishment, properly regulated, and of sufficient quantity; a pure and limpid water to quench their thirst; and bathe them, whenever the temperature is much increased, while they are wailing in the mire. It is also requisite that the pigs should remain in their sties in cold and rainy weather. In the course of the summer, it is always necessary to give, from time to time, some nitrated, salted, and acidulated food. The Rochefort cheese is a useful stimulant for those that are weak and feeble; and the administration of any bitter decoction will often be productive of benefit. During the principal ravages of the epizootic, I have seen benefit derived from small quantities of camphor and nitre, mixed with a decoction of sorrel. To this some have added, and with considerable benefit, a small quantity of mercury. The nasal membrane then secretes more abundantly, the urine is clear and more frequent, and the evacuation of the faecal matter is more easy and copious. This mode of treatment may be continued eight days. If a pig is evidently ill, it should be separated from its companions; and even their abode should be changed, and fumigation should be practised every third day. As soon as a pig is attacked with disease, he should be separated from the others, placed in a warm situation, some stimulating ointment applied to the chest, and a decoction of sorrel administered. Frictions of vinegar should be applied to the dorsal and lumbar region, with aromatic fumigation about the belly. The drinks should be emollient, and slightly mixed with nitre and vinegar. If the fever now appears to be losing ground, which may be ascertained by the
regularity of the pulse, by the absence of the plaintive cries that were before heard, by a respiration less laborious, by the absence of convulsions, and by the non-appearance of blotches on the skin, there is a fair chance of recovery. We may then be content to administer, every second hour, the drinks and the lavements already prescribed, and to give the patient his proper allowance of white water, with ground barley and rye. When, however, instead of these fortunate results, the symptoms are redoubling in intensity, it will be better to destroy the animal; for it is rare that, after a certain period, there is much or any chance of recovery. Bleeding, practised at the ear or tail, is seldom of much avail, but occasionally produces considerable loss of vital power and augments the putrid diathesis."

FOUL SKIN.

Washing the animal with a solution of chloride of lime, and keeping it clean, will generally cure this disease, provided it has not been suffered to go so far as to have assumed a malignant character.

HEAVINGS.

This disease takes its name from the principal symptom by which it is characterised, and is scarcely to be regarded as curable. "In its first stage," says Mr. Richardson, "when indicated by loss of appetite, and a short hard cough, it might run some chance of being got under by copious bleeding; and friction with stimulating ointment on the region of the lungs. Minute and frequent doses of tartar emetic should also be given in butter; all food of a stimulating nature carefully avoided, and the animal kept dry and warm. Under these circumstances there would be no reason absolutely to despair of a cure; but it would be advisable at the same time, if the pig, when this primary stage of the malady is discovered, were not in very poor condition, to put him to death." The cause of the disease is damp lodging, foul air, want of ventilation, and unwholesome food.

INFLAMMATION OF THE LUNGS.

This disease is frequent among pigs. Professor Duyk says, that the only hope of saving the patient, is by attacking the complaint in its early stages. Bleeding should be immediately resorted to. A dose of the following ingredients may be tried to stave off consumptive tendencies:

<table>
<thead>
<tr>
<th>Ingredient</th>
<th>Dosage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Spirit of sweet nitre</td>
<td>½ oz.</td>
</tr>
<tr>
<td>Digitalis tincture</td>
<td>20 drops.</td>
</tr>
<tr>
<td>Emetic tartar</td>
<td>1 drachm.</td>
</tr>
<tr>
<td>Hydrocyanic acid</td>
<td>10 drops.</td>
</tr>
</tbody>
</table>

If, after the first stage, incipient inflammatory action passes over, warmth and milk diet will be necessary; and the sooner the animal is fed the better. Mr. Youatt says, as soon as the first symptoms are perceived, the animal should be bled; the palate will, perhaps, be the best place to take blood; purgatives must then be given, but with caution. Epsom salts and sulphur will be the best, administered in a dose of from two to four drachms of each, according to the size of the animal. To these may succeed sedative medicines, composed of the following ingredients:

This forms a very soothing and efficient medicament for moderate-sized pigs, and will often produce very satisfactory results. Cleanliness, warmth, and wholesome, cooling, nutritious food, are likewise valuable aids in combating this disease.

JAUNDICE.

The symptoms of this disease exhibit themselves in a yellowness of the white of the eyes, and also of the lips, and sometimes in a swelling of the under portion of the jaw. In treating for it, the food given to the animal should be restricted, and an aperient given to it every day. Aloes, combined with colocynth, in proportion to the size of the animal, may be administered. French veterinarians have recommended a decoction of woodbine-leaves, with shoots; but we are not prepared to speak of the effects of this preparation.

LEPROSY.

The symptoms of this complaint usually show themselves in a small humour in the eye, the head drooping, the breathing short and hot, accompanied with giddiness, and a discharge of matter from the eyes. When the
AND THEIR VARIOUS BREEDS.

Lethargy.

The symptoms of this disease exhibit themselves by the animal apparently labouring under depression, with the head drooping, the eyes occasionally red, a general torpor, and a great desire to sleep characterising the whole appearance. It is caused by the want of cleanliness, improper food, and bad air. In treating for it, the animal should be fed as copiously as possible at the back of both the ears, or at the tail. Besides this, administer an emetic, consisting of a decoction of chrometic flowers, or a dose of emetic in accordance with the size of the patient. After this, reduce the quantity of food usually allowed, and mix with each morning's meal a little sulphur and nitre.

Mange.

Mange is, by some, supposed to be caused by the presence of a minute insect, called *acarus scabiei*, or “mange-fly,” burrowing beneath the cuticle, and, in its progress through the skin, causing much irritation and annoyance. Others, again, ascribe it to a diseased state of the blood, which eventually conveys its morbid influences to the superficial tissues. But whatever may be the cause, the symptoms of the disease are sufficiently well known. These consist of blotches, scabs, and sometimes multitudes of minute pustules, on different parts of the body.

In treating for this disease, it is recommended, by Mr. Richardson, that the animal should fast for five or six hours; after which, to a pig of average size, give Epsom salts, 2 oz., in a warm bran wash. This quantity is, of course, to be increased or diminished as the size may require it; but would suffice for a pig of from 15 to 20 stone (8 lbs. to the stone). It should be previously mixed with a pint of warm water, to which should be added about half a gallon of the warm bran wash. It will act as a gentle purgative, and be found highly beneficial.
PIGS, [PARTURITION.

Give afterwards, in every meal, for three days or a week—according as you observe the state of the disease—one tablespoonful of flour of sulphur, and as much nitre as will cover a sixpence. When you perceive the scabs begin to heal, the pustules to retreat, and the fiery sores to fade, you may pronounce your patient cured. But, before that pleasing result will make its appearance, you will perceive an apparent increase of violence in all the symptoms—the last effort of the expiring malady, as it were, ere it finally yields to your care and skill.

There are, however, some very obstinate cases of mange occasionally to be met with, which will not be so readily subdued. When the above mode of treatment has been put in practice for fourteen days, without effecting a cure, prepare the following:—

| Train oil | 1 pint. |
| Oil of tar | 2 drachms. |
| Spirits of turpentine | 2 " |
| Naphtha | 1 " |

Add as much flour of sulphur as will form the above into the consistence of a thick paste. Rub the animal, previously washed, with this mixture, and let no portion of the hide escape. Keep the pig dry and warm after this application, and suffer it to remain on the skin for three entire days. On the fourth day, wash it off once more with soft soap, adding a small quantity of soda to the water. Dry the animal well afterwards, and allow it to remain quiet, having again changed its bedding for a day or so. Continue the sulphur and nitre as before. The patient being convaiscent, whiten wash the sty; fumigate it, by placing a little chloride of lime in a cup, or other vessel, and pouring a little vitriol upon it. In the absence of vitriol, however, boiling water will answer nearly as well.

MEASLES.

Mr. Youatt describes this disease as rather a sub-cutaneous than an actual affection of the skin, consisting of a large number of small watery pustules, which take up their seat between the skin and the fat, and scatter themselves, besides, throughout the cellular tissue and the adipose matter. Some have supposed it to be a milder form of leprosy—a supposition which has a good deal to support it. The measles in the hog is not always fatal; but it has a very deleterious effect upon the quality of the flesh, making it pale, flabby, tasteless, and little disposed to take salt. In the adoption of remedial measures, the animal should be made to fast for twenty-four hours, and then have a warm drink, containing an ounce of bole armenian, and a drachm of carbonate of soda. Cleanliness should be carefully attended to; and at every feeding, or three times a day, it should be given thirty grains of flour of sulphur, and ten of nitre. The ancients treated a hog affected with the measles in the following manner:—After being put into a sty, and kept three days and nights without food, they took five or six apples, picked out their cores, and filled up the holes thus made with flour of brimstone. The holes were then stopped, and the apples thrown to the measly hog. He first tasted one or two, then one or two more, until he ate them all. He was thus treated for five or six days, by which time he was quite well, and as wholesome as ever.

MURRAIN.

The murrain bears a great resemblance to leprosy in its symptoms, with the addition of shortness of breath, staggering, and a discharge of viscid matter from the eyes and mouth. The treatment should consist of cleanliness, coolness, purging, bleeding, and limitation of food. Cloves of garlic have been recommended to be given. Garlic is an antiseptic; and as, in all those febrile diseases, there exists, more or less, a tendency to putrefaction, it is not improbable that it may be found useful.

PARTURITION.

Of all domestic animals, the pig suffers least from parturition. This, however, is not a disease; still, as it frequently requires surgical care, we have placed it in this chapter. No animal is so easily delivered as the pig, which, when her time is near, generally discovers considerable uneasiness; first, by being angry with every one of her species that happens to fall in her way, and then by collecting straw, and carrying it to the place she seems to have chosen to litter. She must not be interrupted in this, or prevented from doing it. It is
her nature thus to act; and when that is satisfied, she will be more reconciled to her condition. When her bed is made, she should be taken into a house somewhat dark, about eight or nine feet square, which will be room sufficient to admit of her turning herself in every direction. Mr. Richardson recommends for this, a bath to be run round the house, six inches from the ground, and six from all sides of the house, well stayed below, and on each side, by perpendicular and horizontal pieces of wood. This will prevent her lying close to any one side of the house, and keep her from crushing to death any of her offspring during the throes of parturition. At the commencement of her troubles, attention is necessary, to see that she is all right. She must be kept as still as possible, unless needing help, which is not often the case. It does, however, occur; as, when a false presentation, a sinking of the pig into the uterus, instead of its being presented in the vagina, or a contracted orifice shows itself. In the latter instance, a veterinary surgeon, of correct anatomical knowledge, is indispensable. The most usual false presentation is when the pig comes sideways, and so chokes the passage. In such a case, a mere turn with the hand will make things as they should be. If the pig has sunk down, it may be necessary to have a child's hand introduced, to raise up the young animal to its proper position. This will succeed when all other methods fail. As soon as each pig is delivered it should be placed before its mother, and it will soon begin to select its teat. Once selected, it will generally keep to it, if its right is not disputed by a stronger brother. If any pig should be extremely weak, and the weather very cold, it may be taken near the fire, and wrapped in flannel. So soon as parturition is completed, the sow will begin to cleanse— or, in other words, eject the placenta; which, when accomplished, should at once be removed, or she may begin to eat it, or learn from it to devour poultry, lambs, and, very probably, her own produce. As parturition usually begets thirst, let the sow have a quart of slightly warmed milk, thickened with a little bran. This is one of the best of medicines. As soon as she has cleansed, and all the young ones have been suckled, she should be gently driven out to state. "A little care of her bowels, plenty of bran and milk food, given in small quantities, with frequent turning out for short periods in a sheltered place, will be necessary at first. If much fever or constipation should take place, a little sulphur—two heaped teaspoonfuls—in her milk will relieve her; nor will she refuse the milk which contains it, if it is thickened with a little wheat meal. Barley, and even oatmeal, must be avoided for the first three or four days. Afterwards she may have any kind of food whatever, except meal, which, useful as it is to store pigs, should never be given to those that are suckling."

**QUINSY.**

This disease consists of an inflammatory affection of the glands of the throat; is of frequent occurrence, and often proves fatal. Acidulated drinks, tonics, cleanliness, warmth, and strict attention to diet, accompanied with active cautery to the root of the evil, is the treatment prescribed. In Mr. Richardson's treatise, we find shaving away the hair, and rubbing the parts affected with tartar emetic ointment, recommended. "Steeping with very warm water is considered useful. When external suppuration takes place, it may be regarded as rather a favourable symptom than otherwise. In this case, wait until the swellings are thoroughly ripe; then, with a sharp knife, make an incision through the entire length, press out the matter, wash with warm water, and afterwards dress the wound with any resinous ointment, which can be obtained from the nearest apothecary. If this cannot be obtained, a very tolerable substitute may be made by blending yellow soap with coarse brown sugar."

**RABIES.**

This is one of those diseases which is, perhaps, developed in the greatest possible degree in the pig. All hope of recovery should be at once abandoned, and the animal slaughtered by shooting, and buried whole. If there is any chance of preventing the affliction, it is by immediate incision of the part where the animal has been bitten, and an application of the cautery. Medicines may alleviate the symptoms, but the disease is incurable.
SWELLING OF THE SPLEEN.

In the hog the spleen is of great length, and, throughout its whole extent, of nearly uniform thickness and breadth. The symptom which indicates the disease called ratille is perceived by the animal leaning towards one side, bending towards the ground, and drawing itself together, as it were, from internal suffering. The cause of this proceeds from overeating, which, in the animal, has injured the condition of the secretions, and obstructed the excretory ducts. As a curative, strong aperients, to produce copious evacuations, are recommended; also bleeding, if the disease has continued some length of time. French veterinarians recommend the expressed juice of the leaves and tops of wormwood and liverwort, to be given in quantities of half a pint to a dose. The decoction of these plants, produced by boiling them in soft water for six hours, is more readily obtained than the expressed juice; and this may be given in doses of from half a pint to a pint and a-half, according to the size, age, &c., of the patient. Scammony and rhubarb, mixed up in a bran mash, or with Indian meal, may be given the following day, or equal portions of blue-pill and compound colocynth pill, formed into a bolus with butter; and the animal, having been kept fasting the previous night, will probably swallow it. If not, it is recommended to keep the pig fasting for a couple of hours longer, and then it will take it. Lower the diet, and keep it on reduced fare, with exercise, and, if you can manage it, grazing, until the malady has quite passed away. If you then wish to fatten, do so gradually. Be cautious of at once restoring the patient to full diet. Indeed, it would be better to keep it for a month as a store; and then feed at regular intervals, always removing whatever food is left from each meal.

SPAYING.

Spaying of female pigs is an operation which usually requires considerable care; and is generally performed when the pig is about three weeks old. The whole litter is usually cut at prices varying, in different localities, from 1s. 6d. to 2s. 6d. per litter, great or small. In performing the operation, the little animal is first laid on its right side, and the two hind legs are stretched out straight, so as to allow the mid-flank to come fairly under the eye and hand of the operator. An incision, about two inches long, is then made with a round-pointed knife, and the thumb and finger are introduced to search for the ovaries, which, from their being separate at one end, and presenting a convoluted or knotted appearance to the eye, are easily found. These are collected together, and folded in a downward direction over the edge of the wound. When the operator finds that all are exposed, he cuts them by a little pressure of the knife towards the skin, and the uterus falls back into its place. He now stitches up the orifice, and the animal usually very soon recovers. The operator should clean his knife well after every cut; secure the whole of the ovaria, and be careful not to stitch up any of the intestines with the skin. If this be done, death is almost certain to follow. Though this operation is usually performed at or before the pig is a month old, it may be safely done at any reasonable age of the animal.

STAGGERS.

This complaint is caused by excess of blood to the head. Bleed freely from behind the ears, and purge.

SURFEIT.

This is another name for indigestion. The symptoms are—loss of appetite, swelling of the region about the stomach, &c., and frequently throwing up the food. The illness will, in general, pass away of itself, provided the animal be kept from any kind of food for a few hours. A small quantity of sweet grains, with a little bran wash, may then be given, but not nearly so much as the animal will take. For a few days the food had better be limited in quantity, and also be of a chilly, liquid nature.

TETANUS.

The common name for this disease is Lockjaw, and is by no means an unfrequent malady in pigs. It is often produced in young ones by castration, especially if, after this operation, they are highly fed for a few days. The disease is frequently fatal, and soon brings the life of
the patient to a termination. Bleeding, lotions, warm baths, and friction, with stimulating oils, are all recommended; also purgatives, if the mouth can be forced to admit them; if not, anodynes and enemas must be given.

TUMOURS.

Tumours, or hard swellings, make their appearance on different parts of the animal's body. Give aperient medicines; keep the animal clean, and administer a change of wholesome food.

These are all the principal diseases to which swine are subject. The remedies accompanying them are such as have been found most effectual; but where these fail, a skilful practitioner should be called in, that the life of a valuable animal may not be sacrificed.

MEDICINES USED IN THE TREATMENT OF DISEASES IN SWINE.

ANTIMONY.—This is rarely given alone; but, in combination with sulphur, it forms a cooling and cleansing medicine. When combined with sulphur, hog's-lard, or palm or train-oil, it forms the common mange-ointment.

ARSENIC.—Used in cases of disease of the skin. To form a solution of sufficient strength for external application, use from one ounce to an ounce and a-half, dissolved in a gallon of water. Arsenic, in the metallic state, is of a bluish-white colour, subject to tarnish, and grows first yellowish, then black, by exposure to air. It is brittle, and, when broken, exhibits a laminated texture. Its specific gravity is 5.703. In close vessels it sublimes entire at 53° F., but burns with a small flame if respirable air be present. The arsenic met with in commerce has the form of a white oxide. It is brought chiefly from the cobalt works in Saxony, where zaffre is made. Cobalt ores contain much arsenic, which is driven off by long torrefaction. The ore is thrown into a furnace, resembling a baker's oven, with a flue, or horizontal chimney, nearly 200 yards long, into which the flames pass, and are condensed into a greyish or blackish powder. This is refined by a second sublimation in close vessels, with a little potash, to retain the impurities. As the heat is considerable, it melts the sublimed flowers into those crystal-line masses which are met with in commerce. Arsenic is used in a variety of arts, and enters into metallic combinations, wherein a white colour is required. It is a deadly poison when received into the stomach. The best remedies are mucilaginous liquids and milk. Syrups and linseed tea are of service. Vomiting should be excited by tickling the throat with a feather.

ARSENIC ACID is formed by the distillation of the white oxide with nitric acid; or by exposing it to chlorine vapour. It is a white concrete substance. The arsenic acid has a sour, and, at the same time, a metallic taste. It reddens vegetable blues, attracts humidity from the atmosphere, and effervesces strongly with solutions of alkaline carbonates. With alkalies, earths, and oxides, it constitutes a class of salts, called arseniates. The arseniate of potash was introduced into the materia medica by Dr. Fowler, for the cure of agues; but it is not used in the diseases of swine.

CALOMEL.—This drug being very dangerous, should, where used at all, be given with extreme caution. In combination with an equal portion of tarterised antimony, it may be administered in cases of great emergency. To form an active emetic, take from two to three grains.

CREOSOTE.—In cases of virulent cutaneous eruptions this is a useful medicine.

CROTTON OIL.—In cases of severe constipation, from one to three drops may be given of this powerful purgative.

DIGITALIS.—Valuable as a sedative in cases of fever.

EPSOM SALTS.—A purgative, used in almost every ordinary case. In a general way, the dose is from half an ounce to an ounce and a-half.

GENTIAN.—Used as a stomachic. A portion of it should be given with every aperient draught, with great care and consideration.

GINGER.—Used as a tonic. It is also an excellent stomachic.

LINSEED OIL.—In cases of considerable intestinal inflammation, this may be given as a purgative.

MERCURIAL OINTMENT.—In conjunction with the sulphur ointment, this is used for the mange and scab. The proportions are, one part of the former to eight parts of the latter.
NITRE.—In febrile cases this is used as a cooling medicine. The dose is from one to two drachms, dissolved in the water the animal drinks.

Palm Oil.—This is esteemed the most valuable emollient for forming the basis of all ointments for cutaneous eruptions. Under the name of *Palme*, Linnaeus arranged several genera, which he placed apart in an appendix to his work. The same plants constitute one of the seven families or tribes into which all vegetables are distributed by Linnaeus, in his *Philosophia Botanica*. They are defined to be plants with simple stems, which, at their summit, bear leaves resembling those of the ferns, being a composition of a leaf and a branch; and whose flowers and fruit are produced on that particular receptacle, or seat, called a spadix, protruded from a common calyx, in form of a sheath or scabbard, termed by Linnaeus "spatha."

SALT.—Valuable for purifying the blood. A little of it should regularly be mixed with the food of the animal.

SULPHUR.—An excellent cooling medicine, and one of the best, if not the best, gentle aperient for common use. In mange-ointment it forms the principal ingredient.

TARTAR EMETIC.—Used as an emetic.

TOBACCO.—A decoction of this plant, when mingled with equal parts of digitalis, is efficacious in cases of mange and other cutaneous diseases.

TURPENTINE.—Useful in cases of worms, which it destroys. There is no danger in administering it to swine.

VINEGAR.—Used in cooling fomentations. Its specific gravity varies from 1.0135 to 1.0251; and it differs also in its other properties, according to the liquid form in which it has been procured. It is very subject to decomposition; but Scheele discovered, that if it is made to boil for a few moments, it may be kept afterwards for a long time without alteration. Besides acetic acid and water, vinegar contains several other ingredients, such as mucilage, tartar, a colouring matter, and often, also, two or more vegetable acids. When distilled at a temperature not exceeding that of boiling water, till about two-thirds of it have passed over, all these impurities are left behind, and the product is pure acid diluted with water.
DIVISION VII.

POULTRY.

CHAPTER I.

ORIGIN OF THE DOMESTIC FOWL.

From the earliest records of time, the cock seems to have been known to man, and to have held an important place in his estimation, not only on account of his qualities as a table fowl, but on account of the heroic courage with which, as a game bird, he is animated in combating for victory over an antagonist. His origin, however, is involved in obscurity. We have no means of deciding where was situated the Eden in which the Adam and Eve of our domestic fowls were first placed. All, we believe, are agreed that it was in the East; but it is very singular that they are no longer found in a wild state, any more than the camel is; that their originals are a matter of theory and speculation rather than of certainty; and that, if we assign them to India, we can do so only by a process of reasoning based upon probability, rather than fact. Presuming, however, that India was the country of their origin, we find it stated, on the highest authority, that the range of the wild common fowl does not extend, westward, beyond the lofty ranges of mountains that form the natural boundary of India in that direction; and yet the domestic bird is said, by the same authority, to have been common among the western nations from the remotest antiquity. As different views of this subject have been taken by different writers, we will bring the theories of each before the reader in a form as condensed as we possibly can.

One supposes that the early patriarchs, before leaving the eastern cradle of mankind, were fortunate enough to possess themselves of an individual wild species of cock and hen; which, by some means, they managed to tame, and attach to either themselves or the locality in which they settled. By constant care these became domesticated; and their offspring, inheriting the attachments of their parents, became still more civilised, and consequently less inclined to wander from the place of their birth. To what species, however, did this first pair belong? Mr. Edward Blyth, Curator to the Asiatic Society's Museum at Calcutta, and one of the ablest ornithologists of the day, adheres to the opinion that all the domestic varieties of fowl are derived from one wild species of jungle fowl—namely, from that common in the Bengal Presidency, and the countries to the east and south-east of it, and not at all from Gallus Sonneratii, as has been so often suggested. "In the formerly Burmese province of Arakan," says Mr. Richardson, following Mr. Blyth's argument, "many of the tame hens are scarcely distinguishable from the wild, and only so by being a little coarser in the leg, with a tendency generally to a greater development of comb; and these hens, hardly removed from the wild, are free breeders. Domestic cocks, of various breeds, may often be found to match, feather by feather, with the wild bird, even some of tolerably gigantic dimensions; and the voice is absolutely that of an English game fowl. This is of importance, as the notes of the two other Indian species are so utterly different; the difference of voice among the races of domestic fowls being as nothing in comparison. Moreover, the wild hen signallites alond, after the same fashion as the tame one, her deposition of an egg; and thus it is that the eggs are occasionally found, though not very commonly."

Mr. Blyth remarks, in reference to the researches of M. Sundevall—"He might well have sought in vain for traces of the wild Gallus Sonneratii in the domestic poultry of India, inasmuch as though, curiously enough, I have found that species of South India far more easily domesticable than the Bengal jungle fowl—the
latter is, beyond all question, the exclusive aboriginal stock from which the whole of our domestic varieties of common poultry have descended."

Mr. Blyth continues—"However different these may be, whether the silky fowl of China, the gigantic Chittagong race, or the feather-legged bantams of Burmah, their voice at once and unmistakably proclaims their origin, and is as different as can be, in every cry, from that of G. Sonneratii; besides that we continually meet with common domestic cocks which correspond, feather by feather, with the wild bird, the peculiar notched comb of which is again retained invariably, even when the comb is double or compound. This much premised, however, it is remarkable that the domestic poultry of India do not approximate to the wild race in any respect more closely than the common fowls of Europe; and I have sought in vain for traces of intermixture of jungle-fowl blood in districts where the species abounds in a state of nature."

A friend of Mr. Blyth's, in one of his sporting excursions in Cuttack, came upon the nest of a jungle hen, in the hole of the trunk of a tree. It contained nine eggs, which he took home with him, and placed under a common hen. The chickens were all reared, and lived with his other poultry, being permitted to go at large to feed during the day, whilst, at roosting time, they returned home with the other fowls. He, however, set no particular value on them; but observed them sufficiently to be able to state that they interbred with the other fowls, and that the breed finally merged in the general stock. From this, taken in connection with other facts, Mr. Blyth is certain that our domestic poultry are derived from this particular wild species; and of the tame pea-fowl being descended from the vital Indian one. He further says, that the peculiarities of many of the domestic breeds are not such as occur among any wild birds whatever; such, for instance, as the silk fowl, with its black skin and periostecum; the frizzled birds, with their feathers twisted the wrong way; those with supernumerary toes; and the feather-legged varieties. This theory, however, is apt to startle us when we think of the gigantic Cochin-Chinas and Malays, the tiny Bantams, the superb Polish, and the droll Rumples and Negro fowl, being all the progeny of one single Indian species. This supposition, however, is coincident with that maintained by some in reference to the origin of all the varieties of the dog.

Mr. Blyth goes on to say—"It is a curious instance of how little is currently known of the zoology of India, that, to this day, authors who write on the history of the common fowl, generally repeat the statement, that 'its original stock is very uncertain; but it is supposed to be descended from a wild species still met with in the island of Java.' The truth being, that the genuine wild common fowl is familiarly known to every sportsman in all Northern India, and is with justice highly prized as a game bird—abounding in all suitable localities, from the sub-Himalayan region on the north, to the Vindhyan range on the south, and spreading farther southward, along the eastern coast of the peninsula, to some distance beyond Vizagapatam; while to the eastward it likewise abounds in Assam, and all along the eastern side of the Bay of Bengal, throughout the Burmese countries, the Malayan peninsula, Java, and Sumatra. G. Sonneratii begins to replace it on the Vindhyan range of hills, bordering the great table-land of the peninsula to the northward; and wholly replaces it in Southern India generally; while in Ceylon two other wild species occur, the hen of one of these being figured by the name of G. Stanleyi, in Hardwick's Illustrations."

In support of his position, Mr. Blyth bids us look to the crest of a Polish fowl, and see how different it is to the crest of the pea-fowl, or of the Impyean Lophophorus, consisting of hackles similar to those of the saddle and neck. The same is the case with the feather-legged breeds. It is observed that the tarsal plumets of owls, grouse, &c., are of a character peculiar to themselves; while the foot plumes of pigeons, and some other fowls, bear a striking resemblance to those of the corresponding joints of the wings. That animals long domesticated fall into singular varieties, we have sufficiently shown in the case of the dog, which has entirely lost the uniformity of appearance which, with the exception of a few, is found in the numerous wild animals belonging to that species. Even among fish
there are endless varieties. The domesticated Chinese gold fish is continually varying as to the number of both its fins and tails. In place of one, some of these have three tails; whilst, in point of shape, the changes are endless. These circumstances have a strong tendency to make us cease to wonder at the varieties found in other species of animals—in the dog and the domestic fowls. These are much more under the influence of domestication than the fish; they are in much more constant association with man; whilst the cross-breeding that is continually taking place amongst them, may be expected, in the course of time, to produce feathers, so different from those which characterized their originals, as to give them all the appearance of a new and distinct species. In the common fowl we might expect extraordinary varieties. Every day experimentalists are trying to produce new breeds, which, in their turn, will produce other breeds, and so on, until the originals are lost, and an entirely different character of fowl is the result.

The principle that "like produces like," applies to fowls, as much as to the horse, or any other species of animal; and it is from a knowledge of this fact that the breeder acts when he desires to produce another variety in such animals as he may have under his care, and will breed together.

With respect to cross-breeding, Mr. Tegetmeier remarks:—"Should it be deemed desirable to cross the Dorking, for the purpose of producing a hardier fowl, such a plan as the following seems to offer the best chance of success; being based upon the fact that, in cross-breeding, the pullets usually resemble the mother, and the cockerels the father. Early in the year, so as to obtain a brood in May, put two or three large Dorking hens with a short-legged compact Cochin cock, either a common buff, or a grey Shanghai, or Brahama Poutra. From the chickens, select those pullets possessing, in the greatest degree, the Dorking character—viz., having fine bone, short white legs, and compact body, square on the limbs; in the following season mate them with a good Dorking cock. The progeny will be three-fourths Dorking; and, if care is taken in the selection, will show very little trace of Cochin blood; whilst the size and constitu-

[ORIGINAL FOWL.]
the wolf as we have done the dog. How is this? How is it that the wild animals, with which we are acquainted, are now found to be so difficult to be brought into a state of domestication? Are we in these matters the inferiors of those who lived in pre-historic, or even anti-traditional times? — for it must have been in these that cattle and poultry were brought under the subjection of a household. These are questions easier put than answered; but, as the subject may be found discussed in Ornamental Poultry, by Mr. Dixon, we must refer those who are interested in the subject to the pages of that gentleman's work.

In placing the various arguments, by the different investigators, before his readers, Mr. Richardson says— "It is candidly acknowledged—and a very important admission it is, though there is no possibility of refusing to make it—that the wild types of several of our domestic animals no longer exist, while that of our fowls is thus precisely indicated! The wild origin of the camel in the old world, and of the llama, and alpaca, in Chili and Peru, and even of the little guinea-pig, which was found domesticated among the natives of Brazil, is quite unknown. Neither the guanaco, nor still less the diminutive vienna, will suffice for the former, nor the restless and other wild caiques for the latter. Respecting the wild original of such an every-day and familiar creature as the domestic cat, our knowledge is anything but superabundant. Great doubts are entertained whether either the true wild horse, or the true wild ass is known, or the parent of the humped ox (a most decided species); and it is far from clear that the so-called wild yaks are the true origin of the tame breeds. Amongst birds, it is not pretended, or even hoped, that the wild stock of the knobbed or China goose (Anser Cygnoides) is still in existence; although there must be in China several tame breeds of that remarkable bird. The original type has probably been exterminated for ages."

Of some of our domestic creatures, therefore, there is no idea, among our best-informed naturalists of the present day, of indicating the wild ancestor; but of others such a notion does prevail. Respecting a few, there can be little or no doubt. Of the Indian buffalo, there can be no mistake; nor of the hogs of different countries, from several nearly-related wild races, though the origin of the Chinese hog is probably lost. Amongst domestic birds, the pea-fowl, the turkey, and the guinea-fowl, come from an undisputed parentage, which are still found wild in their native home; but there are other companions, of which we are unable to speak with the same degree of certainty. It is doubted whether we know the true wild origin of the domestic canary-bird. Mr. Blyth actually remarks, "that the albino (or what we can call them?) of all green birds (amongst others, the yellow wagtail) are yellow; for instance, parrots, bee-eaters, &c.;" and, as he observes, the tame canary-bird has a true albino eye! The origin of the Pigeo turtle-dove is uncertain. The voice of the wild Turdus rirorius is quite different. Mr. Hodgson has clearly shown that certain very large and short-tailed Asiatic breeds of sheep are derived from the wild amnon; the fighting rams of India may have their origin in ovis vigule; but though the species of Asiatic wild sheep are remarkably numerous, there is no other that seems to have contributed to any domestic race; and it is probable that the wild origin of the long-tailed, tame, and other sheep, is no longer in existence. The list of "doubtfuls" might be extended; but the object here is merely to show that there is such a list, and to impress it on the reader's attention.

Whether the several varieties of Domestic Fowl are of ascertained or doubtful descent, must always remain an open question. Naturalists, generally, think that it required more than one wild type to produce the many different species which we now find adorning the poultry-yard; whilst Mr. Blyth, who has had great opportunities of observation, adheres to the idea of one Indian species being the common parent of all the forms, sizes, and colours which exist. Notwithstanding this, however, there are circumstances which he acknowledges and points out, suggesting considerable difficulties in the way of establishing his theory.

As other naturalists affirm that the wild type of our tame cocks and hens has no existence, it is no more than fair that their reasons for entertaining such an opinion should be stated. Geological progress has proved that many species of beasts and birds have become extinct, and are now, instead of walking
POULTRY.

on the face of the earth, or soaring through the fields of the air, lying buried in the depths of the morass, or imbedded in the various strata which help to form "the great globe" which we inhabit. In the Geology of Sir Charles Lyell, we find a notice of some of the species that have become extinct in our own island. Besides those which have been driven out from some haunts, and, everywhere, reduced in number, there are a few which have been wholly extirpated; such as the ancient breed of indigenous horses, the wild boar, and the wild oxen; of which last, however, a few remains are still preserved in the parks of some of our nobility. The beaver, which was eagerly sought after for its fur, had become scarce at the close of the ninth century, and, by the twelfth century, was only to be met with, according to Giralda de Barri, in one river in Wales, and another in Scotland. The wolf, once so much dreaded by our ancestors, is said to have maintained its ground in Ireland so late as the beginning of the eighteenth century (1710); though it had been extirpated in Scotland thirty years before, and in England at a much earlier period. The bear, which in Wales was regarded as a beast of the chase, equal to the hare or the boar, only perished as a native of Scotland in the year 1057.

Many native birds of prey have also been the subjects of unremitting persecution. The eagles, larger hawks, and ravens, have disappeared from the more cultivated districts. The haunts of the mallard, the snipe, the redshank, and the bittern, have been drained equally with the summer dwellings of the lapwing and the curlew. But these species still linger in some portion of the British isles; whereas the large capercallie, or wood grouse, formerly natives of the pine-forests of Ireland and Scotland, have been destroyed within the last fifty years. The egret and the crane, which appear to have been formerly very common in Scotland, are now only occasional visitants.

"The bustard (Olis tarda)," observes Graves, in his British Ornithology, "was formerly seen in the downs and heaths of various parts of our island, in flocks of forty or fifty birds; whereas it is now a circumstance of rare occurrence to meet with a single individual." Bewick also remarks—"That they were for-
assumed that they left no doubt in his mind that the huge bird was one of the gallinaceous tribe."

When new species, multiplying widely, and requiring large supplies of food, are introduced into a country, the older tenants of the soil must necessarily be reduced by want, and some classes must be destroyed. The millions of wild cattle and horses which are established in the New World, from the latitude of 25° N. to 40° S.; the sheep and goats which have multiplied enormously there, as well as the cat and the rat, the latter having been introduced unintentionally in ships; the dogs which have at different periods become wild in America, and hunt in packs, like the wolf and the jackal; and "the many millions of square miles of the most fertile land, originally occupied by a boundless variety of animal and vegetable forms, which have been already brought under the dominion of man, and compelled, in a great measure, to yield nourishment to him, and to a limited number of plants and animals, which he has caused to increase; must convince us that the annihilation of a multitude of species has already been effected, and will continue to go on hereafter, in certain regions, in a still more rapid ratio, as the colonies of highly-civilised nations spread themselves over unoccupied land."

Those who have closely studied the poultry question have doubted whether living creatures do undergo, from generation to generation, such changes as would be evidenced by the conversion of a wild jungle fowl into the marked and distinct sorts which constitute our races of domestic fowls. "They doubt the progressive transmutation of species, and are more inclined to regard them as immutable. That animals do vary, they readily allow; but they also believe there is a limit to their variation. The pea-fowl, for instance, and the guinea-fowl, ought to have branched off into as many breeds as the common fowl, if the theory of derivation from the jungle fowl were true. These innovators also say that each creature has its natural disposition implanted in it from the first, which no art of man can alter; that there are tameable and untameable species of animals, unconquerably shy, and unhesitatingly confiding; that they are reclaimable, partially reclaimable, and utterly irreclaimable; and that those authors who, by a pleasant legerdemain, so easily transform one of the Indian galli into a barn-door fowl—who put the Sonnerat's jungle cock, or perhaps some quite apocryphal bird beneath a bushel, hocus-pocus a little, lift up the cover, and then exhibit a veritable chanticleer—write as if they had only to catch any wild bird in the woods, turn it into a court-yard for a week or two, and make it straightway as tame as a spaniel;—an educational feat as yet impracticable with most of the creatures which fall into our hands."

Taking these various arguments into consideration, it has been suggested that many varieties of fowl are aboriginal (though no longer to be met with in a wild state), and are not the results, but the proteges of domestication; that the wild race, the one which formerly ranged the primeval woods and jungles, is now extinct; and that many of our domestic animals are the survivors of extinct races—survivors, because domesticable—of exterminated, because defenceless creatures—and many natural historical difficulties vanish, and become reconcilable with what we see around us.

There are other theorists who think that the various breeds of poultry bear an analogy to the different races of mankind, as found in the different parts of the habitable globe. "Either," they say, "you must commit the heresy of asserting that Adam and Eve were not the common parents of all mankind, or you must give up your doubts about domestic cocks and hens. Either you must allow the native Australian man to be a distinct and peculiar species of Homo, or you must admit the more than probability of the Bengal jungle fowl being the original type of our domestic fowls." In meeting this argument, Mr. Richardson observes—that, "passing over the fact that no one wild original species of man is pointed out to fulfil the office of type to the existing human inhabitants of the world, in the same way as the Bengal jungle fowl is supposed to be for domestic fowl—omitting all that, it may be fairly remonstrated that the argument is not a generous one, inasmuch as it takes an unfair advantage of people's dislike to shock the feelings of others, especially in matters which, in the slightest degree, touch upon Scripture history; it is exactly the same kind
of opposition as was made to geological truths some years ago. Were an obser vant and reflecting naturalist, driven by pressure and persecution, to make such a recantation, it would be of as little value to his opponents, as a triumph, as Galileo's denial of his deliberate statement that the earth moved; and might, like his, be quietly followed by the private assertion that the earth did move nevertheless. But suppose that, to avoid the charge of insincerity and cowardice, our speculator were to seize the dilemma by one of its horns, and render himself liable to be suspected of believing the native Australian man to be a distinct and peculiar species; other naturalists, of deservedly high reputation, have previously entertained the same suspicion, and declared their doubts whether the negro and the European have proceeded from the same origin. It is impossible to say that much has yet been done in the way of taming and incorporating into civilised Anglo-Saxon society any one tribe of Australian natives. They still remain, as yet, both physically and morally undomesticated. What are the prospects of the aborigines of Tasmania? Even the more domesticated New Zealanders diminish in numbers, while they are trying to fall in with the ways of civilised life. Their constitution cannot stand it. Neither has the Red Indian proved a reclaimable animal. Captain Fitzroy's well-mean experiment with the boy and girl from Terra del Fuego cannot be called a successful one. Darwin's description of the wild men he saw there, in his voyage in the Beagle, impresses most readers with the idea of beholding a totally distinct species of human creature.

"Some people are bold enough to aver, that the more they consider, the more they are convinced that the solution thus given of the mystery about the derivation, or rather non-derivation of many domesticated from wild creatures, is correct; and they also feel equally assured that there are certain races of men, whom to concentrate and domesticate, is to destroy. Immense sums, and great pains have been extended on the education of children of the Australian aborigines. They are found docile; they learn to read and write, even more quickly than white children; but, as they attain the age of puberty, they either die, or take to the woods. A gentleman in Australia had two orphans, whom he saved amidst the slaughter of a hostile tribe. They were faithful even to death; one was killed at his side—but nothing could prevent them from periodically associating with their black brothers and sisters. The New Zealanders, on the other hand, are perfectly capable of civilisation; but, in spite of that, their numbers decrease."

The possibility that our domestic fowls are, perhaps, rather a chance possession than otherwise, is strengthened by the acknowledged fact that animals, in a state of nature, and unprotected, are liable to extermination, not only in consequence of the assaults of man, but from the persecutions of other species, often those most nearly allied to their own. A few years ago there was a violent onslaught made upon the hawk tribe, in consequence of their imagined propensity to destroy game. In some of the sporting journals and periodicals, letters appeared upon the subject; some fearing that the whole race of the Falconidae would fall victims to the cruel prejudice which had risen against them; whilst others rejoiced in the destruction of these beautiful birds. One of the latter says—"Your description of the hen-harrier is excellent, &c. You will, I have no doubt, remember how plentiful hen-harriers and other hawks were here, when we took the ground; you will therefore scarcely credit it, when I tell you that I have not seen a hen-harrier for the last two years; I have exterminated them by trapping them at the remains of what they killed themselves. In five years we have killed upwards of 500 head of vermin; and the result is, that we have now five head of game for every one we had on our taking the moors. We have had two merlins' nests here every year since I have been here. They build in the long heather, similarly to the hen-harrier; I have known them carry grouse poults to their young heavier than themselves. The sparrow-hawk builds in trees, and is very destructive to grouse in the months of April and May; she kills principally the hen birds, these being, at this season of the year, very slow and heavy in their flight, and consequently fall a very easy prey; I have trapped hundreds of hen sparrow-hawks at grouse and partridges which they had
POULTRY.

killed, but I never trapped the cock sparrow-hawk at the remains of a grouse or partridge, although I have frequently taken him with the remains of small birds that he had killed; I have known a sparrow-hawk take nine grouse poults to her nest in less than twenty-four hours.

I have seen the sparrow-hawk build for years in succession in the same tree, although the hen bird was killed every year, and sometimes both birds. They sometimes build in an old hoddie's nest. When they build for themselves, their nest is very similar to that of a wood pigeon."

Here is an instance, amongst others that we have already adduced in the progress of this work, of the exterminating war which is occasionally made upon certain species of the lower kinds of animals; these, however, sometimes find defenders, and several rose up to propitiate mercy for the doomed hawks. One who signs himself "Merlin," says—"Of your numerous correspondents who have given their vote against the poor hawks, but one has attempted to discriminate between the different species; and, although describing the most fatal mode by which each may be destroyed, he has not pointed out those against which game-preservers have no just cause of complaint."

In woodlands, the female sparrow-hawk, and on moors the hen-harrier (called sometimes the ringtail and gleed), are the only species deserving of death for any breach of the game-laws. The former bird does destroy a few partridges and young pheasants during the summer and early autumn (although its principal quarry is the young wood and house-pigeon); the harrier anything it can meet with, from a grouse to a frog upon the ground, over which it makes its daily beat. Against these birds, the pole-trap, so generally recommended, is almost useless, although certain to capture the harmless mouse-hunting little kestrel, as also the equally harmless long-eared owl, particularly when baited, as one correspondent advises, with a living mouse, which, he tells us, "is certain death to any hawk in the neighbourhood." One would have thought that this fact alone was sufficient to enlighten the writer as to the usual objects of pursuit amongst the birds he would exterminate. To the agriculturists the little hawks are of the greatest service, by destroying, in the course of the year, immense numbers of these true "pests of the farm," and if they ever do interfere with the game-owner's property, it is by picking up a half-dead chick or two, artificially reared under a hen confined to the coop, and therefore incapable of defending her charges.

To game, in a state of nature, they do no injury whatever. At certain seasons of the year, it would do little local good, even supposing all the charges against the birds were true, to destroy every hawk over a tract of country; because, being, like others of their feathered brethren, more or less migratory birds, the majority of those which, during the breeding season, frequent our woods and wilds, and elsewhere, and the comparatively few which remain in this country, shift their quarters before that period arrives.

We know how useless it is to attempt to argue against prejudice, and therefore shall refrain from pointing out how much enjoyment to the lovers of animated nature—and these are not a few—the presence of some of these victims to the game-keepers' art in the smiling landscape affords—particularly when, to this prejudice, is added the feeling which could prompt one writer to advocate the hanging of human transgressors "on the first lamp-post;" and in a subsequent epistle, when treating on his feathered foes, to recommend that the chain, by which the trap is secured to the pole, should be fastened about a foot from the top; by which humane contrivance, the hawk, when caught, is suspended mid-air by the mangled limb.

As there are a few remaining who still retain a love for the use of these birds, in the management of which, activity, both of body and mind, is required, it might be suggested to those who will catch them, that by the use of small traps without teeth, and where the jaws do not quite close, and are wrapped with some soft substance, as tow, profit may be combined with humanity; as they would find a ready sale of such birds as the peregrine, hobby, or merlin, if offered with unbroken limbs.

Were it not for the gamekeeper and the sportsman, the red-legged would soon get the upper hand of the grey partridge in many English counties; the Norway rat has made the black old English rat exceedingly scarce; and the mute swan of our parks and streams,
if carried to Australia, and suffered to fly wild there, would, in the course of years, drive the native black swan into as narrow quarters as the European settlers did the human aborigines of Tasmania. Domestication affords a refuge against this exterminating warfare, in which no quarter is given; but in which, species that refuse to accept the asylum, and which obstinately shout for "death or liberty," must take the consequences of their choice, and disappear.

A singular instance of extermination, as having occurred in modern times, is given by Mr. Richardson. "It happened in the island of Tristan d'Acunha, where poultry, introduced by the first settlers, became wild, and multiplied to an extraordinary degree. About 1822, cats having unfortunately been imported, began to multiply still more rapidly, and entirely destroyed the wild poultry, and much of the tame. Similar cases are very likely to have occurred in early ages, and point to the probable distinctness and antiquity of the present races of domestic fowls."

Having placed the conflicting theories before our readers, we may observe that the inquiry is not one of mere curiosity, but of secondary importance—though it is extraordinary, that our efforts to tame the pheasant, the partridge, and the quail, have proved unavailing. A fact of this kind has induced many to entertain the belief that the races of domesticated animals were never wild; and the following observations are not without weight upon this point:—

"In the first place, there is no evidence of a greater number of kinds of domesticated animals now in the world, than have been from the earliest period of history; and, in the next place, there have always existed as many kinds of domesticated animals as have been useful to man in his most civilised state. As the civilisation of man increased, so have the variety and quality of domesticated animals increased; but the number of their kinds has not enlarged. There were horses, asses, camels, dogs, cattle, sheep, and goats, in the days of Abraham, as well as now; and these constitute the largest proportion of our domesticated animals. Many attempts have been successfully made to tame single individuals of wild races; but such animals, though tamed, are in quite a different state from our domesticated animals. Some wild animals exhibit a degree of familiarity. The swallower builds her nest in our windows, and the robin enters our dwellings; whilst the blackbird and sparrow are constantly before us. This familiarity, however, does not amount even to tameness, far less to domestication. It appears, indeed, that wild animals are preserved unchanged, for the great purpose of Providence, throughout the globe, and that Nature has presented to man only such animals as are obviously most suited to his wants. With these he must be satisfied. What wild creature would be desire to substitute for any one of our animals? Should we desire it, Nature (i.e., the Creator) has placed such a barrier in our way, that it is impossible for us to make a single wild creature available to our domestic purposes. We may exercise our ingenuity, judgment, and even caprice, in moulding the habits and qualities of domesticated animals to our tastes, wants, and conveniences. There the field of experiment is open to us—not to an unlimited, but to a great extent; but Nature will not permit us to make a single predatory excursion among her wild animals."

Of the power of man to impress modifications of great apparent amount on the forms and properties of animals and plants, there is sufficient proof to be found in the field of the farmer, as well as in the garden of the horticulturist. Every ox, sheep, and pig; every plant and apple; every cabbage and cabbage-rose, is an instance of the case with which the natural constitution of organised beings may be changed, and of the wide difference which may be made from the progenitor of the stock, as it appeared when man received it from the hand of Nature. These changes, however, are only permitted, and not adopted by Nature, and endure only so long as man continues to extend to them his fostering care and supervision. Let him be taken away; let human labour no longer till the field, or prune the garden; tend, or feed domestic animals; and the scene soon changes. The natural war of the various tribes of the animal and vegetable worlds recommences. The species that had developed their secret powers whilst in a state of social alliance with the lord of the creation, when deprived of his assistance, are no longer capable of maintaining
their ground. The weak either perish, or are speedily destroyed, whilst the strong become fierce and pugnacious. The sheep and the ox become the prey of the dog and the wolf; whilst the garden-flower, renouncing the dress and habits of its artificial home, assumes those of the daughters of the field. All change. The bond which bound them together has been broken. The alliance has ceased between them; and the sweet flavour and beautiful exterior of the products of the orchard, are assailed by a democratic aggression of thorns and brambles. In this struggle they either perish, or preserve their place only by becoming as rude and as coarse as their neighbours. The crab, the sloe, and the weed may remain; but the fragrant apple, the luscious plum, and the curtiled cauliflower, are to be found no longer. Vicissitude has become the rule.

CHAPTER II.

THE DOMESTIC FOWL AND ITS VARIETIES; THE HAMBURGH; DORKING; GAME FOWL; SPANISH; POLISH; COCHIN-CHINA; MALAY; BANTAMS; RUMPLES; SILKY; NEGRO AND FRIZZLED; SCOTCH BAKIES; DOLTON GREYS; PARIS SHOW.

THE HAMBURGH.

In treating of the varieties of our domestic fowl, we will confine ourselves to such as may be deemed the most suitable for the collection of the amateur; and, where we can, endeavour to indicate their points of excellence according to the opinions of the best authorities. The first that we shall treat of are the Hamburgh fowls, which all partake of one common type, and which are remarkable for the beauty and purity of their distinct races. They are very fertile in producing eggs; are of moderate size; excellent table birds, but are non-setters. There are said to be thirteen points in a Hamburgh; but one of the most successful breeders of this kind of fowl, says—"That he never yet saw a bird possessed of the thirteen points which some of the Lancashire breeders say a good Hamburgh ought to have. In the silver-spangled variety the cock should have large white ear-lobes; a well-formed, compact comb, nicely pointed; breast regularly span- gled; back and hackle white; tail white, with perfect spangle at the end of each feather; legs slate-coloured; eye large; carriage erect. The hen should be one mass of spangles—the back spangled as perfectly as the breast; tail white, with spangles at the end; hackle span- gled or bled; legs, comb, &c., the same as the cock. The ground-colour of both must be pure white, neither muddy nor splashed. In the Northern and Midland counties, Hamburghs, both gold and silver, are more extensively reared, and more highly prized, than all the other varieties of fowl put together; although their constitution is considered, by many, to be less robust or hardy than that of some other breeds. In the pencilled, the cock should have comb and ear-lobes like those of the spangled; body (of the golden) a rich gold colour, with tail nicely bronzed. The hens pencilled from the hackle to the end of the tail; hackle of a clear gold-colour; comb, eyes, legs, &c., same as cocks." The points considered necessary by the Lancashire breeders, are thus given in the Rev. W. W. Wingfield's Poultry book:—

Comb.—Best double; best square; best piked behind.

Eyes.—Largest and whitest.

Neck.—Streaked with green black in middle of feather, fringed with gold at the edges.

Breast.—Largest moons; brightest green black, free from being tipped with white or red at the end of the moon; clear red from moon to bottom colour.

Back.—Ditto, ditto, ditto, ditto.

Rump.—Ditto, ditto, ditto, ditto.

Wing.—Four points:—1st, bow: bright green, black, and clear red. 2nd, bars: two distinct bars, formed by largest, clearest, brightest, green...
POULTRY.

black means; bright red from moon to bottom colour. 3rd. flight; clear red. 4th, the lacing or top of the wing above the flight: large, clear, bright, green black spots on the end of the feathers; clear red from spot to bottom colour.

Tail.—Bright dark-green black; full feathered.

Legs.—Clear blue.

General appearance.—Best feathered hen.

For a considerable time our knowledge respecting the different varieties of Hamburgh fowls was both imperfect and confused. Mr. Hallam, however, in his Illustrations, published at Birmingham, has done much to diffuse more correct ideas on this species of fowl; and as he is regarded as high authority on this subject, we acknowledge our obligations to him for the following observations:—

"Nothing, probably, has occasioned greater perplexity to the poultry fancier, or interposed more frequent obstacles to the satisfactory prosecution of his plans, than the multiplicity of synonyms by which the several varieties of Hamburgh fowls have been long known in different parts of the country. For a considerable time there appeared to be no help for him; and any efforts to identify one or other class, under the changing and arbitrary designations applied to them, were little less arduous than the attempts to determine who was 'Junius,' or 'the Man with the Iron Mask.' If he had any faith in books, he would naturally enough resort to some of the published treatises on the subject of domesticated birds, which, however, instead of extricating him from his difficulties, only 'darkened counsel by words without knowledge,' and rather added to, than lessened his embarrassments. The path of knowledge, proverbially rugged and toilsome, was, in this instance, beset with accumulated discouragements; and instead of receiving assistance, he was removed farther than ever from the attainment of his wishes, by finding, with one exception to be presently noticed, the objects of his search indiscriminately described as 'creoles,' 'pleasants,' 'corals,' 'moonies,' 'moss fowl,' 'Bolton bays,' 'Bolton greys,' 'Dutch fowl,' 'Chitteprats,' 'everlasting layers'—and so on, through a wearying catalogue of local and conflicting terms. To simplify the nomenclature of the Hamburgh fowls, and to apply to each of their specific variations such definitions as would be easily understood and universally recognised, was, therefore, a necessary undertaking; and it may be said to have been satisfactorily accomplished by the principle of classification laid down in the prize list of the great Birmingham Exhibition, which has become an authority in all matters of the kind.

"Of modern English Poultry books, that of Mawbray stands first in the order of time. He speaks of 'the coral, or Bolton greys,' as 'apparently the crack breed of their vicinity, but entirely unknown in the metropolis;' and appends a description of them, by the Rev. Mr. Ashworth, vicar of Tamworth, in the following terms:—'Small sized, short in the leg, and plump in the make. The colour of the genuine kind invariably pure white in the whole lappel of the neck; the body white, thickly spotted with bright black, sometimes running into a grizzle, with one or more black bars at the extremity of the tail: they are chiefly esteemed as very constant layers, though their colour would mark them for good table-fowl.'

"The Hamburghs are now classified in the Birmingham prize list as follows:—

2. Golden Spangled Hamburgh.
4. Silver Spangled Hamburgh.

The use of the terms employed to distinguish what were erroneously called sub-varieties, is entirely discontinued, all the Hamburgh fowls being included in the four classes thus enumerated. It should also be mentioned here, that all birds having crests or top-knots, are distinguished in the same list as Poland fowl; an arrangement now universally adopted.

"The Hamburgh fowls, however designated, have been for a considerable time, and still are, held in much estimation in this country, on account of their attractive appearance and great utility. The silver pencilled have met with zealous cultivators in Yorkshire and Lancashire, as 'Chitteprats,' and 'Bolton greys,' 'creoles' and 'corals' are the titles they have received in the South and elsewhere. They are handsome and prolific; though persons who have paid attention to them incline to the opinion that they are somewhat less hardy than the others. But when the situation and other circumstances in which each is placed are
exactly alike, such an impression may, after all, be more fanciful than real. Single combs may occasionally, at rare intervals, be met with amongst them; but when they are of pure blood, no variety of our domestic poultry transmits their own characteristics to their offspring with greater constancy. They are, at present, more frequently met with than the gold pencilled, to which they must yield the palm, so far as mere beauty of colour is concerned. In this respect the latter are not surpassed by any of the inmates of our poultry yards. The cock, with the rich metallic lustre of his sickle feathers, and the glowing hues of the rest of his plumage, is a peculiarly handsome and brilliant-looking bird. There is no difference between the two, except as to the ground or foundation-colour, which in one is golden, and in the other silvery white.

"Mr. Edward Lowe, of Comberford, near Tamworth, had a pair of the gold pencilled, which formed part of the pen which gained the first prize and silver medal for a cock and three hens, at one of the Birmingham Exhibitions. They were never shown elsewhere. This gentleman, who has been a very successful cultivator of the variety, gives the following results of his experience of them:—'I find that a hen, now twelve months old, which has laid about five eggs each week since Christmas, weighs exactly three pounds six ounces; and a cock bird, ten months old, weighs three pounds five ounces. If in good condition, and at full maturity, the cock should weigh at least four pounds, and the hens three-and-a-half pounds each. I have had them at these weights soon after moulting, and before the hens commence laying; but I find them produce such an excessive number of eggs, that they always feel lighter in hand compared with their apparent bulk, and no amount of food which they are able to take seems sufficient to keep up their flesh. I have never been able to ascertain the exact number of eggs that one hen will lay in a year, but I know that some of them have produced more than two hundred. Under very favourable circumstances, a single hen might produce at least two hundred and fifty; but I should say about one hundred and seventy would be the average for any given number of fowls. True-bred Hamburghs never show any inclination to sit; and this, which is considered by many one of their best qualities, might prove a serious difficulty to many poultry-keepers who are not able to keep another sort of hens as incubators. I keep a good many game fowls, and the two sorts work well together, though, of course, I am obliged to have them on separate walks, as the Hamburghs are very timid, shy fowls, and easily distressed. When the chickens are produced healthy and right, I always find them endure quite as much hardship as any other. For ornamental as well as useful purposes, the pencilled Hamburgh fowls are certainly unrivalled; and I decidedly give the preference to the golden variety, because they do not show the dirt in a wet season so much as the silver. Their plumage is equalled by none, and their symmetry and qualities of flesh are only surpassed by the game fowls; and they are the greatest producers of eggs of any breed we have."

In the formation of an estimate as to the relative value of particular breeds of fowls, it is important to consider not only the number of eggs which the hens will lay in a given period, but also the proportions in which they are likely to be produced at particular seasons. As chickens, the silver spangled are vivacious, hardy, thriving little creatures. They are thickly clothed with dark-grey down, presenting a mottled appearance; and it is not until they are nearly full-grown that the true character of their feathering is clearly manifest. The cocks are not unfrequently black-breasted, a peculiarity occasioned by the increased size of the spangles, and from the overlapping of the feathers concealing the white portions of them from view. Many persons do not object to breed from a bird of this description, and some of the very best chickens, both cockerels and pullets, have emanated from such parentage. According, however, to exhibition requirements, the breast of the cock must be marked in the same manner as that of the hen, or they will be deficient in an essential qualification. In some localities the taste runs in favour of a black breast; but, according to accredited standards of judgment, it is founded in error, and will not hold good. Their qualifications for the table are also very considerable; for although they are inferior to some other varieties as regards bulk, for firm plumpness they are unsurpassed.
**Silver-Spangled Hamburgh. — Male.**

Head of moderate size; eyes large and full; beak strong, pointed at the end, and slate-coloured; wattles large, and of a rich bright, transparent crimson, hanging freely. Comb large and double, but not overhanging the head; the points should be sharp, thickly set together, and not open or cupped; it should rise a little in the centre, narrowing behind, and terminating in a point; it should hang loosely, and move as the bird moves. The comb of the cock is much larger than that of the hen; but it should, nevertheless, be remarkably neat, and really ornamental, and not have the appearance of a heavy and unnecessary excescence. The ear-lobes should be large and well-defined, of a creamy white, and appear as if they were raised from the cheek. The neck and tail hackles should be a pure white, and full and long, covering together nearly the whole of the upper part of the body; but not too thick on the neck. The cock should be clearly spangled on the breast and on the lower part of the body; and the wings should also be marked with rows of spangles, and distinctly laced on the edges; the lacing being bold and unbroken — this forming a very important property. The sickle, and other principal feathers of the tail, should be pencilled in the centre of each feather, one half being black, and the other half perfectly white. The other tail-feathers should be of a rich blue black; the tail should also be full and well spread. The legs should be strong, and slate-coloured; a white or yellow leg would disqualify a pen of otherwise good birds. An average-sized bird, at his full growth, will weigh from four-and-a-half to six pounds, which some fine specimens may be found to exceed.

**Female.** — Head small, and snake-like; eyes bright, lively, and surrounded by a peculiar dark rim. Comb double, of moderate size, and upright; but so loose as to follow every movement of the bird, without hanging over the front or side of the head; the back part of the comb should terminate in a point; the projections on its upper surface should be small, sharp, and placed at equal distances; and its colour a bright transparent red. Ear-lobes white, and of good size. The neck feathers distinctly pencilled with black along the centre; each one of these markings extending, in width, to one-half the surface of the feather. The breast and the whole of the body of the hen, with the exception of the neck, should be clearly and distinctly spangled; the wings being also marked with rows of spangles, and regularly barred with straight lines or ‘lacings’ along the edges of the large coverts; the lesser coverts are laced round the edge. The principal tail-feathers margined with black, and perfectly clear and free from ‘mottle,’ or stain; the legs a clear slate-colour; tail spread out and elevated; and the carriage and general appearance of the bird should convey the impression of great vivacity. The ground-colour of the body throughout must be pure white, and the markings, whether pencilled or ‘mooned,’ an intense glossy black. An average-sized hen will weigh from three-and-a-half to five pounds."

The following is the basis, which is given by a "Dublin Amateur," of great experience, for judging these fowls:

**THE COCK.**

**Head.** — Surmounted with full, globular, floating crest, pure white, each feather pointed with black. — The comb rudimentary, or in two small *spicula*; the smaller the better. — The beard full and black, or pure white pointed with black.

**Hackles.** — Pure silvery white, each feather clearly tipped with black.

**Breast.** — The largest moons best defined black, most free from being tipped with white at the end of the moon; best and purest white ground-colour.

**Back.** — The largest and most distinct black edging, according to the size of the feather, on purest white ground.

**Saddle.** — Ditto.

**Wing.** — Divided into four parts: 1st, The shoulder: the best and purest white, with largest and most distinct black moons. 2nd, The bars: to have two distinct bars crossing the wing, composed of the largest, clearest, brightest, and best black lacing on purest white. 3rd, The flight: the cleanest and purest white. 4th, The secondary flight feathers: the clearest, best, and most distinct black lacing, on purest white ground.

**Tail.** — The fullest and purest white, most free from mousing, and most distinctly laced with purest black.

**Leys.** — The clearest and best blue.

**THE HEN.**

Identical in markings with the cock, except the head; the crest most globular, largest and purest white, with best and largest moons at the end of the feather.

**Golden.**

Descriptive points of both cock and hen the same.
as in the silver, the difference being only in the ground-colour variety.

THE DORKING.

Dorking fowls, comprising the Surrey, Sussex, and Old Kent fowls, attain to a heavy weight, produce eggs of considerable size, and are very superior table-birds. They derive their name from a town in Surrey, where they are bred and fattened in large numbers. Their leading characteristic is an additional toe on each foot. Their varieties, in which the fifth toe is absent, are known as the Sussex or Surrey—heavy, short, square, and plump fowls. Good hens weigh from seven to nine pounds, and cocks even heavier. They stand low on their legs; are wide in the breast, with plenty of white and well-flavoured flesh. The hens are generally good layers; and their eggs, smaller than those of Spanish, and larger than those of Polish fowls, are white and well-flavoured. In point of colour, there are pure white Dorkings, mostly somewhat smaller than the tinted birds. These, it is generally understood, require to be furnished with a double comb. Of the darker hues, there is a great variety; some are speckled birds, with white pea-like spots upon a rich brown ground; and the cuckoo Dorkings, banded with grey and white, are both very handsome and very highly esteemed. For coloured birds, either a single or double comb is admissible, though many fanciers of experience prefer the former.

In the Birmingham Prize Lists, all the coloured Dorkings have been classed together, without distinction of comb; but single and rose-combed birds are equally eligible. All the Dorkings are good incubators, though their heaviness and their extra member render them somewhat clumsy nurses.

A breeder at Dorking furnishes the following information in reference to these useful fowls:

The Qualities of the Bird.—There can be no dispute as to the size to which the white Dorking will grow, compared with the coloured birds; but, since the commencement of the poultry shows, there has been added, I should think, about 3 lbs. to their weight; and doubtless, with care, even this may be increased (if necessary), though I certainly think a fowl of five, six, or seven pounds' weight is quite sufficient for the table—in fact, the perfection of size. I have been testing several different breeds of fowls; and I think I can say, perfectly free from all prejudice, that no one will compare with a white Dorking at five months old—it is the very model of a perfect table-bird.

Their Laying Qualities.—They do not, as a rule, by any means enter into competition with the Polands, Hamburgs, or Cochins, as layers; though, during the season, they will lay a great many eggs, and these of a large size, and very delicate in flavour. By rearing early birds, eggs may be procured in winter, as the pullets generally commence laying in November.

As Sitters and Mothers.—In this department they certainly are unequalled, with the exception, of course, of the coloured birds. They sit remarkably close; are very courageous in the protection of their young; good foragers; and, what is a very great advantage, remain a long while with their chickens before turning them off.

Mode of Rearing, &c.—There is a prevalent idea that they are delicate; but certainly my experience will not indorse such an assertion. Last year I reared very few; but the year before, the results were these—seventy-three chickens hatched; one of these had to be cut out of the shell, and, wonderful as it may appear, every chicken was reared with the exception of this one, which was killed by the hen treading on it: so much for the delicacy of these birds. Of course, this was under as favourable circumstances as could be; that is, they were well and judiciously fed, kept scrupulously clean, and had a run on what is, perhaps, one of the most beautiful commons in England—I allude to the one called "The Holmwood," and which adjoins the town of Dorking. For the benefit of the mere novice, I will now explain our mode of feeding, &c.;—Let the chickens be undisturbed under the hen twenty-four hours after hatching, only taking care occasionally to remove the loose shells; after this time, place the hen under a coop, and feed the chickens with equal parts of hard-boiled egg and stale bread crumbs, well chopped up together; let the next meal consist of ground oats, mixed with either milk or water into a stiff crumbly mass; this to be followed by chicken grouts. Let the chickens be fed every hour varying the meals as above; at the expiration of a fortnight, a little crushed barley may be added; and, at the end of a month or six weeks, they may be allowed to run and fare as the older fowls—supposing, of course, that you feed all your poultry liberally, and with various foods. Pursue this plan; and when you see a hundred beautiful white fowls roaming over some green lawn or fields, I think you will have no cause for regret that you have chosen for your favourites a breed that can be equalled by none for its useful qualities, and is surpassed by few in beauty.

Till the Cochin-Chinas came into fashion, the Dorkings—whose proprietor had utility in view—held the highest place in all poultry-yards. The abundance with which they supply the London markets, both as capons and chickens, is incalculable; and the breed, notwithstanding the excessive favour shown towards its modern rivals, still preserves, in the estimation of buyers, a very forward place.
In Mr. Dixon's *Ornamental and Domestic Poultry*, we find the following remarks upon this kind of fowl:—For those who wish to stock their poultry-yards with fowls of the most desirable shape and size, clothed in rich and variegated plumage, and, not expecting perfection, are willing to overlook one or two other points, the speckled Dorkings are the breed to be at once selected. The hens, in addition to their gay colours, have a large flat comb, which, when they are in high health, adds very much to their brilliant appearance, particularly if seen in bright sunshine. The cocks are magnificent. The most gorgeous hues are frequently lavished upon them, which their great size and peculiarly square-built form display to the best advantage. The breeder and the farmer's wife behold with delight their short legs, their broad breast, the small proportion of offal, and the large quantity of good profitable flesh. When fattened and served at table, the master and mistress of the feast are satisfied. The cockerels may be brought to considerable weights, and the flavour and appearance of their meat are inferior to none. Those epicures who now and then like a fowl killed by dislocation of the neck without bleeding (the more humane way), will find that this variety affords a tender and high-flavoured dish.

"Dorkings are better adapted than any other fowl, except the Malay, to hatch superabundant turkey's eggs. Their size and bulk enable them to afford warmth and shelter to the turkey-poults for a long period. For the same reason, spare goose's eggs may be intrusted to them. But, with all these merits, they are not found to be a profitable stock, if kept thoroughbred and unmixed. Their powers seem to fail at an early age. They are also apt to pine away and die just at the point of reaching maturity. When the pullet ought to begin to lay, and the cockerel to crow and start his tail-feathers, the comb, instead of enlarging and becoming coral red, shrinks and turns to a sickly pink, or even to a leaden hue; and the bird, however well fed and warmly housed, dies a wasted mass of mere feathers, skin, and bone."

As a remedy for the above-mentioned weakness, a fresh, well-selected cock-bird or two should be introduced into the walk, every second or third year at farthest. With such precaution carefully attended to, the race will generally be much improved. The arrangement is the best that can be devised; but the necessity for adopting it shows that the cocks of this breed are deficient in vigour.

A high authority gives us the following description as a basis for judging the grey Dorking:—

**The Cock.**

**Body.**—Long and square; the back and belly, breast and behind, forming nearly parallel lines.  
**Head.**—Comb erect, single, rather low than high, serrated, free from cheek behind or side sprigs; waxy eyes orange-red; cheeks crimson-red; ear-lobes small, whitish; wattles turgid, rounded, not pendulous.  
**Neck.**—Hackles bright straw colour, either perfectly free from markings, or having the mid-rib black, and webs straw colour; if marked, markings must be distinct.  
**Back.**—Same colour and same markings as hackles.  
**Saddle.**—Ditto.  
**Wing.**—Shoulder clear straw colour, crossed with a broad, rich coloured steel blue bar; flight feathers white, having the secondaries spangled or partly laced with black on the inner web.  
**Breast.**—Largest, clearest, and best black, least splashed with white.  
**Tail.**—Very full, black, well carried, shot with iridescent colours.  
**Legs.**—White, shorter in proportion than other breeds.  
**Foot.**—Five-toed; the articulation of the hind and rudimentary toe to be perfectly defined.

**The Hen.**

**Head.**—Comb, when in high condition, falling to one side, serrated, free from cheek behind or side sprigs; waxy eyes orange-red; cheeks crimson; ear-lobes whitish; wattles rounded.  
**Neck.**—Hackles, mid-rib black; edges silvery white, well defined.  
**Back.**—Shaft white; webs minutely dotted with black on whitish ground, presenting a grey appearance.  
**Saddle.**—Same.  
**Wing.**—Shoulder same grey as back; shafts broad, and very distinct straw colour; flight, dark brown.  
**Breast.**—Reddish fawn colour.  
**Tail.**—Full rich brown, with minute black markings; edges approaching silvery.  
**Legs and Feet.**—White; toes, five in number; articulations clearly defined.

**Dorking (White).**

**Head.**—Comb single or double; if the former, subject to the same rules as the grey Dorking; if double, the duplicate to be distinct.  
**Body.**—Clear white.  
**Tail.**—Full and well carried.  
**Legs.**—Five-toed; articulation of toes well defined.

**Dorking (Pheasant and Speckled).**

Of doubtful purity; no markings to be relied on.

819
THE GAME FOWL.

The *Game Fowl* is, in the estimation of many, one of the most beautiful of birds. His flesh is excellent; whilst the hen is a fair producer of eggs, a good sitter, and attentive mother. Both male and female, however, are very troublesome, from the extraordinary combative qualities with which they are endowed. The cock has long been known for his fighting propensities; and mankind having early discovered this, made them administer pleasure to their own destructive tendencies. "Cock-fighting is indeed so old," says an article in the *Sporting Dictionary*, "that we hardly know whence to derive its origin. Asia, however, has the credit of first fostering it; and it seems to have been cultivated by the natives amongst their earliest games. The first records of China note it. In Persia, it was early encouraged, in conjunction with hawking and quail-fighting; nor was it to be wondered at, that, as man became belligerent, he would, in order to extend his conquests, commence his education by observing the offensive and defensive operations of animals, thereby the better to regulate his own. When Themistocles was engaged in warfare with the Persians, he was struck with admiration at the bravery and determination displayed in the battles between the cocks of that people; which was such as to occasion him to exclaim to his admiring army, 'Behold these do not fight for their household gods, for the monuments of their ancestors, nor for glory, nor for liberty, nor for the safety of their children, but only the one will not give way unto the other.' This so encouraged the Grecians, that they fought gallantly, and obtained the victory over the Persians; upon which, cock-fighting was, by a particular law, ordained to be annually practised by the Athenians. The inhabitants of Delos were great lovers of the sport; and Lanagra, a city of Bœotia, the Isle of Rhodes, Chalcis and Eubœa, and the country of Media, were famous for their generous and magnanimous race of chickens. It also appears that they had some peculiar method of preparing the birds for battle. Cock-fighting was an institution, partly political, at Athens, and was continued there for the purpose of cultivating the seeds of valour in the minds of youth. But it was afterwards perverted and abused, both there and in other parts of Greece, till it became a common pastime and amusement, without any moral, political, or religious intention, as it was, until lately, followed amongst us."

In his form and aspect, and in the extraordinary courage which characterises his natural disposition, the game fowl exhibits all that either the naturalist or the sportsman recognises as the *beau-ideal of high blood.*

He is somewhat inferior in size to other breeds; but his shape, approximates more closely to the elegance and lightness usually characteristic of a pure and uncontaminated race. Amongst poultry, he is what the Arabian is amongst horses, the high-bred short-horn amongst cattle, and the fleet greyhound amongst the canine race. Such being the character of this variety of fowl, it would doubtless be much more extensively cultivated than it is, were it not for the difficulty attending the rearing of the young; their pagacity being such, that a brood is scarcely feathered before at least one-half is either killed or blinded by fighting. Their elegance of form, and brilliancy of colour, however, render the breed objects of great admiration. They are of all colours; and each variety seems to have had its patrons, the rule being to mate the cock with hens of the same feather, or "rightly plumèd to the cock," as Spetchly has it. Deviations from this rule are frequent, as we find the same to be the case in all kinds of animals which have been reduced to a state of domestication.

When a cock is selected, he should be placed with from four to six hens, bringing them together in November or December. If he be young, the hens may be full-grown; if two years' old, then the hens may be young pullets, in the case of a strong breed being desired. Mark attentively how he bears himself to all his hens, as it frequently happens that one or other of them falls under his displeasure, in which case she should be removed. Choose the best-shaped eggs, and neither the earliest nor the last laid; and, to avoid mistakes, mark them, and place them under an old game hen—the old being excellent mothers. Their place for sitting should be private, and free from all annoyance or intrusion.

When hatched, the young should be regularly and often fed, in small quantities at a
time, after the first day or two. Their food should be:

- Macerated eggs boiled hard.
- Crumbs of white bread.
- Lettuce-leaves and meadow ants.
- Maggots from grains.
- Steeped oats and small wheat.
- Curds, with new milk.
- Bread, toasted, and steeped in chamber-ley.

The varieties of game fowl bred in this kingdom are very numerous, and, to the uninstructed, their designations very unintelligible. For the purposes of combat, the black-breasted reds have been the favoured variety. The recognised breeds are, according to Spetchly:

1. Black reds.
2. Silver black-breasted ducks.
4. Dark grey.
5. Mealey greys.
7. Spangles.
8. Furnesses.
10. Cuckeers.
12. Red duns.

"In all these," says Spetchly, "good birds may be found. From them, however, have been raised crosses innumerable; and it is the aim of the fine breeders of the present day, to have their birds as much as possible uniform in feather, blood, and constitution."

The best month for hatching game chickens is March, as it has been generally found, that when hatched in this month, they prove to be the most Hardy birds. We should state, however, that whatever may be their beauty and high courage, game fowl will be very troublesome in a poultry-yard of various breeds, especially if another chantecler is kept; for although their smaller size might lead to the supposition that they will not be the aggressors, this is a mistake. Their indomitable spirit forces them to quarrel with every other bird; and their activity and strength render them dangerous to the heaviest adversary.

**THE SPANISH FOWL.**

The Spanish fowl is one of the largest breeds; a productive layer of full-sized eggs; and, in the great majority of cases, a nonsitter. Its plumage is black; and it is a little smaller in size than the old "shakebag;" but in every other quality, in which excellence is to be expected, it surpasses that bird. The back of the Spanish fowl is tinted with a glancing green; whilst the feathers of the legs, thighs, and belly are particularly decided in the hue, and of a velvety aspect. In its carriage it is stately, having a grave and majestic deportment, such as might be supposed to become the monarch of the poultry-yard. When in condition, he is not only a beautiful, but a useful bird, with white cheeks, and large comb and wattles, very highly coloured. The legs are of a leaden colour, and so are the feet, except the soles, which are of a dirty fleshy hue. A full-grown cock weighs about seven-and-a-half pounds; the hen about six-and-a-half.

These fowls have long been established in Great Britain and Ireland; and exhibit no constitutional peculiarities which suggest difficulties in either hatching or rearing. As table-birds, they hold a place in the very first rank, their flesh being particularly tender and juicy; whilst the skin possesses that beautifully clear white hue, so essential in birds designed to be consumed by the gourmand. The hens are the highest class of layers; and of all the naturalised and indigenous varieties of fowl, they, with other sub-races of the same type, produce the Andalusians and Columbians, being the largest and best-flavoured eggs. Besides, they are prolific, and extremely easy to feed. Spurious specimens of this fowl are often in the market; consequently, a buyer should know all the points of a fine bird before he enters the market. To purchase a spurious fowl will cost as much as the other; will be as expensive to feed, but will not bring an equal return in the way of profit. By applying, in the first instance, to a breeder of known respectability, much disappointment will be avoided; and though the price demanded may appear high, it may not, perhaps, be higher than what would have been paid for a bad article. Even should a few shillings extra have to be laid out, it is better to do so willingly, as, in the long run, it will be found the most prudent plan. It may here be observed, that the addresses of the leading amateurs and dealers in poultry, may be learned by consulting the catalogues of the principal shows throughout the country.

Spanish fowls have occasionally changed their plumage, and become perfectly white.
A person writing to a sporting paper, says that he has seen a perfectly white Spanish hen which had once been entirely black; and inquires if such a thing is not very uncommon, and if any of his readers can account for such change; it had not the plea of cold, like the partridge and mountain hare. We have heard of several instances of a black Spanish fowl becoming a white bird; and recollect one exhibited at a poultry show as a white Spanish fowl, which we were told had undergone this curious change.

In forming a judgment of the excellence of the Spanish fowl, the following are the points to be looked at:—

**THE COCK.**

*Head.*—Comb erect, serrated, surface waxy, free from side sprigs or warts; not too high; face pure opaque white, as well over the eye as the cheek, separated from the comb by a distinct line of black feathers; ear-lobe pure white, free from pink or blue tints, and very large, meeting under the wattles; eyes orange; beak blackish horn colour; wattles long and pendulous; all the body black, brilliantly glossy; legs black.

**THE HEN.**

To match; distinctive marks the same, except in the comb, which should fall over on one side.

**THE POLISH FOWL.**

*Polish fowls* have a top-knot of feathers instead of a fleshy comb. They are generally non-sitters; lay medium-sized eggs; are of middle weights, and great favourites with the epicure. Why these birds are called Polish, or Poland, we are unable to say, as there is no evidence of which we are aware, to show that they originally were imported from Poland. They are birds which frequently exhibit great courage, whilst their beauty is unquestionably very considerable, although that property has, in one point at least, formed a subject of dispute. This point is the beard; but the best way of determining the merits of this appendage of the head, is by making both bearded and un-bearded specimens equally eligible to prizes. There is now only one class for bearded or un-bearded Polish of each colour—the same applying, in this case, as in Dorkings.

The impression, however, is, with many, that the ruffs, or beards, should be taken as one point in favour of the birds which are adorned with that appendage. Mr. Wright’s opinion is, that the bearded fowl will, in every case, be found to be the best in all respects. It is quite true, that while the un-bearded varieties have greater delicacy of form and plumage, the bearded are endowed with considerably more constitutional vigour.

“The favourite varieties of Polish fowls, are the Black, with white crests; the Golden Spangled, and the Silver Spangled. The Golden Spangled is of no ordinary beauty; it is well and very neatly made; has a good body, and no very great offal. On the crest, immediately above the beak, are two small fleshy horns, resembling, to some extent, an abortive comb. The wattles are small; the hackles on the neck are of a brilliant orange, or golden yellow; and the general ground-colour of the body is of the same hue, but somewhat darker. The thighs are of a dark brown, or blackish shade, and the legs and feet are of a bluish grey. The full-grown cock weighs about six pounds, and the hen five-and-a-half pounds; the eggs moderate in size, and very abundant. In the Silver Spangled varieties, the principal difference is, that the ground-colour is a silvery white. But the spangles themselves have been the subject of serious feud; and the Birmingham list now discreetly contents itself with calling them Golden and Silver Poland; which it has the greater right to do, inasmuch as the degree of disposition of the markings is not so rigidly laid down for Polish as for Hambrough fowls. Besides these, there are pure white Polands, entire dun-coloured Polands, and other combinations of hues. A much-desired variety—white, with black top-knot—like the common cuckoo, ‘tuneful bird, seldom seen, but often heard’ of—is to be met with in every Poultry-book, and would make the fortune of any one who could produce a pair or two alive.”

In England, these fowls are esteemed rather a fancier’s than a farmer’s stock. Their non-sitting disqualification renders them unsuitable for agricultural purposes; but their flesh is of the very highest excellence. They are reared in Egypt, in immense numbers, the practice of artificial hatching supplying the constitutional defect of the birds. A vast number of Polish fowls are bred in the department of Calvados, in France, especially in the neighbourhood of Caen, whence they are brought to Le Havre by various conveyances, for the supply both of the town and the shipping. No care is taken.
to keep the breeds pure, and they are found with or without beards, as the case may be. A warmer and drier climate than that of Great Britain seems to be more congenial to the Polish fowl. The chickens are very slow in growing, and it is difficult to distinguish the sexes at an early period of their life. Still they are exceedingly pretty objects, as they carry their little downy top-knots on the very day of their entrance into existence.

In reference to this fowl, one, who seems to have studied its nature and qualities, says, that in judging of the points of this kind of fowl, he would suggest the following as a good basis to go upon:—

**Fowls with Crests.**

Improperly called Poland or Polish; no record to be found of fowl so named.

**White-crested Black.**

*The Cock.*

Head.—Surmounted with a globular, floating crest, in two parts; smallest amount of black on forehead, and fullest and clearest white falling equally on all sides.—The comb rudimentary, in two small spicula.—The ears fullest and clearest white.—The beak, horn colour.—Wattles full.

*NECK.—* Best brilliant shining black, free from white or any other colour.

*Body.—* Ditto.

*Wings.—* Ditto.

*Tail.—* Ditto.

*Legs.—* Blackish grey.

**The Hen.**

Similar in all respects to the cock, the crest appearing more globular on account of a difference of shape of feather.

**Black-crested White.**

The reverse of the foregoing, believed to be extinct; the greatest desideratum of the poultry fancy.

**Creasted White Fowl.**

Description as to form of crest the same; the colour best and purest white.

The Sultan fowl, or Serai Tā-ook, is, by some, supposed to belong to the Poland species. "In fulfilment of a promise of long standing, to Mr. Tegetmeir," says an intelligent writer, "to send him the first Sultan fowl which should die, for the purpose of ascertaining whether these fowls are possessed of the peculiar conformation of head of the Polands, I lately sent a hen for post-mortem examination; and he stated, 'the structure is of that very remarkable kind, found in the Polands.' When the young chickens are hatched, the embryo crest shows itself as in the chickens of other Polands; and, in all their habits, they pronounce themselves of that variety. So much for their kind.

"The Sultan is a short-legged, plump, compact fowl of medium size. The tuft on the head is large, compact and globular; it has a muff, whiskers, and gravel eye. The plumage is abundant, and of a pure white. The legs are well hooted and vulture-hocked; there are five toes on each foot. It is a brisk, active fowl, and exceedingly ornamental.

"In their own country, Turkey, they are known by the name Serai of Tā-ook; literally translated, 'Sultan's Palace Fowls,' or 'Fowls of the Sultan's Palace.' The first fowls resembling the kinds which attracted my notice, were Dr. Burney's Ptarmigans; but they were very inferior to those imported in 1834 (which, with their progeny, have taken so many prizes since that time), being very poor in the crest, less compact in form, unmuffled, and without the fifth toe. But, like the handsomer Sultans, they were good layers of large eggs, and non-sitters.'"

**COCHIN-CHINA FOWLS.**

The Cochín-China fowl is of great weight; very prolific of eggs and young; a good incubator, but not of a decidedly good quality for the table.

This species of fowl, on its appearance amongst us, produced a perfect mania in the poultry world; and we are principally indebted to her Majesty and the late Prince Albert (who, in April, 1816, sent two fine specimens to the cattle-show of the Royal Dublin Society) for having first made them known to our poultry-yard.

Since that time the breed has been extensively cultivated; and now, whenever there is a poultry exhibition, the representatives of the celestial empire are sure of having a place. The large prizes awarded for these fowls, and the extraordinary prices they realise at public sales, show the excess to which a passion may be carried. At Kensington, a collection, consisting of a few birds (with their young chickens) which had obtained the prize and the extra medal at the Birmingham Exhibition in
POULTRY.

Cochin fowls.

December, was sold at what might well be considered fabulous prices. For a cock, £3 5s. was given; and for a hen, £5. The entire sale realised £100. At a sale by auction of Cochin-China fowls, in King-street, Covent Garden, and at another in Deptford, light buff-coloured specimens fetched the highest prices. A pair of chickens, hatched March 6th, the pullet being “fine and light,” fetched £3 17s.; “a light-coloured cock,” hatched in the same month, was sold for £2; “a beautiful light-coloured imported hen, 1851,” for six guineas; and another light-coloured hen, and a light-coloured cock, both hatched in 1851, sold for £5 each. Inferior specimens averaged about 10s. a head. The Deptford specimens were much too leggy to fetch very high prices. One lot, a light cockerel and pullet, was sold for £3 5s. “But what is still more extraordinary,” says Mr. Richardson, “we are assured that a gentleman, well known as a breeder near London, lately sold a pair of fowls for thirty guineas, and another for thirty-two guineas. The same person has been offered £20 for a single hen; and has sold numerous eggs at one guinea each. He has also been paid down, twelve guineas the half-dozen for chickens just hatched, to be delivered at a month old. Nay, we are credibly informed that as much as £60 per pair has been given for the pure breed. The collection of Cochinchina fowls formed by Mr. Andrews, of Dorchester, was sold by him to Mr. Catlin, for £250.”

From the circumstances, we may reasonably infer that the breed has, for some years, been pretty generally distributed over the eastern coast of Asia, and that to establish the precise place of its origin, would be a matter of considerable difficulty. This fact will, to some extent, account for the many spurious specimens, or impure-bred birds, which have been brought to Britain from the southern ports of China, as this is the district of the Malay variety of which we shall by-and-by speak. The birds, therefore, from Shanghae, are, perhaps, of the purest blood. At all events, to separate them into two classes is decidedly a mistake, as no sufficient marks exist to establish a Cochinchina as a distinct bird from a Shanghae.

The author of the Poultry-keeper’s Calendar, furnishes us with the following interesting remarks:—“There are, doubtless, many handsome and profitable kinds of poultry, in different parts of the world, which are unknown and unnoticed in England. In Russia, there are some which are so much valued there, that it is almost impossible for strangers to obtain from specimens having been early introduced by Mr. S. Moody, of Manchester, from that city. The terms Cochinchina and Shanghae are, therefore, used synonymously. Cochinchina is a country about one-third larger than the British Isles, and ranges from about 9º to 23º north latitude; while Shanghae is one of the most northerly ports with which we trade in the Chinese dominions, being situated in a much higher latitude than Cochinchina. It is quite possible that birds of this kind may have been imported from both parts of China, and have originally sprung from the same stock; or, if different varieties exist, there is certainly some difficulty in discriminating. As commercial intercourse has long been established between the Chinese and the Cochinchinese, either country may have imported them from the other. At Shanghae they are known by the term Loo-Choo— the name of a group of islands lying off the channel coast. It is also well known, that birds of large size, with feathered legs, and having all the principal features of these birds, have been imported to Adelaide, in Australia, from Singapore. Some years ago, they were in the very southern part of the Malay peninsula.

From these circumstances, we may reasonably infer that the breed has, for some years, been pretty generally distributed over the eastern coast of Asia, and that to establish the precise place of its origin, would be a matter of considerable difficulty. This fact will, to some extent, account for the many spurious specimens, or impure-bred birds, which have been brought to Britain from the southern ports of China, as this is the district of the Malay variety of which we shall by-and-by speak. The birds, therefore, from Shanghae, are, perhaps, of the purest blood. At all events, to separate them into two classes is decidedly a mistake, as no sufficient marks exist to establish a Cochinchina as a distinct bird from a Shanghae.

The author of the Poultry-keeper’s Calendar, furnishes us with the following interesting remarks:—“There are, doubtless, many handsome and profitable kinds of poultry, in different parts of the world, which are unknown and unnoticed in England. In Russia, there are some which are so much valued there, that it is almost impossible for strangers to obtain from specimens having been early introduced by Mr. S. Moody, of Manchester, from that city. The terms Cochinchina and Shanghae are, therefore, used synonymously. Some years ago, they were in the very southern part of the Malay peninsula.
them; and, in Turkey, the Cochin-Chinas were known and highly prized while still strangers here, having passed into that country by way of Asia. A few years back, while the Cochin-China fowls were yet unknown to me, and after I had met with only disappointment in an endeavour to discover, in the Spanish, the good qualities often attributed to them, I was told of some fowls to be found in Turkey, possessing size and other good qualities in great perfection, and, of course, became immediately very anxious to buy some of these rare birds. Several of our friends, at that time living in Constantinople, and their friends, kindly placed themselves in full pursuit of these wonderful fowls, but without success; and we were, after some time, obliged to give up the idea of having them. At length, one of our Constantinople friends came to London to see the Exhibition, and, on his return, I sent by him a Cochin-China cockerel and two pullets, as a present to his father. During the voyage, many persons from the different ports came on board to see these wonderfully large fowls, with a strange, unearthly crow; and, on the arrival of the ship at Constantinople, it was found that those were the very same fowls which I had been so anxious to obtain from Turkey; which had, however, become very scarce there, and which, if ever sold at all, were only to be purchased at an enormous price.

"About eight years ago, a young sailor, who had served in our family before he went to sea, brought me a fowl from the Cape of Good Hope, of a kind which I have never seen since. He (for it was a cock bird) was entirely jet black, with long scarlet wattles, and a very full roze comb; the shape of his head and neck was Malay-like, and his tail drooping. He was very upright in carriage, and he looked tall, even by the side of a fine Spanish cock. He was certainly very handsome. Of his other qualities I had little opportunity of judging; for very soon after I had him, he and his rival, the Spanish cock, got together and fought, although we had fancied them securely separated, and both ultimately died from the injuries which they then received. I never but once saw a bird like him, and which I have always thought must have been brought over at the same time; for the same sailor had two cocks with him in that voyage. This second bird I saw exhibited at a poultry exhibition in the Zoological Gardens, Regent's Park: he was mated with hens very unlike himself, and the coop was labelled 'Crow Birds.'"

In the essentials of size and power, the Cochin-China fowls excel every other kind of poultry; whilst the softness of their colour is the admiration of many. This generally consists of rich glossy brown, or deep bay, with an occasional mark on the breast, of a blackish colour, and of the shape of a horse-shoe. This mark, however, is not to be taken as an infallible sign of the breed. The comb is of a medium size; sometimes, but not always, slightly serrated; and the wattles are double. The plumage is bright, and has a peculiar softness to the touch; whilst the prevailing and most admired colours are buff, yellow, cinnamon, and grous.

In exhibiting the Cochin-China fowl, colour, beauty, symmetry, weight, and general excellence are of great importance. Various rules have been laid down for the guidance of amateurs in the purchase of these birds; and having been framed, the following general outline can safely be given:

1. Moderate length of legs, inclining rather to short than long. The legs yellow, or yellowish, in front, with reddish or flesh-coloured sides, and well covered to the toes with feathers. Fowls without feathered legs (that is, "not booted," to use the technical phrase), do not possess one of the essential characteristics of a first-rate bird. The more densely the outside of the leg is feathered, and the nearer in colour the leg feathers are to those of the other parts of the body, the greater the beauty, so far as the booting is concerned.

2. Head, rather small and narrow; face red; comb somewhat diminutive, single, and not too deeply serrated; even (i.e., not bent in and out) and upright.

3. Tail very short, so as to be almost buried in the rump feathers, especially in the hen. Pure Cochin-China fowls have no "scimitar tail-feathers." Some were exhibited at Lewes, which had these feathers naturally, and were, therefore, disqualified.

4. Wing, the extremities of which should be almost hidden under the breast feathers before, and by the saddle feathers behind.
5. Body deep from back to breast; wide on the rump, and very broad behind, which part, as well as the thighs, ought to be covered with downy feathers, in such abundance as to give them a very large appearance. Tail and wing very small; thigh remarkably thick, and the stilt short; dense fluffiness of the stern and thighs; legs well-feathered, or booted, down the outside.

In matters on which there are many opinions, it can never be an injudicious plan to give what are esteemed the best, by those who have a large acquaintance with the subject of which we are treating. Accordingly, from others which we will presently give, we select the following for insertion here, as being from an amateur of great experience:

“The cock bird is of a dark-red colour, with a dark hackle, edged with yellow; very fluffy about the thighs; each fluffy feather presents a very peculiar characteristic—viz., being semi-double, or as if it had been split from the apex to the base (I have never found the feathers thus in half-bred birds); the wings very short, and doubled under; comb single serrated, but not deeply so; legs short, flesh-coloured in front, pink down the sides, and somewhat feathered; a few sword feathers in the tail; the crow generally ending in a prolonged kind of roar; weight about 10 lbs. Hens partridge-coloured; lay abundantly, very dark, middle-sized eggs; weight about 7 lbs. or 8 lbs. each. Chickens feather slowly; cockerels even more so than pullets. When about three months old, cocks weigh 4½ lbs.; hens, 3 lbs. to 3½ lbs. each: roost on the ground at night; all of a quiet disposition, seldom or never fighting. Hens excellent sitters and kind nurses.”

The remarks of Mr. Trotter, of Henley Mill, near Hexham—written in further illustration of the Essay for which the Royal Agricultural Society, in 1851, awarded him a prize—merit notice here. They are valuable, as coming from a gentleman of great practical experience, who carried off several prizes at the Northumberland and Durham Society’s show, for the best Cochins, Dorkings, Spanish, and Pencilled Hamburghs.

“Beneath the vent,” he says, “there is a much greater abundance of fluffy feathers than in other varieties of fowls. The feathers on the thighs also partake greatly of this fluffy nature. The outside of the legs, and the outside toe, ought to be profusely covered with feathers. The wings are so short as almost to deprive the birds of flight; in fact, it is with difficulty they can mount a balk two feet high; it is therefore necessary to have the balks where these fowls are kept, even lower than I have already recommended. These fowls having great length, breadth, and depth, attain to almost incredible weights, averaging about 11 lbs., if good specimens. The hen weighs seven, eight, nine, or even sometimes as high as 10 lbs.; but as some commence to lay much earlier than others, a greater difference prevails in their weights than in those of the cocks.

“The most esteemed colour of these fowls is ginger; but as there are pure bred birds of almost all colours, including black and white, I am in favour of selecting them as much by their shapes as by their colour. No judge of ‘short-horns’ would, when acting in that capacity, give preference to an animal of fine roan, the shape of which was less perfect than one of a less admired colour—such as red or white—providing the character of purity were evident. Neither do I think any judge of fowls ought to give advantage to any Cochins on account of colour, if the shapes are less perfect than others of less admired colours. The colour of the legs varies in different specimens; but a pinky is most admired. Their eggs mostly partake of a chocolate colour, but differ very much in deepness of hue: some approaching almost to pink, while others are only a few shades removed from white.”

As a basis for forming a judgment, the following points are given by a Dublin amateur:

**The Cock.**

*Head.*—The beak, in the lighter varieties, yellow; in the darker, horn colour. —Eyes pearl, or orange red. —Comb low, single, serrated, free from sprigs, and smooth. —The wattles full and round. —Earlobe very full, falling to a level with the wattles.—Face brilliant crimson.

*Neck.*—Orange, varying in tint according to variety.

*Back.*—In the light-coloured varieties, orange; in the dark, orange marone.

*Wing.*—Shoulder, and throughout, graduated tints of orange yellow in the light colours; in the dark, orange marone; flight feathers bay.

*Breast.*—In light colours, buff; in partridge-coloured, brown, with dark markings, sometimes pheasanted; in grouse-feathered, black breastad.
### COCHIN-CHINA FOWLS.

**Tail.**—Black, scanty, and drooping.

**Legs.**—Feathered to the toes; yellow; the skin, in the dark varieties, inclining to red at the back.

**Wing.**—In the lighter varieties, pale yellow, free from blotches of dark colour.

**Thighs.**—Fully covered with long loose feathers.

**THE HEN.**

**Head.**—Small; comb single; eyes pale orange, or pearl colour; wattles same as cock, but smaller in proportion.

**Neck.**—Graceful; small at the insertion of the head. In the lighter varieties, the hackles graduated tints of pale orange buff; the lower feathers brown in middle, outside webs orange. In the lemon colour, free from marking. In the partridge, mid-feather brown, edge golden.

**Black.**—In the lighter varieties, gradations of yellowish buff, according to class. In the partridge, brown, with yellow shaft and light edge. In the grousse, a darker brown.

**Saddle.**—Ditto; feathers very long and loose, almost obscuring the tail.

**Tail.**—Brown.

**Wing.**—Yellow; well feathered to the feet, according with body colour.

**Thighs.**—Very full-feathered; webs long and disunited.

Of the gentle disposition of the Cochin fowl, much has been said; for it seems quite averse to any display of pugnacity; whilst it may, with safety, be inclosed within a fence of not more than three feet high. From this circumstance, its desire to wander cannot be deemed very great. There are instances where it has been kept in a flower-garden, in a space of about thirty feet long and twelve wide, inclosed by galvansised iron network only three feet high; and it never attempted to get over. The feathers of the wings being short, and well doubled under, or clipped, entirely prevent its flying, or "over-leaping" a fence.

An amiable trait in the character of Cochin fowls, is the tameness which they evince in all their relations with man. Domestication, in their case, seems to be brought to the highest perfection: as they will not only readily feed from the hand, but permit themselves to be handled without betraying the slightest uneasiness. At first sight, however, they do not seem so attractive as other fowls. In this country, we have had, constantly before our eyes, clean-legged poultry, with plenty of tail: it is therefore some time before we become accustomed to this eccentricity; but when the eye has become used to it, there are no finer-looking birds in the poultry-yard than they are—the cock birds weighing from 10 to 12 lbs. each, and the hens from 8 to 9 lbs. In the specimens, the cocks are best—upright fellows, square built, and abundantly feathered on the legs and thigh, with only a bunch for a tail, and a bright crimson saddle. Long golden-reddish feathers fall over each side of the back, just beyond the wings. The hens have a very small tail, and the fullness of the thigh is more marked in them than in the male bird. The crow of the cock birds is not like that given by the common chanticleer, but ends with a note similar to the growl of a dog.

It is not unnatural for the Cochin-China to roost; but their wings are so defective, that they cannot attain any considerable height by flight; and, if enabled to mount up by a ladder, they are apt to main themselves in leaping down. A bench, with a top, six inches broad, and raised a foot from the ground, with the floor swept out, and fresh sand every morning, is the best roosting-place that can be made for them.

There appear to be several distinct varieties of the Cochin-China race, some of them being square-built, and others resembling the Malay; which are considered the purest breed. The latter throw out the indispensable single comb, before and while laying, and, to a great extent, lose the Malay-like appearance about the head. The white Cochin-Chinas are a splendid variety, of robust shape, and equally hardy with the others. There is also a variety termed the "Lovell breed," which, for fullness of breast, generally surpass all others; but the breed is scarce. A careful and judicious cross between the large Shanghai birds and the Cochin, has been found to improve the progeny in size and constitution; but, for breeding purposes, the shortest-legged Shanghai must be selected, and those with most of the properties of the Cochins.

A correspondent of the *Cottage Gardener* says, that he succeeded in producing, from a very large imported hen, and a magnificent cock, three or four decided grouse-plumaged pullets; and so definite is the colour, he says, that strangers, one and all, exclaim, "How like the grouse!" They are large, strong upon their legs, and have the usual quiet demeanour of the Cochin. The dark-red and partridge-coloured cockerels, which attain to a considerable bulk, are preferred by some; while others
prefer those of a medium size, deep in the breast, broad across the back, and with short legs. Putting aside all these minor points, however, which are mere matters of taste to the fanciers of these fine birds, we may safely say, that the light-coloured varieties are in general highly prized; while, for strength and weight, the dark birds are superior; but for beauty, the yellow, fawns, and buffs carry off the palm. Red cocks, with hackles of a uniform gold colour, produce a variety of good light birds, especially if with light hens, and thus materially strengthen the stock.

In rearing and keeping these birds, rice, boiled and kept well, and stirred for six minutes, so that the grains are separated one from another, should form a portion of their food. When young, it is particularly grateful to them. In the spring, when the hens are laying, the most suitable food is the best heavy barley, with occasionally a few oats and wheat, and, once a-week, some offal meat, such as sheep's pluck, well cleaned and cut in pieces; sheep’s noses, with the hair scalded off; worms, plenty of chickweed, and now and then a cow-cabbage.

When moulting, barley, oats, wheat, Indian corn, and soft meat of barley meal, with the best sharps, mixed rather stiff together—not exactly scalded, but made up with warm water—should be given. Fowls are fond of a variety of food, and like it frequently to be changed; but for staple food, give them the best heavy barley. Put some lettuce-seed into the ground early, and, as soon as fit, transplant in a warm place. Give the fowls plenty of these, as well as cabbage-leaves, as they like most kinds of green meat. To be kept up, they must have their meat constantly by them. It will not do to feed them at stated times, for then they glut themselves, and do not lay so well; whereas, if the food is by them, they take it regularly.

In rearing chickens, much attention must be paid to their food, giving them frequent changes, and tending them with great care. Bread scalded in milk, rice, grits, barley; and, for a change, put some rice into the side-oven with water, leaving it to be scalded only to such an extent as will make it separate or granulate easily; the same with barley; and as soon as the chickens eat well, let them have barley-meal. They should also have, once a-day, some chopped meat, such as beef and mutton; and of chopped green meat, such as lettuce, they will eat abundance.

An eminent writer on poultry states, that he allows three pints per day of grain to twelve fowls, besides a dish of potatoes, and a quart of middlings made into porridge. He also gives them the run of a small orchard a few hours each day.

To attain those heavy weights for which this breed is distinguished, the birds must not only be liberally, but judiciously fed. To the growing chicks, the materials necessary to form bone, as well as flesh and sinew, must be supplied. "At Birmingham, a cockerel, otherwise perfect, was supposed to have suffered some injury or fracture in the legs; but he was only rickety. His frame abounded in all requisites, except phosphate of lime, which, of necessity is a great essential. It should be remembered, that quadrupeds suck in this building-material of their skeleton with their mother’s milk, which contains it in sufficiency; but that gallinaceous birds, to attain weight and corpulency, must take it with their food. Therefore calcined oyster-shells, broken egg-shells, chopped bones, pollard mixed stiff with milk, and such like, should be allowed to be freely eaten ad libitum."

The whole of the Cochin-China race are excellent layers—a circumstance which, in an economical point of view, adds greatly to their value. With the exception of a short interval at moulting, they lay the whole year round; and a supply of young pullets would produce eggs even at the time when the old ones cease laying. A hen exhibited by her majesty at a Dublin show, laid ninety-four eggs in 103 days. Pure birds will generally lay from thirty to thirty-five before wanting to sit. The number of Cochin eggs laid at poultry shows, especially when the exhibition is one that happens to be open for several days, and the fowls, therefore, have to be on the spot some time before and after, is surprising. But this may not be a subject of wonder, when it is recollected that most of the birds are in the best possible health and condition. On such occasions, the poor things are sadly puzzled to know what to do with their inconveniently-timed produce; and to see a hen,
POULTRY.

after a few moments of uneasiness, carefully roll her possible chicken up into one corner of her pen, frequently affords considerable amusement to the looker-on.

As to the fecundity of the China fowl, it is thus testified to, by the Rev. W. W. Winfield. He says—"A remarkable instance of the merits of Cochin-China, as layers, has just come before me. A young Punchard hen was brought home on the 24th of last December. She laid on the 25th, and continued to do so, till, in 96 days, 95 eggs were laid: 10 more eggs were then laid in 20 days—making, in all, 105 eggs in 116 days; she then sat and reared a brood." Mr. F. W. Rust, of Stonemarket, Suffolk, says that he had a hen, which, on two occasions, laid two eggs in one day; the first time on the 16th of April, within three hours, and the last on the 12th of June, within the hour. Captain W. W. Hornby, R.N., of Knowsley Cottage, Prescot, Lancashire, reared pale buff-coloured Cochin-China cockerels of the very first class; and states that one of his hens laid two eggs in one day, but that she did not lay on the following. The eggs of the Cochin-China are not quite so large as those laid by the Malay, and the colour is generally a pale chocolate, or yellowish-white; but some are nearly white. They have a very delicate flavour.

An essential object in the hatching of these birds, is to infuse fresh blood into your stock, by purchasing a fine young cock, or eggs of good breed from some party on whose stock reliance may be placed. As eggs obtained in town are often inferior, try to get them from the country; and, if possible, see the parents. The eggs will carry perfectly safe, if placed in a box, with the large end uppermost; and well bedded in bran—not sawdust, as the turpentine may injuriously affect them.

The usual time of sitting and hatching is from nineteen to twenty-two days; but it may be a day sooner or later. If, however, an unusual delay takes place, it may be attributed to staleness of the eggs, or unsteadiness of the sitter at the commencement of sitting. Sometimes young chicks, from various causes, die in the shell, either from some fault in the parent birds, or the eggs having been stale; from want of warmth or steadiness in the sitter; or from their being put in a situation which is too dry. But the same mischances are likely to occur with other birds. If the eggs are fresh, they do not require a longer time for hatching than those of ordinary fowls; but instances have occurred of a couple of days longer being required for the purpose of incubation. As sitter and nurse, the Cochin-China hen is decidedly superior to the Malay, the length of the limb of which makes her an awkward sitter, whilst it also renders the task irksome to her. The hens should be set early in spring, and not later than the middle of April. But if in March, it allows a chance of mild open weather during April; and the birds will be finer grown in the ensuing autumn than if hatched later. Cochin-China hens are kind and attentive mothers to their young brood, and generally remain with them for a week or ten days after beginning to lay, which is usually one month after hatching.

Mr. Bronghton Kingston, of Exeter, a successful breeder of the Cochin fowl, gives the following results of his experience:—"I commenced with a pair of young fowls, whose grand-parents were imported birds. The pullet began to lay on January 14th; on March 3rd she hatched sixteen chickens, and again began laying when these were five weeks old. On May 27th she brought out another fine brood, and recommenced laying in about a month. On August 12th she hatched a third brood; and in six weeks laid again. In October she wished to sit a fourth time; but, being so late in the season, I prevented her. On the 13th of December, 1851, she again began to lay, and continued to produce her daily eggs, having laid, that year, 104 eggs. Of the March brood, some of the pullets began to lay when about eight months old; and several of the cockerels weigh about 9½ lbs.; cockerels of the May brood, about 6 lbs. As regards the hardy nature of the breed, I need say no more than that I have not lost a single chick from illness."

After setting his hens, the breeder should be careful to have them off their nests at stated times, and see that they are liberally fed with barley and soaked bread. The strongest chickens come from the eggs of hens twelve months old, or the second season of their laying. To have a healthy stock, cock birds should be changed every two years, and never
be bred from the same stock, if it can be avoided. By this method the quality of the breed will be kept up. It is quite as easy to have good birds as mongrels. Chickens, to be large, must be abundantly and nourishingly fed, on the same principle that a race-horse, from the day he is foaled, has his milk-cows kept for him. At ten weeks old, they are just at the age when they have scarcely a feather to cover their nakedness. After this age, however, if they are kept warm, and fed generously, they speedily become covered with feathers. They usually prefer oats to barley, which are, in some respects, better for them.

The principal circumstance in which the treatment and management of the Cochin-China fowls differ from that of the lighter varieties, is in the mode of their roosting. They do not require to be coddled. At Shanghai, the winter weather is, at least, equally severe as it is with us in England. The vacant space beneath the greenhouse stage, makes an excellent winter roosting-place. If kept clean, and they are prevented from getting into the house, there will be little fear of their injuring the plants.

These heavy birds, indeed, should not be allowed to ascend a high perch. Those permitted so to do, invariably become deformed in the breast-bone; and have an unsightly appearance, independently of their health being greatly impaired. When a hen's ladder is placed against the perches, the fowls will make use of it in mounting to roost; but in coming down, they almost always use their wings alone. Many persons attribute this deformity in the breast-bone to injury sustained in these hasty descents (which are often as bad as a fall); but it proceeds rather from the great weight of the fowl bearing upon one point for so many hours together. Where this is the case, either high or low perching is likely to be injurious. But, be this as it may, high perching is proved to be so, to heavy fowls.

Broad perches, near to the ground, are sometimes provided for them; but a bed of straw, either on a wooden platform, or in a basket, so large as to avoid any danger of injuring the plumage, is to be preferred. The straw should be shaken up, cleansed every day, and renewed once a-week, or oftener, if necessary. The purchase of this straw occasions an additional outlay of money; but this will be found no loss to those who have even a small garden, as the rotted straw, mixed with fowl's manure, forms a valuable addition to the dung-heap.

When ordinary care is taken of the Cochin fowl, it is not found more delicate in habit, or more difficult to bring to perfection, than any English fowl; and the chickens are quite as easy to rear. Cross-bred chickens are sometimes very delicate, subject to roup, and difficult to raise; but this is seldom the case with the pure breed. On the contrary, these are generally thriving, and hearty-feeding chickens. Where common poultry are fed twice a-day, it is desirable to feed the Cochin-China three or four times, and to give the food so abundantly that some may be left after the fowls have satisfied themselves.

Viewing Cochin-China fowls as subjects of profit or loss, it has been contended that the Polish fowl may be more profitable than some of the Cochin-Chinas; but, if they are fed alike, it is certain that the best Cochin breed will surpass the Polish in the number of their eggs. Some are of opinion that the Spanish are a more profitable variety than the Cochin; but a gentleman, who has paid much attention to the subject of profit and loss, says, that "after a fair trial of almost every breed—the Spanish being the last—I have given them all up but the Cochin-Chinas, and now keep no others. From March, up to the 1st of May, I have hatched 131 chickens, and disposed of a large number of eggs—all from six hens. I have now chickens, hatched the first week in February, weighing 9 lbs. per pair; and one of the pullets laid an egg before she was four months old."

It has frequently been asked, whether the brown or white Cochin-China fowls are the more productive?—and whether the latter are so superior to the former as the great difference in price would lead us to expect? But no very marked difference in productiveness has yet been observed. The extra price is asked and obtained for the rarity of the colour—many fanciers being willing to pay something more for an article which their neighbours do not possess. The same conventional value is attached to most other objects of fancy.

Cochins are highly esteemed as table birds; and, as such, may be turned to profitable account. The great size and weight which they
attain, at a very early age, render them desirable for the table; and they cost but little for food in the short space of time required for rearing them. As four months old, there should be no difficulty, under ordinary circumstances—allowing a good run and fair feeding—in getting pullets to three-and-a-half pounds, and the cockerels to five pounds, live weight; and, by being then cooped, they may, with ease, be grown still larger. In flavour they are most excellent, and their tenderness is unsurpassable. Another valuable produce of the Cochin-China fowls, and consequently a source of profit, is their feathers, which are nearly equal to goose down.

All circumstances considered, in reference to the Cochin fowl, it may safely be said that it is the most profitable for the poor man and the farmer; viewing it, not as an object of fancy, but as productive stock. The early period at which the pullets begin to lay, is capable of being turned to valuable account by thecottager while getting his stock together, by the restoration, during the scarcity of winter, of the little capital expended during the year. Thus the owner, who has raised or purchased chickens in the spring, may obtain a brood or two late in the summer, or early in autumn, and have chickens ready for the table about Christmas, which might partly or wholly replace his original outlay.

If any of the fowls exhibit symptoms of disease, a jalap pill should be given, and they may be crammed a little with stiff barley-meal.

The whiteness, or searby appearance of the cocks' comb is a kind of disease which does not appear seriously to affect their health; but it greatly mitigates against their appearance, and should be taken as a true sign that the birds are not in a perfect condition. The disease is not confined to the comb only, but spreads itself down the neck, both before and behind, denuding it of its feathers, and leaving only their stumps. For the cure of this, some have considered high-feeding to be best; but the following recipe has been given by Mr. Payne. He says—"A lady friend of mine, who has just returned from India, after a residence of eight years, happened to see my fowls, and told me that the 'Kulm fowl'—which I believe is the 'Malay,' and of which she kept a considerable number in India—was subject to the same disease, and that the natives, upon discovering it, applied coco-nut oil and turmeric. She strongly advised me to do the same, which I did immediately, and with the most complete success; for it stopped the spreading of the disease at once, and very soon restored the comb to its original colour: but for the return of feathers, I must wait till the moulting season."

An experienced amateur thus speaks generally of the Cochin-China, or Shanghiae fowl:—"A great deal has been said and written about the colours and tints of these fowls. I say tints, because even the buffs are subdivided into lemon-buffs and buffs proper; and if it may be included in tint, as it is allowed to be equipotential in merit, to the cinnamon. Then we have the various grades of shade, till we come to the downright partridge colour. Some amateur, or some scientific colourist, should take the lead, and lay down a new scale of degrees in this matter; it would be useful, and, I opine, it would be acceptable. Supposing such a one should say at once—There are three grand divisions of these coloured birds; viz., the buffs, the cinnamons, and the partridge-browns—not forgetting the whites and the blacks of this race. These three divisions of coloured birds are again subdivided into the self, the pencilled, and the spangled, or mottled, buffs, cinnamons, or partridge-brown. I do not see why a pencilled bird should not be as good as a buff-coloured one: they are as fine in the buff and feather, and decidedly, as I could show by reference to my own stock, much prettier specimens. I have two pullets of one year, and another of the year preceding, of exquisitely fine buff, charmingly pencilled (almost as richly laced as a gold or silver-laced Bantam), and of fine shape and luxuriant proportions—of finer development, as a whole, than any I possess. But, however this may be determined, one thing is very certain—no yard will ever remain, throughout the year, as it may be constituted in spring. Shape, size, gait, and weight, may be assumed as permanent characteristics; not so feather. In the birds of the air, and of the water, and many others, as the ostrich, the emu, &c., feather is as invariable as the other characters. But either it never was so from the creation, or it has become otherwise from circumstances
and time immemorial, that the domestic races of poultry vary their plumage ad infinitum. Not only do white or black Bantams, cuckoo-Dorkings, and game-fowls sport in the feather, but the more uniform breeds, the black Polanders, the Minories, and even the Spanish, take a white speck spot, and even feathers, when the fit is on them. So with the Shanghaies. The breeder may start in spring with buffs, cinnamon, or partridge-coloured parents, and their progeny in November will display all the colours of the rainbow, except, to be sure, the blue. Nay, they may put on the affirmative of due proportions of the whole as white, or the negative as black specimens. The yard may be kept to one colour by cutting the sporters, and the propensity to sport may be checked, but, I believe, never subdued. Fancy must direct choice in colours, and the leading fanciers will give the éclat to their preferred colour. It is true that the lighter tints are of the more delicate feathers, perhaps of the more delicate flesh. But the dark birds are the finest, largest, and, almost invariably, the fairest specimens, which are, at the same time, of good growth and weight, of good buff colour, and so rare, that they are very highly prized.

"The Cochin-Chinna, or Shanghai fowl, which has made so great a noise, and brought about so great a revolution in poultry-yards and poultry shows of late years, may possibly retire from public estimation with no less silence and rapidity. For, unquestioned as its novelty of form, beauty of plumage, and gentleness of disposition and manners are, its usefulness as a supply for the tables of the upper classes, though not as a contributor to the couch and the pillow, by its soft and silky redundance of fluff and feather, have been long under anxious consideration. It is well to speak of the game-like flavour of its delightful flesh, and to dilate on the pounds avoidupois which they individually rise to. Is it as well to be silent upon the large proportion of offal?—to ignore the fact of the boasted game-like flavour being unattained by the shortness of substance so acceptable to the refined palate?—to be blind to the colour, and insensible to the pachydermy? Regarding them as such exceedingly pleasant inhabitants of the yard, and ornamental to the lawn and the pleasure-grounds, we grieve over the defects we are bound in candour to admit. The frequent announcements of salesmen and auctioneers, of whole stocks and yards to be disposed of, is far from a disallowance, much less a contradiction, of our position.

"In respect to size and weight, there is much solid ground for scepticism. Doubtless there have been individuals of large developments, with legs several inches in length and three in girth, and a great length of middle claw, which would be important items if reducible to broth or jelly; but such growths are not average, or even usual. In my own yard, and in every other I have inspected, I have seen nothing approaching these models. I do not say that Mr. Sturgeon may not, out of ten or twenty scores of annual produce, have been able to select a very few of such specimens as, at the second or third year, may have reached twelve pounds in the male, and nine in the female; but even that gentleman, the spirited and highly commendable proprietor of the breed, does not achieve or speak of more. I have heard mention of even greater weights. Inspection has convinced me of the soundness of the late Lord Althorp’s advice to graziers, ‘Not to look at their own cattle with too much partiality;’ so as to see them in points of view which sober eyes cannot find or allow. I think I should not be hazarding too much to say, that the weight of Shanghaies does not absolutely exceed that of the finest Dorkings; and, relatively to use—sinking the offal—would fall below it. I have possessed both in their best forms and degrees.

"The propensity to incubation, in the female of this breed, is so remarkable, so persevering, so irremediable, that, while it would make a few hens desirable to the general breeder, it is a serious drawback to them as sale stock. They begin to lay their winter supply of not large, but delicious eggs in the midst or end of November, and lay regularly, for six or eight weeks, one egg a day. Then they assume the broody humour, and are with difficulty diverted from their purpose. After some eight or ten days’ seclusion, they reappear as layers to the extent of from ten to twenty eggs, when they again claim the sweet of maternity. Then you cannot easily turn them from their purpose. I have frequently taken hens
off their nests, put them down on the floor, and left them, only to find them hours after in the same spot, and in precisely the same accidental posture, like dead things, as I left them. They are the sweetest, gentlest, and most rational of irrational mothers. The chicks are hardy and ‘fendible’—a very excellent Yorkshire word, with which the next edition of Johnson may be enriched. It is a very, very rare occurrence for one to die, or to be weakly. The soft and warm fluffiness of the hens makes their brooding most effective.

I may add that they are most conformable creatures in this, as in most other respects. They will sit wherever you wish to place them. One winter, about the beginning of January, I diverted some hens from this purpose for a week or two; in February, they became again broody, while the weather was yet untoward. I brought them from their laying-nests in the poultry-house, and placed them on eggs in cupboards in my kitchen. They then sat, hatched, and got through the chickenhood of their offspring as kindly as could be. It was a subject of mirthful observation to my household, that the same hens, when again, in May or June, they became prone to multiply, bounced up, in profound fussiness and importance, to the kitchen, and demanded, by pecking at and opening the door that stood ajar, admittance to their comfortable winter quarters. They were, unresistingly, put on eggs in a new place; but, as that was not far from the kitchen door, they sometimes repaired, after their periodical recreations, to the old and favoured, instead of their new locality, of which they only needed a gentle memento to resume their maternal duties. I have spoken of the rarity of a weakly chicken; and I add, that I do not remember ever to have lost one, except by some such death as the mother treading on it, or a door blowing-to, and killing one.

Table Qualities.—Since writing the above, I have sat down to a young Cochin-China, or Shanghai chicken. It was a deformed bird, though otherwise very handsome, and therefore condemned. Its weight, ready for spit, was only 5½ lbs., but of fine appearance, sent up turkey-wise. The quality of the meat was better than I expected. Still, its flesh must be pronounced coarse in fibre, compared with the old breeds of poultry. There was great whiteness, plumpness, and juiciness—the substance as beef to veal, or as codfish to turbot—not denying that both the antecedents in the contrasts are excellent eating. The legs were, apparently, of whiter meat, and more delicate consistency, than is usual with the legs of chickens or of turkeys. It will be obvious, hence, that I do not consider their table-excellence unsurpassable or unsurpassed."

In judging these birds, another amateur suggests the consideration of the following points:

**Head.**—Beak to harmonise with colour. Eyes red (pearl eye too Malay like.).—Comb single, small, straight, evenly serrated, fine in texture, and free from excrescencies.—Earlobe in cock, red, full, and long; in hen, small.—Face, red.

**Body.**—Very square; i.e., broad and deep in the keel, with abundance of thick, soft plumage, giving breadth behind; short neck.

**Tail.**—Remarkably short; in colour harmonising with that of the bird; almost buried in long loose feathers.

**Wing.**—Folded up very close, so as to leave the bluff of the thigh standing out full.

**Legs.**—Yellow, and heavily feathered.

**COLOUR OF CHINESE FOWLS.**

Cinnamon.—Cock and hen both to be cinnamon, and, as far as may be, to agree in shade; hackle marking nothing deeper than a golden tinge; absence of black in tail and flight, a beauty; colour throughout of a uniform shade.

Buff.—Cock and hen to agree in shade to a great degree; marking on neck-hackle to be tolerated in hens; tail, colour of plumage, or mixed with black; plumage clear, unbleeked, and to agree in shade throughout.

Grouse.—Very dark; each feather a mixture of rich brown and black, as in a pheasant. Breast and tail of the cock, black [according to the Dublin amateurs]; hackle richly marked. In the hen, breast like a pheasant.

Partridge.—Dark; the plumage of the hen a minute mosaicing. Cock with black-spangled breast, and dark-red hackles.

Black.—Pure deep black; no coloured feathers.

White.—Pure and clear white; no foul feathers.

Cuckoo, or Grey Shanghae.—All the plumage evenly pencilled, clear grey; no mixture of red or yellow tinge.

**THE MALAY FOWL.**

Malays are a tall race of birds, of high courage, excellent nurses and incubators of other species, but moderate layers themselves, and not easy to fatten to a fleshy state. The name of this fowl implies that it is a native of the
peninsula which forms the southern point of Hindostan; and is a title probably much more correct than most other names of poultry derived from the countries whence they are supposed to come.

Malays stand very high on the legs; are long-necked, serpent-headed, and carry too much offal for the poulterer. They are, accordingly, not so valuable to him as are some other fowls. Their flesh, before cooking, is not tempting in its appearance, and they very often have yellow skins. Their colour is various: some greatly resemble the duck-winged game; others are dark-brown, streaked with yellow. Black Malays are handsome birds; and the white variety, with bright yellow legs, is a remarkable creature. Good Malays, although unprofitable, certainly adorn a poultry-yard; but having a domineering disposition, with the power to indulge in it, they frequently are the cause of considerable annoyance. Chittagongs are members of the Malay family, which is widely spread throughout the East. Crosses with Malays produce fine birds, but they are of uncertain qualities and colours. Their weight is considerable; and their efficiency as duelists terribly certain, if it were the fashion now to indulge in such practices.

Years ago, there used to be a variety of fowls much in request in England, called the "Shakebag," or the "Duke of Leeds' fowl," a nobleman of that name having been a great amateur breeder of them. These fowls were as large as the Malays, but differed from them in the superior whiteness and tenderness of their flesh, as well as in their very superior combative qualities. Mowbray thus writes of one in his possession: "The only one I ever possessed was a red fowl, in 1784, weighing about ten pounds, which was provided for me, at the price of one guinea, by Goff, the dealer, who then lived upon Holborn Hill, in London; and who, at the end of two years, received him back at half a guinea, having allowed me, in the interim, three shillings and sixpence each for such thorough-bred cock chickens as I chose to send him. At that period, the real ' Duke of Leeds' fowl' had become very scarce, which induced the dealers to put Shakebag cocks to Malay hens, by that means keeping up the original standard size, but entirely sacrificing their colour, and delicate flavour of the flesh."

The name of this fowl seems to have arisen from the old practice of cock-fighting, when the fancy used to challenge all-comers, who had their cocks concealed in a bag; and the tremendous size and power of the Duke of Leeds' fowl proving so far superior to all competitors, as usually to insure conquest. The breed eventually obtained the name, par excellence, of Shakebag, since corrupted into Shackbag.

Mowbray informs us that this fine bird was not unfrequently substituted for a turkey; and this, as he facetiously adds, "to the great convenience of poulterers and inn-keepers of Wokingham and elsewhere."

In judging this bird, an intelligent writer suggests the following points for a basis:

**The Cock.**

Head.—The beak, horn colour.—Eyes, orange red, sunk beneath a projecting eyebrow.—Comb low, indented.—Wattles, very small, more properly folds of the skin of the throat than wattles.—Earlobe, rudimentary.—Face, brilliant crimson.

Neck.—Orange red.

Back.—Marone.

Saddle.—Orange red.

Wing.—Shoulder, marone; steel-blue bar across; flight-feathers, bay.

Breast.—Black, with irregular bay markings.

Tail.—Scanty, drooping.

Legs.—Olive-brown.

**The Hen.**

Head.—Same characters as cock, but less developed.

Neck.—Middle of feather brown, edges golden, shaft straw colour.

Back.—Brown, shaft of feathers straw colour.

Breast.—Brownish fawn colour.

Tail.—Brownish black.

Legs.—Olive-brown.

The Malay is widely distributed. It is to be met with largely in India, China, the islands of the Indian Archipelago, the South-Sea Islands, and America. Its introduction into England is of comparatively recent date; and as, in our culture of poultry, varieties of food and climate enter so largely into the consideration, diversities will necessarily arise; and, whether the birds exhibited be brown-breasted reds, cream-coloured, white, or otherwise, all we mean to suggest is, that main descriptive points shall be attended to, and lots assorted. Of the sub-varieties of Malay, there are three well-defined. The first, Temminck's Gigan- teus, long cultivated in India, under different names, stands nearly two feet in height. The second, the variety commonly imported.
from Singapore—that generally seen in the English poultry shows—is a smaller and more leggy breed. The third, cultivated in Ceylon for fighting, is about the size of our game-fowl. In this the comb is of the same character, but scarcely above the level of the skull; no wattles; neck naked; tail very long, carried on a level with the back; feathers very narrow, drooping, almost sweeping the ground; primaries turning outwards—almost leading one to suppose it indebted, for these peculiarities, to Gallus furcatus, found wild in Ceylon. Tail of hen drooping in like manner; colour and markings, same as in description. This last kind is rare.

Another, who has observed the bird in India, thus gives his opinion:

"The Cock.—General carriage and appearance, restless, independent, and commanding; head largely developed, and somewhat eagle-shaped; the bone above the eye projecting and overhanging it, giving it a fiery, savage expression; iris of the eye, pale straw colour; beak very strong, particularly the upper mandible, which is thick, and curves downwards to the apex; neck long and snake-like; the comb a low, double, warty excrescence—the points or papillæ on its surface being very close and minute; face nearly devoid of feathers, the skin being of a bright blood-red colour; throat also nearly naked, and red, extending from behind the ears to a point three or four inches down the front of the neck; wattles and ear-lobes rudimentary; backleathers of neck rising as a thick mane from its upper third, and falling in to the neck at its lower part in front of the shoulders, not spreading over them as in the game-cock. Shoulders of the wings greatly developed, standing out prominently from the body; body broad in front, tapering off, and descending to the rump; breast round and full; skin covering the crop in the centre of the chest, naked, and of a livid red colour, particularly remarkable when the crop is full; tail close, somewhat pheasant-formed, and but slightly elevated; legs rather long; feathers of the thigh very close; leg, or Shank, strong, clean, and of an olive-yellow tinge; foot large and strong; spur thick, not sharply pointed. Colour—general hue of the neck, back, and rump, a deep glossy chestnut-red; the neck backles being brownish-red in the centre, and of a brilliant chestnut-red at the edges; rump hackles entirely of a very deep and beautiful glossy chestnut-red; lesser wing-coverts, a rich glossy lake-red colour; greater wing-coverts of a deep metallic steel-blue, with green reflections; primary flight-feathers a dull black, edged, on the outer web, with chestnut or bay; secondary flight-feathers also dull black on their inner webs, and a light bay on their outer webs, those feathers of the flight nearest the body being tipped with metallic steel-blue; tail-coverts of a metallic blue-black; tail-feathers of a dull black, showing some metallic lustre on their outer webs; general colour of the breast, under part of the body and thighs, a dull black, tinged and blotched with brown.

"Hen.—Shape of head, neck, and body, much as in the cock; tail close, and carried generally more elevated; comb of the same general character as the cock's, but nearly rudimentary. Colour—head and neck a dark chestnut-brown, with brighter edging to each feather; back and body generally a clouded chestnut; tail—inner webs, dull black; outer webs, chestnut; wing-flights, a light chestnut, edged with black; inner webs nearly black; feathers of the throat scanty and short. Some hens, in colour, approach more to the grouse character of body feather, and are some spangled with white. The feathers of the Malay fowl sit exceedingly close to the body of the bird, and are more scanty than in any other variety of poultry."

At poultry shows the Malay's are not favourites, as may generally be inferred from the following remarks, made by one of the committee of the Annerley show:—"In arranging the prize-list, and deciding upon the regulations for the next meeting at Annerley, the committee have been actuated by a desire to conciliate all parties. How far they are justified in doing so, depends upon the co-operation of those who are interested in the rivalry and emulation which properly-conducted exhibitions usually excite. Yet there are, doubtless, some in the poultry world who have still reason to complain. The first cause is the omission of the 'Malay' in the prize-list. Now, this omission has not arisen from any neglect to, or want of appreciation of this class of birds; for its merits are at once acknowledged, and have been fully discussed; but the onus rests entirely with the owners.
POULTRY.

The varieties of Bantam fowl cultivated in England, some thirty or forty years ago, would fill a longer list than they do at present.

The gold and silver-laced, or the laced gold and silver, are the most popular favourites, and were most carefully cultivated under the auspices of the late Sir John Sebright, if they do not owe to him their existence as a breed. The baronet's mode of proceeding is thus described by one who had opportunities of knowing it:—"As I am living only nine miles from Beechwood, it may be interesting to you to learn, that neighbours, who knew the late Sir J. S., say that he sometimes hatched five hundred chickens in a season, but killed all those which showed the slightest irregularity of colour, and only reared a very few. Ordinary people cannot afford to breed fowls on that system; and, even if they could, such wastefulness and wantonness, approaching to cruelty, would not be creditable to them."

Mr. Richardson says, that the forms of the Bantams are usually modelled after the Game and the Hamburg fowls. The Sebright has its legs perfectly naked down to the toes. The cock, of this breed, should have a rose comb, full hackles, a well-feathered and well-carried tail—from which, however, the sickle feathers should be absent, and he is thence said to be hen-tailed—a stately courageous demeanour, and should not be quite a pound in weight. The lacings, which must be fine and regular, should follow the edge of the feather, on a golden yellow or creamy-white ground. The bird is of high courage, and will fight with great resolution. The attitude of the cock is proud and haughty; his head being thrown back so as nearly to touch the feathers of his tail, much in the style of a fan-tail pigeon. Well-bred birds fetch high prices.

The white Bantams, kept by her majesty at the Home Park, are of a perfectly white colour, and exceedingly small size; they appear also to have exhibited some peculiar traits of habit and disposition. The cocks were so fond of sucking the eggs laid by the hen, that they would often drive her from the nest in order to obtain them. They have even been asserted to attack her, tear open the ovarium, and devour its shell-less contents. In order, if possible, to subdue this unnatural propensity, her majesty's keeper first gave the cocks a hard-boiled, and

**BANTAMS.**

Bantams are high-spirited little birds; good layers; delicate to eat; useful as destroyers of insects and small vermin; and pretty domestic pets, but dreadfully combative.

836
then a marble egg to fight with, taking care, at
the same time, to prevent their access to the
hens or to any real eggs. After a few weeks
the birds gave up their unprofitable labour,
and, as the keeper had anticipated, wholly
abandoned, for the future, all attempts to
destroy the hen or the actually laid egg.

"The black Bantam," says Mr. Dixon, "is a
beautiful example of a great soul in a little
body. It is the most pugnacious of its whole
tribe. It will drive, to a respectful distance,
great dunghill cocks five times its weight. It
is more jealous, irascible, and domineering, in
proportion to its size, than the thorough-bred
game-cock himself. Its combativeness, too, is
manifested at a very early period. Other
chickens will fight, in sport, by the time they
are half-grown; but these act to work in good
earnest. One summer we bought a small
brood, as soon as they could safely be removed
from their mother. There were two cockerels
amongst them. They were little things, beau-
tifully shaped, but ridiculously diminutive—
fairy chickens, some of our friends called them.
They had not been with us long before the
liberal supply of barley began to excite them;
and the two littleimps spent the greater part
of their time in fighting, which only made us
laugh, judging serious injury impossible. But
shortly observing one unusually triumphant
(for it had always been a sort of drawn game
between them), and the other walking about
in an odd uncertain manner, though firm and
fearless, I found that this latter had both its
eyes closed from wounds received the day
before. I carried it to my dressing-room, to
relieve it by sponging, and set it on the stain-
cloth, while I went to fetch some warm water.
Still blind, it began crowing vociferously.
In a few minutes its eyes were unsealed, and it
was returned to the yard. But battle after
battle was immediately fought, and we were
obliged to eat one of the combatants to pre-
vent the mutilation of both. We can, con-
sequently, confirm the statements of those
who praise the excellence of their flesh, par-
icularly if it be accompanied by a little good
bread sauce. One, that I have seen, was in the
constant habit of fighting, or rather sparring,
with a little spaniel that belonged to the
same owner. Though apparently attacking
each other with great fury, they never seemed to
be really in earnest. The arrival of strangers
was generally the signal for the commence-
ment of this sham fight, which ended without
bloodshed as soon as one or both of the com-
batants were out of breath. The spaniel was
mostly the first to give-in, when the victor
evinced as much triumph as if he had van-
quished a feathered foe.

"The black Bantam, in his appearance, is a
pleasing little fellow. He should have a full
rose comb, clean and sinewy legs, glossy
plumage, with almost metallic lustre, of a dif-
f erent tint to the glancing green of the Spanish
fowl; arched and flowing tail, waggish impu-
dent eye, and self-satisfied air and gait. The
hen is of a duller jetty-black, is less knowing
in her manner, and, I think, in every way of
inferior capacity. These little black hens
have great credit for fulfilling their maternal
duties well; but I have found them less
affectionate and careful than other Bantams.
They are great stayers at home, prowling very
little about, and therefore are desirable in
many situations, such as suburban villas that
are surrounded by captious neighbours. They
will remain contented with the range of a
moderate stable-yard, and the least bit of
shrubbery; and will do much good by the
consumption of numerous insects. They are
reputed good layers during winter; but that
will depend on the liberality with which they
are fed. Cooks say that their eggs, though
small, are "very rich;" which means, perhaps,
that they contain a greater proportion of yolk
than those of larger fowls. Guinea-fowls' eg-
s are prized for the same quality; and any
one may, at breakfast, observe how much less
a proportion of white there is in them than in
those of the Turkey. Black Bantams' eggs
are smooth, tinged with buff, decidedly long-
oval in most individuals, and with a zone of
irregularity towards the smaller end in some.

"The new-hatched chicks are covered with
black down, which occasionally has a greyish
east under the belly: bill, eyes, feet, and legs
black. The female chicks are not bigger than
the queen of the black-and-yellow humble
bees, and their slender little legs appear fitter
to belong to an insect than a chicken. A
desire to obtain the largest possible brood,
induced me to hatch some under a great
Dorking hen, because she can cover so many

S37
POULTRY.

eggs; but I only overreached myself. The big hen was too heavy and clumsy to officiate as nurse to such fragile atoms."

The Creeper is also a small variety of Bantam, with very short legs. In addition to these diminutive races, there is another, the Jumper, mentioned by Buffon, as being so short-legged, that they are compelled to progress by jumps. They are prolific, as well as excellent sitters, the hen having been known to hatch two batches of eggs in succession, without even an intermediate day of rest. These dwarf fowls were described by Aldrovandi, more than two hundred years ago; and also, much further back, by Pliny, under the designation of the Adrian breed.

A gentleman of known experience suggests the following points for a basis:—

SEBRIGHT BANTAMS.

The Cock.

Head.—Best helmet comb; best, fullest, and clearest black eyes.—The ears, best, largest, and clearest white.

Neck.—Hackles, shortest and clearest red, and best, laced with black.

Breast.—Clearest and best red, and laced with largest and clearest black.

Back.—Ditto.

Wings.—Ditto.

Saddle.—Ditto.

Tail.—Hen-tailed, most erect, clearest and best, red; the two longest tipped with best and clearest black; the other feathers best, laced with black.

Legs.—Clearest and best blue.

THE HENS TO MATCH.

General Appearance.—The smallest, most symmetrical, and best-feathered birds.

SILVER SEBRIGHT BANTAMS.

Characteristics the same, on clearest and best white ground.

INDIAN BANTAMS.—(Clean Legged).

The Cock.

Head.—The comb, best double, best square, best spiked behind.—The eyes, brilliant orange.—The ears, roundest and clearest white.

Neck.—Hackles, best, fullest, and clearest golden red.

Back.—Best and richest golden marone.

Saddle.—Ditto.

Tail.—Best carried, fullest, and best glossy green black.

Breast.—Clearest and best reddish fawn colour.

Legs.—Best and clearest olive, or best and clearest yellow.

Wings.—Shoulder, best ant and richest marone; flight feathers, best and clearest bay.

BANTAMS.]

THE HEN.

Head.—The comb, best double, best square, best spiked behind.—The eyes, brilliant orange.—The ears, roundest and clearest white.

Neck.—Hackles, best and clearest brown in middle, edged with golden; shaft, straw colour.

Breast.—Clearest and best fawn colour.

Back.—Clearest and best brown, and clearest and best straw-coloured shaft.

Tail.—Ditto.

Legs.—Clearest olive, or clearest yellow.

In reference to the name of a species of Bantam, formerly called the Calcutta Jungle fowl, several amateurs have written their opinions, and suggested what they deem more appropriate designations. One says—"It has been hinted, that it would be better to name these birds, lately imported from Calcutta, Indian Feather-legged Bantams. The owner considered it better to let them keep the name under which they were purchased at Calcutta, until some certain intelligence respecting their origin should make a change advisable. When new fowls have been imported, the owners have often appeared to seek a well-sounding name, rather than one which should continually point to their origin. If the last rule had been observed, the nomenclature of fowls would be less puzzling than it is in many instances. The little fowls in question were called Jungle fowls; but it seemed likely they had been domesticated, as, although very wild, they were not sufficiently so for wild fowls. They came over in the Lady Jocelyn screw-steamer, where a lady passenger kindly took them in charge, and fed and noticed them after every meal during the passage. Calcutta Bantams would be a better name for them than the above."

Another says—"The little fowls which won prizes at Birmingham and Colchester, and entered under the title of Calcutta Jungle fowl, were bought at Calcutta as Jungle fowl, and have some similarity in the head to the Bankiva, being for a long time very wild. These are the circumstances which attached to them the—probably inappropriate—name of Jungle Bantams. Far from having lost the sickle feathers and hackle, like the Sebright, their furnishing is quite ridiculous for their size. The hackle of the old bird is bushy, and long enough to reach the ground when he feeds; and the tail so well furnished with sickle feathers, that, in
windy weather, its owner is borne along with it, as if it were a sail. The plumage is black, with a brilliant green metallic lustre; and about the head and neck are streaks of white, which increase as the fowls approach maturity, at which time the head is nearly white. The legs are feathered, not booted. The fowls are Bantam-like in size, very plump, compactly made, short in the leg, and exceedingly spirited. The cockerels will fight a cock of any size, and make large Brahmas fly before them. The little hen is a good layer. The eggs are almost invariably fertile. When the chickens are hatched they are tiny black and yellow things, with a slight appearance of a turned ridge on each side of the head, a little distance from the eye. They are active and hardy—exceedingly so, considering the change of climate they have had. The cock is a capital father; as soon as the little hen will let him (for she is a virago when she first gets her brood), he takes as active a part with the young ones as any hen can do, leading and feeding them by day and watching them at night: this attention he continues long after the hen has turned them off.

"The Calcutta Jungle Bantam," says an informant, "is not a Jungle fowl, but a domestic bird from the coast of Rangoon and the Straits, and, although timid, has nothing very wild. The real Jungle fowl I have shot, in great numbers, on the range of hills running through Midnapore to Rajmahal. The cock is very handsome and beautiful, delicately formed, and something less than half the size of the Malay fowl—his carriage and colour much the same; but he has a very small head, with single comb; his legs are not long, but clean, with olive-yellow tinge; he stands very upright; spurs thin, and very sharp. He is courageous, and generally has six or eight hens. The hen is handsomely made; blackish-brown, speckled, with a diminutive head, and very dark-red round the eyes. I have known many attempts to domesticate these fowls, but none succeeded, even when the eggs were set under a house hen; when the chicks were able to provide for themselves they went off."

Another says—"I believe, as yet, India is known to possess but two species of Jungle fowl—Gallus Bankiva and Sonneratii; the former is supposed to be the origin of all our domesticated varieties, although doubted by some. Experience has proved that it can be domesticated, and that the cross is fertile with others, inters. Sonneratii have been bred with Bantams, but rarely; the cross was not fertile, thereby proving it a distinct species. These birds are described as feather-legged; therefore I take them to be Bankiva, bred in-and-in: by which means the feathered leg is produced, and the loss of sickle feathers and hackles, the hen-hackles being produced, as in the Sebright Bantams. I had, many years ago, from India, Bantams identical with Bankiva, although smaller, the hens of which were very wild. By in-and-in breeding I produced the crested Hamburgs (known as such for a century before the erroneous nomenclature of 1818), wanting the sickle feathers, and with feathered legs, which I have found most difficult to eradicate, each year producing one or two, notwithstanding the introduction of new blood. I have a pullet of this sort, which I should have killed, but have kept, thinking some of the curious in varieties would like to have her."

RUMPLESS, SILKY, NEGRO, AND FRIZZLED FOULS.

Rumpless, Silky, Negro, and Frizzled fowls, are interesting birds, and deserve the attention of the fancier. Their leading characteristics are indicated by their names, and the first are found of all colours. They are more abundant in France than in England, and have a singular appearance, reminding one, to some extent, of the English sheep dog. Their appearance never fails to attract attention, whether in the yard or at the exhibition; but they find no favour with the epicure, depriving him of a dainty morsel.

"Of Silky fowls," says Mr. Richardson, "there are several varieties, mostly direct importations from the East, their merits being unduly appreciated, and their cultivation as good as neglected. As an exception, Mr. Bedingfield, of Ditchingham Park, Norfolk, adopting the judicious plan of having only one sort of fowl about his house, selected silk fowls for the purpose. They increased well, laid a sufficiency of eggs, and proved most docile sitters and nurses, both for their own young, and for pheasants and partridges."
Some of the hens would submit to be placed on a nest of eggs that might happen to be found in the park, and took to them directly, hatching them off without further trouble. They were, of course, so posted as to make her sit at once. These silk fowls were of the kind sometimes called Hong-Kong Bantams—small, short-legged, and but slightly furnished with wings and tail, and, in the eyes of some beholders, very pretty. People condemn a thing seen in a dealer’s cage, or an exhibition pen, which they would delight in if they made its acquaintance at a country mansion. Still silk fowls are not show birds, and find but little favour at Birmingham. But till the Cochin-China epidemic had a little subsided (and the remedy of bleeding the purse was boldly practised on patients in an advanced stage of the complaint), the phoenix itself was ’pooh-pooh’d’ into the background. There are silky fowls with black skins; and they make a near approach to negroes.”

Of the Negro fowl, Mr. E. L. Layard, brother of the distinguished Ninevite discoverer, thus writes from Jaffra, Ceylon:—“The kallumas-kukulilo of the natives is, as the name implies, a fowl with black flesh; its bones are also black; and, on table, it is a revolting-looking dish. But taste it! No other fowl, in this country, can compare with it for juiciness and tenderness. I never saw this fowl in England; here it is abundant. The prevailing colour of the true breed resembles a white fowl drawn several times through a sooty chimney! The skin, the eye-wattles, legs—in fact, all fleshy parts bearing the same leaden hues. It is little eaten by the Europeans, on account of its colour. I am, however, glad to get it on my table; and always esteem it (knowing, from experience, its good qualities) as one of my most favoured dishes.”

The Frizzled fowl—so called from the frizzled and crisped appearance of the feathers, and not from a corruption of Friesland, at one time erroneously conceived to be its native country—varies as much in colour as the Rumpless fowl, and is quite as striking to an unaccustomed beholder. The natives of Ceylon, where it is occasionally seen, say that it originally came from Batavia. This agrees with Temminck. It is susceptible of cold, difficult to rear, and mainly prized as a curiosity.

BOLTON GREYS, CREELS, CHITTEPRATS, Etc.

For judging these fowls, the following points are suggested as a basis:

DUTCH PENCILED FOWL (GOLD OR SILVER).

The Cock.

Head.—Best double rose comb, best square in front, most erect, and best spiked on the top and behind.—Wattles full and round.—Ears largest and best white.

Neck.—Clearest and best white.

Breast.—Largest, clearest, and best white.

Rump.—Largest and best clear green, black spot on the end of the feather, and clearest white ground.

Wing (in four parts).—1. Shoulder. 2. The Bars —The clearest white ground; best and clearest edging to upper and lower wing-coverts, forming two distinct black bars on the clearest white ground. 3. Flight.—Clearest and best white. 4. Lacing on top of wing above the flight; i.e., the inner webs of secondary flight-feathers: largest and best clear green-black spots on the end of the feather, and the clearest white ground.

Tail.—Best brown, waved with black; best and clearest silver edging, dotted with clearest and best black spots.

Legs.—Clearest and best blue.

THE HEN.

Head.—The Comb—Best double rose comb, best square in front, most erect, and best spiked behind.—Wattles full and round.—The ears largest and best white.

Neck.—Clearest and best white.

Breast.—Largest and clearest white, each feather ended with clearest black spots, increasing in size, proportionate to feathers.

Back.—Clearest white, crossed with clearest black bars, separated by white shaft.

Thighs.—Clearest white, with largest and clearest black spots.

Rump.—Clearest white.

Wing.—Clearest white, crossed with most distinct and clearest black lines.

Flight.—Clearest white, crossed with clearest wavy black lines.

Tail.—Clearest white, crossed with broadest and clearest black bars; shaft white.

Legs.—Clearest and best blue.

(GOLDEN).

Markings and characteristics the same. on a bay ground.

SCOTCH BAKIES, OR DUMPIES.

“Of this variety,” say the authors of the Poultry Book, “Mr. Fairlie, of Cheveley Park, near Newmarket, the only person, we believe, into whose hands they have yet passed, has recorded so favourable an opinion of their merits as layers and mothers, no less than for
the table, that we shall be much surprised if, either in their present state, or crossed with other fowls, they fail to prove a useful addition to our poultry-yards.

"Mr. Fairlie obtained his birds from Scotland; but all his inquiries have hitherto been unable to trace their origin in, or importation into, that country. Their general character, however, so closely assimilates to that of the Dorkings, that the probability of their being descendants of birds of the latter breed, stunted in growth by the less genial climate of the northern district of our island, may readily be admitted; and this the more easily, when we remember how many would describe the early ancestors of the Dorking race as 'stumpy, thick-set, white fowls.'

"For a detail of their several characteristics and points, let us refer to Mr. Fairlie's own words. 'The Scotch Bakies, or Dummies,' he tells us, 'are a breed of fowls closely resembling the Dorking in form, symmetry, and quality of flesh: the average weight of the full-grown male bird, is from six pounds to seven pounds; and of the hens, from five pounds to six pounds; their legs are singularly short, not exceeding two inches in length from the hock joint; the comb is generally single, erect, and well serrated; the body round and plump, and the tail ample. As layers, they have great merit; for after filling one nest, if the eggs are removed, they at once take to another, filling that also before they sit; during which process they fully justify the oft-repeated remark made at a late Metropolitan Exhibition—"What excellent sitters they must make.' They cover many more eggs than might be expected from their size; for while on the nest, they appear as if they had been pressed flat upon it. They are gentle and quiet when hatching, and subsequently prove fond and attentive mothers, their short legs enabling the chickens to brood well under them, even when standing up. I have found them very hardy; and their eggs are larger, and the shell of a clearer white, than the usual average of an English market egg.'

"In the pen of these birds exhibited at Cheltenham, in June, 1853, the ground colour of the cock's plumage was white; the hackle, breast, saddle, with the flight and tail-feathers, being a little freckled with black. The white earlobe was very fully developed.

5r

"We are glad to learn that the effect of a warmer climate and high feeding will be carefully watched in this instance; and if there is a manifest increase in size within the next two or three generations, the probability of their inheriting some of the old Dorking blood will be thereby greatly increased; while the retention of their present dwarfed proportions would indicate their claim to be considered as a permanent variety.'

In concluding this chapter, we will notice a report of the Paris Agricultural Meeting, at which various breeds of fowls held a prominent place—there being present 400 pens. There were, besides, 1,300 beasts, with goats, rabbits, zebras, lambs, deer, &c., &c., conveniently and tastefully arranged in and about a building splendidly decorated with the choicest flowers, trees (of no small size, transplanted for the occasion), fountains, painted glass, and tapestry.

In the galleries, specimens of agricultural produce, of different countries, were laid out for inspection; whilst, outside, a number of handsome tents were provided for the use and protection of the sheep, pigs, goats, and agricultural implements.

At first the poultry were sadly injured by the scorching sun during many hours of the day, as they were totally without covering, and many suffered greatly. Afterwards, however, an awning was erected, and they did better.

We must, however, remember that the French are not much used to cattle shows; and taking this circumstance into consideration, we may give them credit for the way they managed their first large exhibition of cattle.

It is somewhat curious to observe the manner in which they belied their character, as admirers of what is neat and beautiful, in distinction to that which is coarse and ugly. If you notice a crowd, it is sure to be collected round the coarsest and ugliest animal of its kind, size being the great attraction. It is the same with the poultry; they prefer the Brahmas and the biggest Cochins to the Dorkings, or to any neater or smaller breed.

There are a few, however, who seem to know what a good fowl is; and we shall not easily forget the look of disgust with which a well-known breeder of Dorkings received an inti-
mation from a “stout party,” that she considered his pen of fowls very fine, and could imagine nothing better than a fricassée of his fowls!

In describing the most remarkable breeds of poultry at this exhibition, the reporter begins with the first named in the catalogue, as it is an acknowledged French breed, and is called—

“The Crève-cœurs.”—I tried hard to discover the real merits and characteristics of this fowl,” he says, “but obtained different and very differing accounts. All my informants, however, were agreed on one point—viz., that they were the best sort of fowl for the table that they had in France. This, however, is not saying much, for we know that the French raise large numbers of every kind of poultry for the market; they are not over-particular as to quality, or the appearance a bird presents on the table. It is seldom (very, very seldom indeed) that an entire bird is placed before you; it is either hashed, smashed, pulled, fricasséed, or smothered and smuggled into you in some way; so that often nine persons out of ten would not be up to what they were eating. This fowl has, however, by no means a badly-shaped body; it is long and low, and not very narrow. They gave me an idea of coarseness, yet I have no doubt they are hardy, useful birds in their own country; but their rusty-black feathers, and smutty legs and feet, are anything but pleasing to the eye; nor do I, in any way, commend them to the notice of the English amateur. No two Frenchmen could agree upon what their shape or plumage ought to be; and the birds, in their pens, differed very widely in form and feather. At the same time, we could not but admire them in all their characteristics, which were not of a common order, and which called forth general approbation.

“The Cochin-Chinas” were divided into five classes—viz., yellow, white, black, brown, or freckled, and those not classed in the above descriptions. The cinnamon and buffs are, by common consent, called yellow in France; and it was not at all considered necessary that the birds should be matched. Nothing was more common than to see prize pens composed of a cock and two or more hens of quite different colours. The rule is, that there must be one cock, and not less than two hens, in a pen; but as many more as the exhibitor pleases.

“There are very few Frenchmen who have as yet discovered the value of the Dorkings. We trust they will allow them a fair trial, and have no doubt they will acknowledge their many excellences. The first-prize pen was greatly admired for the size and beauty of the birds.

“We now come to the Dreda fowls. What are they? you will ask. Why, it appeared to me that they were no-breed-at-all fowls. This would certainly apply more reasonably to the birds I saw exhibited under the former name; for of all the jumbles I ever beheld, this was the most complete. There were some with tufts, and some without; some like Silver-pencilled Hamburgs, and some like cross-bred Cuckoos, and so on. I actually did not stop to see who had the honour of the prizes, but passed on to the

“Brahmas.”—This breed has been greatly prized in France. Mr. Baker had a compliment paid him that few can boast of, and of which he might well have been proud. His birds in this class were so good that three first prizes were awarded to him. One of the pens, containing the handsomest cock of the kind I ever saw, he sold for 1,000 francs; and another, I understood, was marked out for the empress. For my part, I never wish to see better fowls than those brought to the exhibition by Mr. Baker, and I heartily congratulate him on his success.

“The other classes of fowls were not well represented. I shall, therefore, abstain from any remarks.

“The Turkeys were not very fine.

“For Geese there were only four competitors.

“The Aylesbury Ducks were good; but the Rouen Ducks were not the truest of their kind.”
CHAPTER III.

CHOOSING OF STOCK.

Among the reciprocal benefits which unite the lover of poultry and his charge, perhaps a habit of early rising takes the first place. At a season of the year when a protracted winter may, in a small degree, have induced a disinclination to early exertion which we are unwilling to encourage, it is a very good thing if our favourite recreation is one which calls us betimes in the morning into the open air. One of our best judges has repeatedly advised that chickens should be fed soon after sunrise. There are few young things in whose case food has to do so much as in that of young chickens. Unlike those animals which come into the world with their clothing of warm fur, young birds depend on food for all the necessaries of life. For them food must secure the requisite supplies for feathers as well as for bone and muscle; and there is never a time when good and frequent feeding are of such vital importance as while the little ones are fledging. A fast of a number of hours is a greater call upon the vital powers of young poultry than they can support. The careful cottagers, to whom is often entrusted the charge of turkeys, are well aware of this fact; and, although they keep the poults shut in, safe from getting wet with the dew, they feed them early.

Poor Richard says, “The eye of the master does more work than both his hands.” Let the owner’s eye, then, whether it be master or mistress, see that the young broods of the different kinds of poultry receive the early attention indispensable for the production of prize birds. Let the fancier see that the poultry-houses (which will naturally be close after being shut up all night) are thrown open to the wholesome morning air; that the twittering, liberated little throng have the wherewithal to satisfy their morning appetites before the twittering changes to complaint; and we believe we may prophesy, that the good which the poultry cannot fail to derive from such care, will reward their owners by a great accession of health.

To whatever branch of scientific culture we turn, whether it be to that of plants or animals, nature seems to point out that there are certain forms and characters more pleasing than others, which must be accomplished to attain perfection; as, for instance, in flowers, pelargoniums, pansies, &c. We can all recollect the long, loose-petalled flowers of former days; the onward progress of improvement pointed out that, the nearer the approach to the circle, the more perfect the form. The gardeners of the time, as in every new theory, ridiculed the idea. We have, nevertheless, seen that, however difficult or apparently impossible it is to change natural forms, it has been done. The same applies to poultry. Sir John Sebright, and other eminent breeders of cattle, arrived at similar results; and it is only by settling and insisting on points, whether of colour, shape, or markings, form of combs, &c., and discouraging shortcomings, that perfection will be generally arrived at. In estimating the qualities of poultry, there are many conflicting opinions, which is a cause of much dissatisfaction to poultry-breeders, particularly beginners; but we see no reason why rules cannot be framed, binding judges—a most important step—which would greatly lighten their labour; because the public, being made acquainted with a given standard, would breed to points. This would also prevent the caprice of judges, so much complained of.

To specify some particulars, we may observe that the eyes of fowls are distinguished as pearl or grey eyes, and gravel or red eyes, of various shades. Some fowls have crests of feathers instead of combs. The Poland crest is large and round, hanging almost over the eyes. A lark crest is narrow, and falling backwards; but although Mr. Dixon honours lark-crested fowls as a variety, we think this crest is nothing but an accident from some distant cross with Poland-crested fowls. A muff, or beard, is a bunch of feathers hanging from the lower mandible. Many of the Poland sub-
POULTRY.

The wing of a fowl is divided into various parts. The primary quill or flight-feathers are those which grow on the last joint of the wing. They are ten in number, are the main instruments of flight, and those which we consequentlv shorten, to destroy the balance of power, when we wish to check the licentious wanderings of my lord or my lady. The secondary quills grow on the next joint of the wing, are shorter than the primary, and are those which are most seen when the wing of the fowl is closed. We believe there are thirteen of these. The wing of a bird, in its skeleton, has been not inaptly compared to the skeleton of the human hand. The joint, representing the thumb, is set with three additional smaller quill feathers, which lie down over the first few primaries in an uncommonly neat arrangement. In the Hamburgs, the spots or spangles on the secondary quills, and those on the first range of the greater wing-coverts, form the bars so much insisted on by judges. The greater wing-coverts are the first few ranges of feathers which lie in order over the quills; and the lesser wing-coverts are the feathers of smaller size and softer texture, which finish up the wing, and pass round its edge so neatly. The under side of the wing is covered with soft feathers, also arranged in beautiful order.

Legs (familiarly, the shanks—learnedly, the tarsi—the part between the knee-joint and the foot) may be clean (or, in other words, without feathers), feathered (with a stripe of feathers down the outside), or bootcd (entirely covered with feathers). Sultans, or Serai Tâ-ooks, Ptarmigans, and some Bantams, are bootcd. Shanghines, Brahmas, Ghoom Dooks, and two or three other kinds, are feather-legged. Spanish, Dorkings, Game Fowlis, Hamburgs, and most Polands, Sebrights, and black and white Bantams, are clean or plain legged. Some feather-legged and bootcd fowls are abundantly feathered on the feet also.

Vulture or falcon hocks are tufts of long feathers, standing out from the hocks.

The tail-feathers are the fourteen stiff ones of the tail. The tail-coverts are the softer curling feathers which hang over these. We believe there are, properly, only two (the centre two) sickle feathers, which are really tail-feathers; the others are tail-covert feathers.

Dubbing—generally, only applied to game-cocks—is cutting off the comb and wattles.

We may mention, that Spanish fowls are, perhaps, the most profitable to keep, provided the owner is lucky enough to have some that may turn out very excellent; but there is uncertainty in this, as fowls breed somewhat at random. There is great difficulty in getting first-rate Spanish fowls, even at a very high price; and there is no certainty that first-rate fowls will produce first-rate chickens. The latter are, besides, delicate to rear, the handsomest being generally the most tender. If you stoop to the now vulgar consideration of the merely useful—eggs and fowls for eating—there is no particular fault to be found with Spanish fowls for the table (especially pullets): they lay a respectable number of the finest eggs which the poultry-yard can produce; and, as to appearance, a little lot of Spanish fowls, in high condition, is no contemptible ornament to the pleasure-ground of a nobleman. High condition is that state of exuberant health which will make almost any fowl handsome and ornamental. It shows itself in the clear beaming eye, and the ruddy comb (according to the time of year); a feeling in the flesh, firm yet pliant; a good covering of meat upon the bones, but not too much fat; and last, not least, crispness and resplendence in the plumage—over which the bird, in fine condition, has as complete control as he has over his other limbs. When a bird is out of condition, the eye looks dull, the flesh is puffy, hard, or absent without leave, and the plumage entirely without gloss. You could not draw a feather without tearing the fevered skin. We speak now of condition, because it is a thing especially to be observed, if you buy Spanish fowls or chickens. Without attention to this, the smart new hen-house may soon be empty again; and perhaps you will blame the species, when you should find fault with your ill-conditioned purchase. To know the points of a Spanish fowl, study what
we have already said of the cock of that species, and get a bird as near to the description as you can; add a couple of black hens, of a cheaper sort, to lay eggs for family use; and the chances are, you will make a better start in Spanish than you would do if you bought a dozen hens and three or four cocks, haphazard, at high prices, and turned all in together to fight it out. The price of tidy Spanish fowls varies from £1 upwards. Dorkings are nice, motherly, good-looking fowls; and first-rate specimens fetch high prices: they are only tolerable layers, but the eggs are large and delicately flavoured. As fowls for the table they rank A; and, in this particular, are popular with poulterers, almost to the exclusion of all other kinds. The chickens are delicate, and so difficult to rear, as to prove disheartening to the most experienced amateurs. You may get good Dorking fowls at 5s. each; but, if anything superlative is desired, prices run up much as in the Spanish.

The accusations brought against Cochins is, that they eat more than any other kind of fowl, and have a continual propensity to incubate. On the other hand, they are tame, tractable creatures, and very good fowls to have where a high fence would be unsightly, as an altitude of four feet is sufficient to keep them in. They are capital layers—a quality often more important than any other to amateurs, who are anxious to begin to keep just a few fowls, chiefly with an eye to the luxury of new-laid eggs. Malays are well worth attention; they are very good fowls, besides having the advantage of being somewhat handsome.

Brahmas have all the merits of Cochins, without their faults, and are as handsome as Malays. Cochin-China fowls may be bought for from almost nothing up to £5 each; very good birds from 10s. to £1 each. Pretty good Malays may be bought for 10s. or 15s. each; and Brahmas at prices varying from 10s. to £2. In trying to give those who purchase fowls for the first time, some idea of their prices, we take those of the usual run of good birds. There is but one first-prize pen of a sort in every show, be it remembered: if, therefore, you want first-prize birds, you must be prepared to give the price which the owner sets on them; for the same reason that makes it necessary to give more for pearls than for pebbles—because they are less plentiful.

Three varieties of fowls come next, varied and equal in beauty, and all very ornamental and very good layers—Hamburgs, Polands, and Game. If you try the first, you may chance to see your fowl perched on the top of your neighbour’s chimney, with an evident intention of extending his travels—a position of your vested property at which you will feel rather annoyed. If you try Polands, all the young chicks may die in rearing; and if you devote your attention to Game fowls, they may take a sudden freak of animosity, and peck out each other’s eyes before you are up some morning. With these little drawbacks, they are all really good and beautiful fowls: only, if you try Hamburgs, take care that your fences are high enough; if Polands, bestow especial care on the young chickens while they are fledging, and for some little time afterwards; and if Game, do not let them get to fighting—if you can help it.

Tolerable Hamburg and Game fowls will cost from five to fifteen shillings each, and Polands from ten to twenty.

Where there is scarcely room for common-sized fowls, or for the large varieties, a few Bantams may be kept. They will always look active and pretty; and the eggs, though small, are deliciously delicate. Pretty Bantams may often be bought for a very few shillings.

The next thing to the price of the fowls, is where to buy them. We have a prejudice against buying at auctions; because we do not think owners would allow birds, likely to do good service to the purchasers, to go for so much less than they can get for them either at home, or by selling them through the medium of a respectable dealer. The best plan is, either to go to a reputable tradesman, or to an amateur, and see and choose the birds at home. Another good way of making purchases is by going to the poultry-shows. There the beginner can look well at the prize birds, and choose the cheaper ones which are most like them. We do not recommend a great outlay to begin with. Buy fowls at a moderate price; see what good you can do with their chickens; gain experience; and then spend a large sum, and get first-rate fowls if you feel disposed to do so.
There are many amateurs who would like to have handsome, productive fowls, but who care little about the fancy. We think they might, with great advantage, turn their attention to systematic crossing. We are as great an enemy as the most fastidious fancier can be, to turning in a lot of different fowls hap-hazard; but we believe judicious crossing may give excellent results in producing fowls which shall be very hardy, fine for the table, and abundant layers. The experimentalist has an almost unlimited field; let him only mark the merits of different varieties, and study to unite, reproduce, and continue them.

Yet a Malay hen run with a Game cock; set the eggs, and save the pullets which are hatched from them. Match these pullets with a good stout-built Spanish cock, and the chickens will prove brilliant in plumage, very hardy, excellent for the table, and will lay four days out of five for most part of the year.

Brahmas and Cochins would be valuable in crossing, to produce hardihood and size. A touch of the Game gives delicacy of flavour to both fowls and eggs. The good properties of almost every kind might be turned to profitable account.

"The great point of selection," says Mr. Richardson, "is the breed which it shall be determined to keep; and this must be mainly decided by circumstances. The wealthy amateur may do as he pleases, but a different rule must be the guide of those who make poultry-keeping a matter of business. A few words of advice shall be hazarded.

"Both for appearance and for profit's sake, it is advisable that the farmer should confine his stock to some one approved breed. To retain several breeds in their purity, requires more personal attention, hired labour, and choice of out-buildings, than he can usually afford. It is best managed by such country gentlemen as have three or four lodges belonging to their park, at each one of which a distinct set of fowls may be maintained, and another or two quartered upon the gardener and the game-keeper, if the former official will submit to be plagued with them. In this way things will go on satisfactorily, especially if the people can be brought to take an interest in their charges, and perhaps to feel a little rivalry as to whose set is the best managed. A large farmer may often attain the same object by making a like use of the cottages of his workpeople. But that is not the thing which he requires. Pure chickens may be had from fowls that usually live together in miscellaneous socialism, by excluding the intended parents in an airy out-building, and rejecting a few of the eggs first laid by each hen. This plan requires constant attention and a pitiless hand, to clear off the many good-looking mongrels that will be constantly displaying their new-fashioned charms in the yard. The farmer had better decide to keep one pure breed only of cocks and hens, especially now that pure-bred fowls often fetch such extraordinary prices.

"If it is asked to determine which variety shall be kept, the counsel given must be accommodated to what the farmer wants. Are eggs greatly in demand in his neighbourhood; and does he wish to be spared the expense and trouble of rearing many young birds? Then let him take some of the non-sitting breeds. At the head of these stand the Black Spanish fowls, and their sub-variety, the Andalusians; next come the Hamburgs—the races that are so highly prized in the midland and northern counties—i.e., the Bolton Bays, the Bolton Grays, the Silver Moonies, and the Copper Moss fowls, according to the numerous local aliases of the four sub-races. Last in profitableness among the non-sitters, though not in beauty nor in excellence of flesh, are the Polish fowls. But the Spanish fowls are larger birds, and consume a good deal. It is true that their eggs are of proportionate size and excellence; but, in the market, an egg is an egg; and we believe that greater numbers will be obtained, at the same cost of food, by adopting one of the Hamburgs as the established colonist of the farm-yard. We therefore beg leave to take the Bolton Bays, or Golden-pencilled Hamburgs, by the hand, and introduce them to the favourable consideration of the farmer and his amiable consort. Whichever breed of non-sitting fowls is selected, the stock must be annually kept up by sending out eggs to the neighbouring cottages to be hatched, and paying, for all reared, a certain amount of head-money, at an age agreed upon.

"If, however, eggs are not the principal desideratum, and Madam has the leisure and good-
will to see to the rearing of numerous broods; if she has also three or four rosy-checked sons and daughters to assist her in the amusement, besides a boy and a maid to do the heavier work—then let one of the often-incubating breeds be destined to people her barn-door paradise with the phileprogenitive set of inhabitants. She may honour the Dorkings and the Surrey, or the Game fowls, or the Cochin-Chinas, with her preference. There cannot be a better sort for the farmer than the race of Surrey fowls, known as Cuckoo fowls. They are somewhat dull and quaker-like in plumage, and inactive in their movements. So much the better: the fowl-stealer cannot spy them out so well in the dusk; and they fatten famously, besides being good layers, sitters, and nurses; and, in short, possessing every gallinaceous virtue. Game fowls are more beautiful, and are equally good parents; their flesh, too, is delicious, but wants the weight of the Cuckoos, and is apt not to dress so white for market. The cocks, as they grow old and jealous, are very prone to kill the other male inhabitants of the poultry-yard, such as turkeys, guinea-fowl, and even drakes, if they fancy themselves insulted by them. They are more suited to the lodge, the dog-kennel, the coach-house court, or even the cottage urchin, than they are to the farm-yard, to which quiet place, when very good, they are apt to give a sort of sporting character. It must be confessed they are often birds of great beauty; but the Cuckoo fowls are much more business-like. The Cochin-Chinas, even yet, are more in the hands of wealthy amateurs and exhibitors at poultry-shows, than available for farmers as a main crop of fowls. The prices asked for specimens that have been cried-up by fanciers, are altogether unprecedented, and will be quoted hereafter, in histories of the present times, as instances of the lengths to which a popular mania will go. Still, some farm-yards are peopled with them; and the effect is good, whilst the result is highly satisfactory."

CHAPTER IV.

SELECTION OF STOCK; INTERBREEDING; EGG-BUYING; HATCHING; FEEDING; FATTENING; HOUSING.

Among the earliest authorities we have on the subject of the breeding and management of poultry, is Columella; but besides him, there is something to be found in Cato, Pliny, and Varro; but all may, substantially, be considered as entertaining similar views. Columella is, however, the grand source of poultry antiquity; and, in our day, by the writers on this subject, he is mostly quoted at second-hand. Gesner made a collection of passages relative to birds; but Aldrovandi was, in his time, the exhaust-less mine of all that was known on the subject. Considering the immense mass of his materials, this ornithologist arranged his matter in marvellous order; but his discrimination was much less than his patience; and his judgment was, perhaps, less than either. We are not aware of there being an English transla-
have then six pages on the food of chickens, succeeded by a number of separate sections, with which we have here little to do, but which remind us that what we have indicated in this brief review, is introductory to a large portion of the subject of this chapter.

Returning to Columella, we find that he allotted twelve hens to one cock. Since his day, however, polygamy, even in the poultry world, has been less fashionable. In the Farmer's Director, by Bradley, one cock is to be satisfied with seven or eight hens. The same number is recommended by other breeders, of equally abstinent principles. These, however, are English breeders. On the other hand, Parmentier, a French writer, assigns fifteen, or even twenty hens to one cock, provided he be young, vigorous, and healthy, which, in our humble opinion, he would need to be. Bosc, another French writer, says that it is only in spring that a cock should have fewer than twenty hens; but as the Gallic bird may have more vigour in him than the Saxon, we will not stay to dispute his opinion. Our own Dixon sensibly says, that the hens allowed to one cock, should vary in accordance with the object in view; but it is the opinion of Mr. Nolan that in order to secure a prime breed, a cock two years old should not have more than five hens. Breeders of game fowl for combat limit the number to four, or, at most, five; their object, of course, being the production of strong chickens. In winter, or in cold or damp weather, Mowbray says, a cock should only have four hens.

Even from these high authorities there are dissentients, who say, that if fowls are kept chiefly for the sake of the eggs, for domestic purposes, ten hens, or even more, may run with one cock; and some of our best judges affirm, that it makes no difference in the number of eggs produced, whether a cock is kept at all or not. If, therefore, it is thought advisable to avoid the expense of keeping a gentleman, a few eggs for setting can be bought, begged, or exchanged. In the case of the cottager, the keep of one hearty fowl, to be set off against the produce of the sale of eggs at a penny or twopence each, may be worth consideration. When fowls are kept with a view to rearing chickens, we think no more than four hens should run with the cock. If a fine, healthy, well-fed bird is allowed to run with four fair ladies only, the owner may fairly expect every egg to prove productive; that is to say, after the danger of the chills of the early season is past.

It is impossible to be too careful in keeping choice hens from the intrusion of any male bird except the one which it is wished to have as sire to the chickens. We know so little of the intricate rules of good breeding, that we entertain a prejudice against brood hens mixing even with hens of different kinds, especially with fowls of colours which would be objectionable in their chickens. Authorities too high to be doubted, affirm, that one stallion will influence not only the one foal, but those which the mare may have in after years. We would therefore keep choice pullets away from other fowls from chickenhood, and never, at any season, allow them to mix with either cocks or hens of a different breed. In assorting the fowls, care should be taken that both cock and hen have not the same fault or deficiency. Too many beauties and perfections they cannot have.

"If you look to the production of eggs alone," says Mr. Richardson, "one cock—if a stout, young, and lively bird—may have as many as twenty-four hens. If, however, you want to obtain strong and thriving chickens, you must restrict them to six at most. If your object be the improvement of a worn-out and degenerate breed, the fewer hens you allow to one cock the better; and you should not, under these circumstances, allow him more than three. But whatever the breed selected, or the object in view, the cock should be in perfect health."

Having, we hope, got over this difficulty as to the number of ladies to be assigned to the Spanish gentleman in black, or any other gentleman, however gaudy may be his colouring, we trust we shall be able to pursue our subject without much interruption from the diverse opinions of opposite parties.

In reference to breeding, if the object in view be strength of constitution, it is a maxim with many, that there is nothing like breeding from two-year-old fowls on both sides; but if great weight is given to beauty and points, it is doubted whether it is not better to pair a one-year-old hen with an old bird. Without
attempting satisfactorily to solve the problem ourselves, the following has been proposed by one of the most eminent amateur breeders of the present day:—"I should very much like to know what experienced breeders think of the three following cases, and from which they would expect the chickens to turn out best:—

No. 1. A two-year-old cock with a hen:

No. 2. A one-year-old cock with a two or three-year-old hen:

No. 3. A two or three-year-old cock with a one-year-old hen." The same gentleman thinks that, for his first breeding season, the young cock should have only two females.

When a hen gets broody, there is no danger of mistaking her meaning. Sometimes she fusses about the yard, with tail set and feathers erect, like an angry turkey-cock. Sometimes she establishes herself in a nest, and, with great avidity, takes possession of any egg which may be there. It is a curious sight to see a broody hen carry an egg. She takes it up under the chin (if we may be allowed to speak of the chin of a hen), holding it carefully against her breast with her beak; and so we have known it conveyed to some little distance, and over a low partition. As no sentimental idea of _meum_ and _tuum_ influences sitting hens, it will not do to set them side by side without a partition between the nests; for the hen gifted with the largest bump of acquisitiveness, will be continually pilfering eggs from her neighbours; in process of which manipulations, some eggs will get broken, others chilled, and, in others, the germ of the chick, very tender during the early period of incubation, will be deprived of life.

After health and strength have been duly considered, the next grand object to enter into the calculations of the breeder, is the age of the birds. In the selection of the cock, he should be neither too old nor too young, but running from one year and a-half to three years and a-half. Some vigorous gentlemen, of good constitutions, retain their power till they are even past six; but these are not to be chosen for breeding purposes; nor are those young fellows, whose premature amative propensities are developed so early as the age of five or six months. It is, in every proceeding in life, safer to rest on a certain than an uncertain basis; and this principle holds good in poultry breeding, as well as in matters of greater importance: therefore, the best plan to pursue, is to obtain a strong healthy bird, in the very fulness of his prime, and so avoid such premature developments, which are always deceptive, as well as the infirmities of age, which, although existing, may not be so readily detected. Extremes are, at all times, dangerous.

As in all fowls, except Brahmas and Cochins, it is a doubtful experiment to move a broody hen, it is best, as soon as a fowl gives warning to sit, by remaining long on the nest for laying, to give her a movable one, which will do for the purpose. If she should steal a nest in a hedge, or any out-of-the-way corner, it should be considered as desirable. If she choose one in the hen-house, most hens will bear moving, nest and all, to a quiet place; but a great many will not like to be taken out of the chosen nest, and placed in another. The brooders should, if possible, be placed where they cannot be interrupted or annoyed by other fowls. Food and water should be put near them, that they may come off and eat when they feel the desire, which will be once a day. Give them gravel as well as food, and some dust to roll in and clean their feathers. A person should be on the watch to know when the hens leave the nest, to see that they do not remain off too long, or get to fighting, and that each one returns to her own place. Most hens remain off from five minutes to twenty.

Sometimes annoyance will be caused by the pugnacity of the cocks. This is said to arise from their temperaments having a large infusion of the amorous element, which causes a great jealousy of disposition. Mascal, or rather his original, Columella, recommends, as a cure for this, that we should "slitte two pieces of thick leather, and put them on his legs; and those will hang over his feet, which will correct the vehement heat of jealousies within him." This direction is approved by M. Parmentier, who adds, that "such a bit of leather will cause the most turbulent cock to become as quiet as a man who is bound both hand and foot."

Dorkings are better sitters than layers; whilst Spanish fowls reverse this order; and these conditions will be found to be pretty generally characteristic of hens partaking of the prevailing colours of these two varieties respectively—the black usually being the best.
layers, and the grey or chequered hens, more particularly those with light-coloured legs, the best sitters.

When a hen is anxious to sit, she intimates her desire by a peculiar kind of cluck, which she continues, even after hatching, and until her brood no longer require her motherly care. At this period the heat of her body is materially increased, which, no doubt, generates an uneasy feeling, should it not be drawn off, either by the gratification of natural desire, or by artificial means. Should she not be desired to sit, a common practice for allaying this heat is immersion in cold water; but to place her in her coop, in some cool, quiet spot, where she may look out upon the grass, is a much more humane method of proceeding.

Should doubts be entertained as to the steadiness of the hen required to sit, she should be tried for three or four days, by having her placed on several eggs of little or no value. If chickens are desired to be hatched by some particular time, and there are no hens clucking, or ready to sit, the desire of incubation may be excited by stimulating food, such as oatmeal porridge well boiled, seasoned with Cayenne pepper; toast, or dry bread, steeped in good ale, or hard-boiled eggs, and fresh raw meat cut small. The practice of plucking the feathers, or using nettles, is a bad one, and far less efficacious than cruel.

There are some hens as constant in their sitting as those we have been describing are the reverse; and birds possessing this temperament will frequently sit until they half-starve themselves, if not prevented. Mr. Lawrence says, that he has had hens which, under these circumstances, reduced themselves to such a pitch of weakness as even to faint; and, after the chickens were hatched, to be so weak as to be scarcely able to attend to them.

Quoting Mr. Richardson, in a previous page, we have observed, that the great point of selection in the breed which it shall be determined to keep, and that this must be mainly decided by circumstances; that the wealthy amateur may so do as he pleases, but that a different rule must be the guide of those who make poultry-keeping a matter of business. This should always be borne in mind. We recommend the farmer to confine his stock to some one approved breed.

INTERBREEDING.

Whilst remarking on the selection of the breed, we would observe, that in poultry, as well as in all other classes of animals, an infusion of different blood, so to speak, is necessary to improve or prevent a degeneracy in the stock.

For exhibition purposes, it has been allowed that cross-breeding is of no avail; but holding the opinion that the exhibition of birds is only a secondary consideration, when compared with their commercial utility, a good prima facie case may be made out how cross-breeding is likely to be advantageously and profitably pursued without interfering, in the slightest degree, with those whose tastes confine them to the production of pure-bred birds.

The two great points to be desired in poultry, are the increased production of eggs, and its own improvement for the table. These are, perhaps, the only legitimate grounds on which we can justify ourselves in entering upon cross-breeding. If either one or the other of these can be obtained, it follows, as a matter of course, that a great benefit will be conferred, especially upon those who keep poultry when the latter may be made to help to keep them. That judicious cross-breeding does materially improve the value—that is, the marketable value—one of many animals, is a well-established fact. For example, a pure Southdown or Leicester sheep is exceedingly valuable, but a cross between the two is more valuable still: the meat not only brings more per pound in the market, but the quality of the wool is materially improved; while hardihood and early maturity are not to be forgotten as important considerations arising from this excellent cross.

Besides this argument, the cross will live and fatten, where the pure-bred will starve and die. The same argument holds good with cattle. Many of the cross-breeds make what is called "the best butchers'" beasts. If such is the case, why may not poultry, judiciously crossed, produce the most profitable varieties? And that they will do so we have not the smallest doubt.

To combine quality with size, of course, is the great desideratum in table poultry. From observation in such matters, the best birds to start with are, perhaps, a cross between Cochins and Dorkings. A good cock of the first
variety, not above three years old, should be selected, and mated with six first-rate Dorking hens of a year old. The pullets of that cross should be mated the next season with Game, and their produce used. It is not recommended to breed from them again on any consideration, as it cannot be done to gain any point of excellence. By the above crosses all the essentials of a good fowl are obtained. In the first place, size is obtained from the Cochin, and one good cross of quality from the Dorking. By the Game cross very little in size is sacrificed, whilst another first-rate cross, in point of quality, is added. We have seen birds of this cross attain first-rate and rapid weight, and, when killed, retain nothing of their Eastern origin, except that peculiar juiciness for which they are remarkable—the flesh being as white as snow, and as savoury as any aldermanic 
gourmand could desire. We believe that this cross cannot be improved upon for table purposes. We have seen the above first cross, crossed with Malay instead of Game; but it may easily be conceived it was a mistake, as the Malay cross was going too much back to the Eastern type, without giving any counter-balancing advantage.

It is great folly to breed further than one cross; or, in other words, to mate cross-bred birds together, as it has been found that the further we get from the first cross the more we are disappointed.

In crossing, it is much easier to produce increased value for the table than increased egg-layers. Indeed, we do not think that any amount of crossing can produce birds which would, in laying, beat some of our present known favourite varieties; therefore, on this head, it is unnecessary for us to enlarge.

If, by cross-breeding, additional size and superior quality can be obtained, it is, to a certain extent, worthy of carrying out—not that we would, on any account, advocate it in the fancy, but it might be the means of supplying our markets with an improved variety of domestic fowl, with a profitable return to both breeder and feeder.

An anonymous writer, who has evidently had great experience in animal-breeding, remarks—"I have bred in-and-in from almost all varieties of pigeons, rabbits, pigs, canaries, and numerous varieties of flowers and vegetables: in each and every case I found that, for the first few generations, they improved, and finally degenerated; in animals, invariably, diseases of the head are prominent; in flowers and vegetables it produced general delicacy. This is forcibly exhibited in some of our favourite flowers; many of the pet roses are useless on their own roots, and we breed them on the healthy brier, which man has not tampered with. I am often, almost daily, in company with short-horn breeders. A common complaint is, of the barren heifers and bulls. I make no exception in their case; I would cross them with the West Highland cattle, and so fulfil our trust and duty to posterity by saving to them a breed which the present system of shows is encouraging all breeders to render degenerate.

"So long as man confines himself to the species, and does not breed too near akin, he will be successful in producing useful animals, especially in the first cross; but it is against nature to decrease the natural size of any animal's head. It is against nature, also, to see a four-year-old heifer standing on four legs that would well become a full-bred yearling colt.

In a recent instance I measured a prize four-year-old heifer, 95 stone weight, and a yearling Flatcatcher: the former I could span, the latter not. As responsibility rests upon all show committees, it would be well for them to consider it. A few years ago, cottagers, about me especially, cried out for something with a little more "blood" when buying their pig: now the complaint is the reverse."

EGG-SELLING, AND BUYING.

We have frequently heard great complaints made about bought eggs; and we have often thought that two reasons may account for the disappointment complained of. Those who sell the eggs are careless as to what they sell; and those who buy them expect better luck than it is in the power of eggs to command.

In selecting eggs for sitting, it should be borne in mind what are the number of hens the cock should associate with. Those of the average size, laid by that particular hen, are most likely to prove productive. The oft-repeated notion that round eggs contain female chicks, whilst long ones produce cockerels, has been refuted over and over again.
Those who sell eggs for incubation, unless they are usually themselves on the spot, to see that every circumstance connected with the transaction is properly conducted, had better keep but one kind of fowl in one locality. As the eggs are laid they should be put by in a box of chaff or bran, with memorandum to state the date when each was laid, the kind of fowl, if different varieties are kept, and the particular hen that laid each separate egg. Eggs more than three weeks old should not travel, as the freshness they are the better. When amateurs have eggs to dispose of, we think it is best to advertise them; and we decidedly recommend pre-payment to be made a condition. To pay for a dozen of eggs which were set weeks ago, is a trifle which may escape a person's recollection; although, perhaps, it ought not to do so; and, therefore, we recommend pre-payment to be made a condition in all such sales. Eggs are sold now at more moderate prices than they fetched some years ago; and numerous letters, to jog the memories of backward payers, become a discount rather more than should be allowed on each sale. Many persons who forget to settle triles of this kind, do so quite unintentionally. If, therefore, amateurs generally made pre-payment imperative, we believe it would prove an advantage both ways. Dealers cannot do this: those who run long accounts with them, and other tradesmen, neglect to calculate the magnitude of the spreading evil they create by doing so; but amateurs, to whom we may reckon selling a matter of less importance, can take the law into their own hands. No one ever yet sold eggs for hatching, without having some complaints, and demands for more eggs, in place of those that have proved unproductive. Whether these demands should be acceded to, must, of course, depend on their apparent fairness. We think those who sell eggs should never promise to make up loss or failure; but many would wish to do so under certain circumstances.

Having spoken of selling, we may say a few words upon buying eggs. In this case we can only depend on the known character of the amateur, or the dealer, from whom we purchase. By holding the eggs in a strong light, we may ascertain, by the size of the air-bladder at the large end, whether the egg is fresh; and this is about all we can do beyond placing reliance upon the seller. In fairness, we must give the eggs a good chance, by having them immediately placed under a good hen, in a place where her sitting cannot be disturbed by other fowls, or entities still more mischievous. If the chickens are in the proportion of two to three, or even to four eggs, we may reckon that we have been well treated, and lucky into the bargain. If it were intended to establish a stock by purchasing eggs, the best plan would be, to buy sittings from different breeders; to bring the chickens up apart; or to place such marks upon them as should distinguish them as they grow older, and then to mate the cocks from one stock with the hens of another. The objection to this plan is, that the fowls, the next year, when their owner would wish to breed from them, would be all young alike. A better plan would, therefore, be, to rear pullets in this manner, and in the autumn, or following spring, to purchase a good mature cock. Then, the owner would at once be in a position to breed fine chickens.

"Caution," says Mr. Richardson, "is necessary in the purchase of eggs for sitting, especially from strangers and from a distance. Mr. Punchard has demonstrated, that skill in the packing of eggs is well bestowed, and that the average amount of productiveness of travelled eggs, may be greatly increased by the way in which they are sent out upon their journey. Much, however, must always depend on the manner in which they are treated in their transit by railway porters and other officials. In the county court of Lynn, Norfolk, an action was, on one occasion, brought to recover the sum of £1 10s. 6d., the value of thirty-six Cochin eggs which had been sent by the plaintiff from Penzance, Cornwall. The box not arriving at the time it was due, he sent to the station to enquire, and was told by one of the clerks that it had not arrived; but on a search being instituted, the box was found in an open shed, exposed to frosty weather. Hence, and Cantelo's incubator, failed in producing from them a single chicken. For the defendants—namely, the East Anglican Railway Company—it was argued that the action had been brought against the wrong parties. In order to recover damages for loss, the plaintiff was bound to show that vitality existed in the eggs when they
POULTRY.

were brought to the station of the company. The box had been under several conveyances—by steamer from Penzance to Bristol, and from Bristol to Paddington by the Great Western, whence it had to be conveyed over the stones, from Paddington, to the Eastern Counties station; and it did not come into the jurisdiction of the East Anglian Company until it arrived at Ely. The judge said that he could not conscientiously see that it had been proved that there was any vitality in the eggs when they arrived; but there was clearly a wrong, on the part of the company, in not delivering the goods as soon after they arrived as possible. The plaintiff was, therefore, nonsuited, without costs on either side. In short, it was discovered that all the law in the world could not bring the addled eggs to life again. Other confiding purchasers of Cochin-China eggs have found that their beautiful chestnut tint has been the result of skilful dyeing.”

Eggs for hatching should be preserved by placing them, with the small end downwards, in sawdust, bran, sand, wood-ashes, or any other substance which will form a soft bed, and, at least, to some extent, exclude the air. If, however, the object is to preserve them for a considerable length of time, with the view that they may be eaten, they should, when newly laid, be dyed in oil, or warm—not hot—pure hog’s-lard. The greasy substance should be rubbed with the fingers into the pores of the eggs, and then they should be packed, with the broad end upwards, in a box or barrel. If they are to be exported across sea, a coat of varnish might be tried upon them; but if they are intended for hatching, all these extraneous substances must, as a matter of course, be removed. In packing them, care should be taken that it be compactly done, so that as much shaking as possible may be prevented. For this purpose various modes are adopted. Some pack in hay in a crate, and others in hay in a hamper. Baily, the great breeder, packs in a crate of hay, and Baker in a hamper of hay. Both plans are good; the chief thing being to give the eggs plenty of room, so that the bumps and thumps of outrageous fortune they are pretty sure to meet with in the railway transit, may not injure them. Some persons pack in a box, with chaff, or in oats; and others tie a wisp of hay round each egg, and fill in the interstices with any yielding commodity. After packing carefully, the owner can do no more than have the package safely conveyed to the railway, and consigned to the mercy of the officials, which we fear is frequently of a somewhat rough kind, considering the fragility of the article entrusted to their care.

HATCHING.

Regarding the number of eggs to be placed under a hen for hatching, from nine to eleven is usually chosen. Much of the ill luck attending hatching is caused by setting too many eggs under one hen. Nine eggs are sufficient for any hen—of course we mean Spanish eggs. The result generally proves this to be so. We all know that the eggs of our prize fancy fowls, which are, to a very great extent, brought up artificially, do not hatch so well as those of commoner kinds. May it not be that the germ in the egg is far more delicate, or, properly speaking, weaker, and requires greater warmth to give it life? This is, however, dependent on the size of both eggs and hen. An odd number is preferred as better adapted for covering in the nest. Be sure they are fresh. During the early period of incubation, hens will sometimes eat their eggs—a circumstance arising from their craving after calcareous matter and animal food, with both of which their appetites should have been satisfied previous to the commencement of incubation.

Never let a poor hen waste the anxiety of three weeks on bad eggs. When she has sat nine or ten days, try the eggs, and take away every one which has no chicken-germ within. It is easy to discriminate between the good and the bad eggs; that is, those that contain, and those that do not contain chickens. The manner in which this may be done is simply holding them up to a good light; but the best contrivance is to make a round hole in the hen-house door. Should this not be convenient, make a hole in the bottom of a box, which will always come in handy for the same purpose, as it can be fixed up pro tem. against the window of the hen-house, or a lamp can be placed inside. The best size for the hole is 1/4 inches in diameter. This will furnish sufficient light to try Spanish fowls’ eggs, and will do equally well for Sebrights. Have this apparatus close
POULTRY.

at hand, where the hens have been sitting beyond a week. Remove the eggs from under each hen, and carefully guard against allowing them to be shaken, or kept away from the fowl long enough to get in the slightest degree cool. Hold each egg to the round hole, and the opaque germ of the chick will be quite perceptible, as well as the delicately-traced blood-vessels upon the shell, which are intended to nourish the embryo until they dry up at the expiration of the period of incubation—as a hint to the chicken that it had better issue forth, and scratch for its own living in this world of ornithological as well as human cares. Eggs which appear to have undergone no change must be removed. It is better to make up each nest to nine good eggs; and if any hens should, by these manipulations, be left at liberty, they may have fresh batches of eggs given to them. It will do no injury to any good steady sitter to remain in the nest thirty days, or even a little longer.

Except in this one examination of the eggs, which must be conducted in the gentlest manner possible, never interfere with the sitter.

The day before that day three weeks on which the eggs were set, especial care should be taken to notice the nest when the hen leaves to feed, and to observe if any of the eggs are chipped. When hatching-time arrives, the bill of the expanding chick presses up one spot of the shell, with starry cracks diverging from it. If there is no appearance of this kind, the hen may safely be left until the twenty-first day, as the chickens generally require no feeding for the first twenty-four hours. The chick, from this first spring in the shell, spreads the cracks by its own force alone, until it opens a door for itself. Then it lies, a little wet and weakly thing, beneath its mother’s warm feathers for some time. When twenty hours old or so, it begins to eat. Then we think it best to place before the mother, in the nest, a tiny basin filled with moistened oatmeal or barley meal. We would give this in preference to a chopped egg, as some do, because most likely the mother will set to work herself, and devour that greedily; and if she does her duty, she is worthy of her hire; that is, her share (sometimes the lion’s certainly) of the good food provided for the chicks. When this is gone, a chopped, hard-boiled egg, mixed up with stale bread-crumbs, and a little water, should be put into a very shallow pan, as the chicks soon want to drink.

"For about twenty-four hours after birth," says Mr. Richardson, "chicks not only do well enough without extraneous nourishment, but will be far more likely to thrive if let alone. The next day they may be fed with crumbs of bread and eggs, boiled hard and chopped fine. For the first four days they require food at least hourly, to supply the rapid increase in bulk and feathers. Damp is fatal to them. Small-grained oatmeal, given raw, or slightly scalded, and suffered to cool down to a very low degree of tepidity, will be found useful and good. Do not forget that, in all probability, thirst will be present before hunger; and there ought, therefore, always to be a flat, shallow pan, or plate of clean spring water left within reach; and the hen herself, glad of a little refreshment after so long a task, will usually lead the way to it."

For the purpose of breaking open its prison-house, and "seeing the light," one would think that there could not be any living thing in the world so ill adapted as a chick when about to emerge into life. Yet Nature, in her exhaustless powers of ingenious operation, enables it to do so. If the chick, however, be weakly, artificial assistance is sometimes necessary to give it the liberty it seeks. The position which it holds in the egg is such, as frequently to render it difficult for such a tender youngling to break its way. The neck slopes towards the belly, to about the centre of which comes the head; whilst the head reposes beneath the right wing. The feet are gathered up, something in the style of a fowl trussed for the spit; and the claws are bent backwards to such an extent as almost to touch the head. It is in this confined position that the shelly wall of the prison has to be broken through. Such is the position; and when we consider the hardness of the calcareous wall that has to be reached, we can hardly conceive anything more difficult for the accomplishment of a chick.

"The process of effecting the breaking of the shell, is a succession of taps from the beak, by which first a crack or star, with many cracks diverging from it, takes place; a hole is soon effected; the sides gradually chip away, and the chicken enters into its new sphere of being.
Sometimes the little bird, on proceeding to leave the broken shell, unexpectedly finds itself retained in its place by some accidental or irregular circumstance. The shell may, for instance, have been well cracked, and yet its lining membrane may be so tough as to defy all the efforts of the inmate to rupture it, and thus still present a barrier—often, without assistance, an insurmountable one. Some chickens waste their time striving to tear this membrane before they have made a sufficient crack in the shell. These had better not receive assistance, as they will speedily find out their error, and go to work in a proper manner."

It is recommended that, in every case, the egg should be looked through before helping the chick. The chicken, which comes forth previous to the complete absorption of the yolk, is sure to be an unhealthy, delicate little thing, walking about like a gallinaceous ghost, ready to fall off its legs at every puff of wind. Before quitting the shell, a chicken ought to have imbued such a portion of nourishment as will, at all events, support its existence for twenty-four hours afterwards. The yolk is designed for this purpose; and any excess of light that may be permitted to strike upon the egg, or any injudicious handling of it as the close of incubation approaches, will generally be the cause of inducing the chicken to strive to get out too soon, which, as a natural consequence, is frequently productive of considerable numerical loss. As every membrane or shell is not alike in point of thickness, another difficulty presents itself in preventing the chick from easily coming forth.

Dipping the eggs into warm water the day before (some poulterers think they will be pecked at), is a plan sometimes adopted; but, as this can produce no real difference upon the consistence of the shell, the plan may safely be pronounced futile. This practice has, therefore, been objected to. Too much heat is another obstacle in the way of the egress of the chick, as the albumen with which it is encompassed, sometimes becomes converted into a kind of glue, which fastens them to the extraordinary abode in which they are inclosed.

The only case in which interference can prove useful, is said to be—"When you find the fracture on the outside of the shell remaining the same for five or six hours, and when, on examining the edges of this fracture, you find them dry and unmoistened by any fluid, you may conclude that assistance is called for, and may proceed to render it with all possible caution. The best mode to be adopted, on such occasions, is to imitate, as nearly as possible, the natural efforts of the chicken itself, which may be done by sharp, short strokes with the back of a knife or key; or, what is better than either, the point of a pair of scissors. Be, however, both gentle, firm, and deliberate, and take care lest you penetrate the cavity of the egg. Having succeeded in making a sufficient opening in the shell, you may, by a careful and tender use of your fingers, extricate the chick. Sometimes a few scales of albumen, or of the lining membrane of the egg, may remain on the bird's plumage for some days. Do not be uneasy about them. Leave them alone, and, as they dry, they will fall off of themselves. In affording your assistance to the embarrassed chick, be extremely tender with your fingers. You may otherwise often kill when your intention is only to cure."

"For my own part," continues the same authority, "my confidence in the unassisted powers of nature is such, that I should be disposed to permit, at least, **eight hours** to elapse before I resorted to mechanical means of interference. A chick so weak as to perish before that time, is not worth striving to extricate; and, on the score of humanity, its death within the shell will be less painful than after quitting it."

When the chickens are all hatched out and dry, we think it a capital plan to move the mother and her family into a clean warm nest, because the one in which she has been sitting will most likely be infested with hens' fleas; and if these get into the young brood—for they love to prey on the young—the evil will be great. In this the chicks may remain over the second or third day, according to their strength, and the state of the weather.

In reference to the vermin "pest," affecting the chickens, two anonymous writers supply the following statements and suggestive remedies, or preventives:—

"Last year my chickens, as also those of
my neighbours, were attacked with lice on the head, which destroyed numbers of them. This year some of my neighbours have the scourge again. When I set a hen, she has always the opportunity of getting a dust-bath whenever she comes off her nest. This she had also last year, and she was, and is, removed to a fresh pen after hatching. The plan I have adopted this season is, before giving the hen her chickens, to dust her well with flour of sulphur under her wings, on her breast, and under her feathers: it can do the chickens no harm. As yet I see none of my former enemies. My houses were perfectly clean last year, as they are this.

"To insure a sufficient amount of moisture, when it is found necessary to set the hen in a spare hay-loft or room, with a boarded floor, I would recommend a plan which I have found, so far, to answer well this season—viz., to place beneath the box in which the hen sits, a piece of matting or carpeting which has been exposed to a good shower of rain. No doubt, the ground is the best place on which to set a hen; and, at this season of the year, it should be in-doors; but it is not every one who has such convenient places, where the kindly-intentioned visits of other hens, adding to the store of eggs for incubation day by day, can be avoided. It would, perhaps, add to the comfort of the hen if, previous to setting her, a little flour of sulphur were dusted under her feathers. This would settle the vermin, which are a source of annoyance, not only to the mother, but to her young progeny. I have found young chickens infested with them, even when the hen, in summer, had sat under the hedge of my lawn, where she had every opportunity of dusting herself."

When chickens are hatched during cold weather, they require artificial warmth, or, at the very least, comfortable housing; and the kitchen of a farm-house affords this in the utmost perfection. Freedom from annoyance, commodious and warm housing, and a sheltered walk, are all that they require. It ought always to be borne in mind, that the dangers which are most likely to prove destructive to the hopes of an amateur in rearing his broods, are wet, cold, bleak winds, neglect, short commons, cats, rats, hawks, and vermin of all kinds. If a hen is left at liberty with her brood, she leads them under shelter at the approach of rain; and many little bright eyes may be seen glancing from their safe retreat, and watching for the return of fair weather. By our interference, the exercise of this instinct in the old hen is often prevented. We place the coop, in the morning, on a warm sunny spot, where—with the addition of good feeding of course—we think they will be contented and happy for many hours. But, in the course of a few revolutions of the long hands of the clock, what changes may happen! The sun either leaves the place, or blazes on it with an intensity of heat enough to give the hen the vertigo; a sharp east wind springs up, and the poor little ones stand pinched and shivering in its blast; or a chilly rain comes on, and beats into the coop. The coops should be visited once an hour while the chickens are very young, and every two hours afterwards. The chickens should then be fed and supplied with clean water, and the coops shifted if necessary. At night, the hen and her chickens may be driven into the hen-house, and a slight shelter, according to the weather, placed before the bars of the coop. Constant attention and frequent feeding are indispensable for chickens. Cats and other hairy and feathered enemies will require unceasing vigilance, and, perhaps, a good gun. For these, too, the services of a well-trained terrier are invaluable; nor are good traps to be despised. With regard to feeding, it is with young chickens as it is with grown fowls—variety is best. Sometimes food of various kinds should be given them in one day; occasionally, a change of the kind should be made from day to day; and, in addition to all that can be given them, the hen should be allowed to roam at large for a little time every day, to seek for her progeny, ants' eggs, worms, &c., taking care to coop her again before she can over-tire the little ones. For the first week, there is nothing better to feed with than chopped hard-boiled eggs. The eggs which are removed from the nests of the sitters, within the first ten days, will do very well to boil for the young chickens.

After the first week, various other viands may be given. Perhaps the best plan for us to pursue here, will be to give a bill of fare. Barley-meal and oat-meal, moistened with water or with milk; grain broken in a mill;
boiled barley; pearl barley rolled in bran or pollard; pieces of meat and potatoes; bones, and any other scraps from the table; swelled rice rolled in bean-meal. Ship biscuit, hemp-seed, canary, buck-wheat, and many other things may be used occasionally, in small quantities, by way of a change.

Should the chicks be very weakly, they may be crammed with crumbs of good white bread, steeped in milk or butter, with well-minced, hard-boiled egg; but, at the same time, it must be noted that their little crops are not capable of holding more than the bulk of a pea—therefore rather under than over feed. If the hen has been much exhausted by hatching, it will do well to cram her with crumbs of bread steeped in port wine; or, in the absence of wine, diluted spirits or ginger cordial may be substituted. Such treatment, however, is very rarely necessary.

For hatching, warm damp weather is wanted. Nothing can be worse than an east wind, especially if accompanied with occasional bursts of cold rain, also from the east.

Sprinkling the eggs, now and then, has been recommended when the hen comes off to feed. For this, of course, warm water must be used. We once placed a little pan of water in a hen's nest, for her to drink from. This she cleverly upset, and gave the eggs a cold shower-bath, which killed all the chickens, or nearly all.

Whilst on this subject of hot and cold water, it will not be out of place to give an extract from Bechstein, which was written with reference to the fledging of young cage birds:

"It sometimes happens, in very dry seasons, that the feathers of the young birds cannot develop naturally. A bath of tepid water, employed on such an occasion by Madame ——, was so successful, that I cannot do better than recommend it." In another passage, Bechstein recommends that the young birds shall be dipped in lukewarm water, so as quite to moisten the quills of the sprouting feathers.

Mr. Bailey—about the highest poultry authority in the country—advises that the old hen be confined under a rip, placed on the grass in a warm sheltered situation, and moved about, as often as necessary, to keep the mother and her brood on a clean spot.

At farm-houses, complete success often attends chicken-rearing with much simpler and cheaper apparatus; namely, by a common wicker coop, which may be bought anywhere for fifteen pence, or a bit of wide flannel sheet, with which to tether the hen.

Some breeders have gone to the expense of making permanent chicken coops, with a comfortable little house, and a run of three feet by six for each brood; but we do not think this so likely to form the best treatment for chickens as any little movable contrivance.

As prevention is better than cure, and example better than precept, we may as well say a few words about hatching difficulties, at such times and seasons as they generally occur. One Monday, under a bright sky and a bitting wind, a breeder divided twenty eggs (of a choice kind, of course—for who thinks of anything else now?) between two willing recipients—well-tried, broody hens. He set one wide, plump, short-legged old hen in a nest nine inches by ten; and she soon gave signs that her quarters were too straitened by breaking four of the eggs. The remaining sixteen, he found, contained twelve chickens, which went through the process of incubation, without further breakage, to the twentieth, twenty-first, and twenty-second day: still no chickens made their appearance. By this time the chicks were cheeping inside the egg-shells, but none were cracked. A drying and bitter east wind prevailed, finding its way through the few crevices that were in the hen-house. In two of the eggs the chickens had died, which left ten eggs under one hen. The other had had a fresh batch given to her when this was discovered. This was a most unsatisfactory state of things; therefore he had the nest (without the hen in it) taken into his house, and placed over a foot-bath, into which hot water was poured, and an old piece of flannel thrown over all, in a manner to give the hen and eggs a vapour-bath, but not enough of it to set her panting. The nest was left in a room with a fire in it, and very soon the eggs hatched.

He believed the loss of the two chickens, which we have mentioned as having died in the egg-shell at an early stage, to have been his own fault; for, finding one hen had but two good eggs, he made up her nest with others, which he gave her cold; and we have no doubt
POULTRY.

these cold eggs chilled the two she had. Another hatching, by the same gentleman, was better managed. He gave the hens good roomy nests; almost all the eggs contained chickens, and the egg-shells began to crack on the twenty-first day. Two or three times in the course of the day, he had the hen-house watered with hot water, so as to produce steam in the place, where, as a matter of course, there were no fowls to roost. The next morning, bonny broods were popping in and out round the mothers; but a few of the eggs were still unhatched. One was a good deal broken; but the white skin looked hard and dry, and the chicken was unable to extricate itself. This he opened carefully, dividing the two skins sufficiently for the chicken to expand itself. He replaced it under the mother, and the next morning could not tell it from the rest. On the twenty-third day, two eggs only remained uncracked. These he opened, and found dead chickens inside, the lives of which might have been saved if he had opened the eggs the day before. We do not blame him for the delay, although it proved unfortunate in this instance, as the chickens were not crying in the eggs, and as we have known the egg-shell to be, sometimes, opened on the twenty-second day, and found that it should have been left a day later.

Premising that a constant supply of suitable food is the great essential which enters into the rearing of the delicate birds, such as turkeys, pheasants, and guinea-fowl, the following hatching-table shows the periods of incubation of a few tame birds:—

All who have bestowed attention on the feeding of stock of different descriptions, tell us that various kinds of food are necessary for the different functions which it is the object of food to perform. One kind is required to give warmth, and to aid respiration; and another to restore the muscular waste of the matured, or to increase the bulk of the growing animal. If we give only warmth-producing substances, the consumers will fail in the increase of bone, muscle, &c.; and if we give too much flesh-producing nourishment, it goes to waste, or becomes injurious. Experimentalists say that peas, beans, wheat, pollard, oatmeal, and some other vegetables, contain much flesh-forming substance; but it is difficult to say what proportion of them should be used, or what quantity given, without doing mischief. We have known chickens to be fed on two meals a day of these nourishing kinds of food, making up the other meals with barley-meal, potatoes, ground corn, and green food; and they have thriven well.

Fowls, however, are blessed with capital appetites, as every breeder can prove by his bill at the corn-dealer’s. The plan of feeding which used to be followed by almost all poultry-keepers (what one may call private poultry-keepers), and which still is followed by some, was to give the fowls plenty of barley, and nothing else. This is neither good for them nor for their owners. Fowls do not thrive on it, and are constantly ravenous. It is proved by the elaborate experiments of M. Reaumer, that each fowl will eat a quarter of a pint of grain per diem, when fed on this kind of food only. A great objection which we find to it is, that it is the most expensive kind of feeding we can use. Mr. Bement, the American writer on poultry, found that eight Poland fowls consumed a peck of Indian corn in eleven days; a peck of oats in six days; a peck of barley in seven days; a peck of wheat in ten days; a peck of millet in eight days; and a peck of wheat screenings in seven days. During the experiment, the fowls had a few boiled potatoes only, in addition.

Opposed to this plan of feeding on grain only, is that of some of our most experienced breeders, who feed entirely on meal dough. We do not think, however, that fowls would remain healthy, year after year, fed on meal food only, with no mixture of hard corn to swell in their interior, and to give work to the gizzard.

“The substances that may be used in poultry-feeding,” says Mr. Richardson, “are very numerous and various—viz., cabbage, rape,
turnips, carrots, parsnips, mangel-wurzel, oats, wheat, barley, rye, and other grains—substances too well known to require enumerating. It will not answer to feed fowls entirely upon any one variety of food; neither will it be found advisable to feed wholly upon any one class of food. I must speak of the latter point first. Fowls require a mixture of green with hard food, fully as much as horses or cattle do. When the birds have the advantage of an extensive walk, they will find this for themselves; when they have no such advantage, you must provide green food for them. Some do so by supplying the birds with cabbages, or other greens, chopped small. My plan is to fasten heads of cabbages, lettuce, rape, or other green herbs, to some fixture, by means of the roots, and to let the fowls pick for themselves. This practice not merely prevents waste; but is, in consequence of the amusement it affords, decidedly conducive to health."

If we make the health and well-being of our poultry the only consideration, everywhere, in the neighbourhood out of doors, is the best run they can have; and if their habitat should happen to include rick-yards, with barns and corn-stacks, stock-sheds, with abundance of litter and unavoidable waste food, kitchen-gardens with hotbeds and vegetables of every sort, and flower-gardens, shrubberies, and wildernesses composed of fine loam well stocked with insects, it will be first-rate for the fowls. But, as the master is pretty sure to dislike the little unavoidable derangement of the corn-ricks likely to follow this free range; and, as the gardener has a prepossession in favour of doing all the raking himself, it is generally necessary to fence in a piece of ground for the fowls. If they can have a run out into a field or lane, although it may be only for a very few hours each day, we are sure they will pick up many things for themselves, and supply wants which, with all our study of their habits, we may probably overlook, or of which we may be ignorant.

The run, even for a very limited number of fowls, should not be smaller than fifteen feet by thirty. If it is twenty feet by sixty, so much the better, or as much larger as can be conveniently managed. When confined to one spot like this, there are many requisites towards health and well-being, with which the fowls must be supplied, that they would find for themselves, if they enjoyed a free range. Some of these are grass, lime, and small stones.

We consider a mixed dietary the best, both with regard to giving different kinds of food, and a change from time to time. An intelligent and large breeder gives whole corn once a day, and meal-dough thrice a day; or corn twice a day, and meal once. The meal-dough is mixed with the hand; with so little water as to leave it dry enough to fall to pieces when thrown on the ground; or it may be mixed with boiling water—not with the hand; that might prove inconvenient—or it may be boiled until quite thick. It can be made of oatmeal, which is very good, but dear; or barley-meal. Either of these, for economy or change, may be mixed with one-third (measure) of middlings or pollard. Potatoes and scraps from the table, bits of stale bread, and pot-liquor to mix with the meal, all make valuable changes in the poultry-yard. These things, and others of a like nature, may form one meal a day, at least, for the fowls.

This gentleman thinks that fowls should have, at least, one meal a day of corn. Different kinds of grain are favoured in different countries. In this country barley is the staple commodity; in America, the fowls are fed almost entirely on Indian corn; in France, a great deal of buck-wheat is used. All these different kinds of grain are good in change, and also oats and wheat. It has been found a good plan to give barley and oats alternately, feeding with each for a fortnight. Wheat, Indian corn, and buck-wheat are used more sparingly, because they are so much dearer; but a little of each is given every day, sometimes for a week at a time, as a change.

In addition to these regular meals of vegetable produce, fowls require a little flesh meat sometimes. When they run out every day into fields and roads, there is no necessity for the owner to attend to this want, except in continued frost, as the fowls find the means of supplying themselves with meat, in the shape of worms, flies, insects of all kinds, slugs, snails, frogs, and such comestibles as suit their palates, and their voracity; nor will a good plump field-mouse escape being turned into hen's meat, if it venture within reach of Dame Partlet's strong beak. But if fowls are
FEEDING.]

POULTRY. [FEEDING.

kept to a smaller plot of ground than will give good scratching-room to the number or it, a little meat will do them good, and promote laying.

Various plans have been suggested for producing poultry game. Oliver de Serres' vermiciter has often been mentioned by writers on poultry. It was a hollow place, twelve feet square, and four feet deep, sloped at the bottom for draining. In this were placed straw, horse manure, and earth, each six inches deep; and over all blood was poured, and garbage of any kind, mixed with chalk. In this manner the pit was filled: the rain soon rendered the whole sufficiently moist to produce putrefactive fermentation, and myriads of worms were engendered for feeding poultry. A miniature vermiciter is described by Mr. Nolan, in his work on domestic poultry. "Place bran in a deep crock; lay on it a piece of carrion; cover it with a glass, so as to admit light, but exclude rain; and in a few days, it will be a moving mass of living insects." Worms thus generated by corruption, may be as good as those which come naturally in mother earth; but we cannot help feeling a prejudice against fowls eating such; besides, the hosts of blue-bottles, with which such a neighbour would infest the place, might prove a great annoyance. When the fowls want meat, scraps from the family refuse, fresh offal from the butcher, or even fresh greaves are better. Care must be taken not to give too much. A quarter of an ounce to each fowl, and that not often, is quite enough.

"I do not think," says Mr. Richardson again, "that one circumstance connected with the feeding of poultry, and that a most important one, is sufficiently well known—I allude to the necessity they are under of obtaining esotized, or, in other words, animal food. Of course, when the birds possess the advantage of an extensive run, they can themselves pick up insects, worms, snails, or slugs; but, in cases where they do not possess this advantage, it is necessary that you cater for them. I have always experienced the best effects, especially as manifested in greatly increased laying, of giving scraps of animal food about twice or thrice a week to the fowls. Bullock's liver answers the purpose well. This I consider to be better in a raw than in a cooked state. In winter, in order to supply the place of the insects and other animal food, which they pick up in summer, I give them, once a week, sheep's entrails, boiled and peppered, together with meat bones to peck at, and also barley made hot in a saucepan, without water, and given warm. Hot potatoes are always good food. Small potatoes may be picked out, and steamed for the purpose. But meat is indispensable, if you wish to have eggs in winter."

Gravel is necessary to birds to aid digestion, and lime for the formation of egg-shell, &c. Stones can be best given by keeping a part of the run gravelled; and lime by throwing down a heap of old mortar, rubbish, oyster-shells either burnt or broken up fine, egg-shells broken up fine, or lime in any other form which will admit of poultry pecking and swallowing small portions.

Of green food, grass is best. Fowls will not do well without green food of some kind; if they cannot run out upon grass, they should have turfs, and a moderate quantity of cabbage, lettuce, or any other green vegetable.

The poultry should be fed with regularity, and have enough to satisfy their hunger. The food should be so scattered abroad that the fowls will have to use some activity to earn the meal; and care should be taken to avoid leaving quantities of food always lying about.

The American principle upon which fowls are fed, is thus shown in the Miner's Domestic Poultry:—"The principal food for fowls should be Indian corn, in some shape—sometimes whole, sometimes cracked, sometimes ground to meal, and occasionally ground to the cob. Then you want oats, buck-wheat, and any other grain you please; but the three kinds here named constitute a good supply for the extensive breeder. Besides the above grains, furnish a mess of boiled potatoes or other vegetables several times a week, mixed with meal of some kind; and be careful to change the diet of your fowls often. In the laying season, a solid feed of shelled corn (Indian corn), given profusely, is too heating; and boiled potatoes, if taken to excess, are too laxative. The careful breeder will always guard against these results, by watching the condition of his fowls. If they are relaxed, a change of food

860
must be given at once, of a more solid nature. A little rye or wheat is an excellent change in such cases. If they are costive, a boiled mash of potatoes will generally be a remedy."

In a work of this kind, it might be expected that calculations would be given as to the most economical mode of rearing poultry; but, as no general rule, alike applicable to Great Britain and Ireland, can be established, we have deemed it better to omit them. Not to speak of the differences of prices which exist between the several products of these countries, there are even differences, in these particulars, to be found in various localities in the same county. This circumstance, alone, presents a difficulty, doubtless, sufficiently great to render all calculations upon this part of our subject nugatory. Respecting the profits of poultry-keeping, the Agricultural Gazette has, at various times, given statements. The following are taken from the columns of that paper, and may enable the inquirer upon this portion of our subject, to form a basis for his own calculations, as they have done for those of others.

The actual cost and receipts for the produce of ten hens and a cock in one year, and of twelve hens and a cock in another, are given. The food was all bought at a high market price, and the produce sold in the village where they were fed. The fowls were kept clean, and well housed and attended. They were fed regularly three times a day when young, and had the run of a large grazing-yard in the day-time.

Profit . . . £ 14 8 10

To produce anything approaching to these profits, however, it is necessary to have a superior breed, in place of the fowls commonly found in the barn-yard; and also to have suitable houses and yards for their accommodation.

With respect to the poultry of cottagers, which are fed on what would otherwise be wasted, or what is collected by the industry of their children, and warmly housed under the same roof as the owner, they often thrive better, and prove more prolific, than the expensively tended inmates of ornamental poultry-houses. The celebrated Aylesbury ducks are an example of this kind. They are often reared under the beds of the cottagers in Buckinghamshire; and dunghill hens, that roost in the "kitchen and parlour and all" of the peasant, often lay, when the choice, everlasting layers of neighbouring noblemen and gentle- men, seem to have retired on half-pay.

A gentleman breeder found, that from the 2th of March to the 7th of May, he had set 98 eggs under nine hens. From this number 32 chickens were hatched, 20 were dead in the shell, and 46 had no birds in them.

The next year he commenced setting on the 2nd of April, and put, altogether, 72 eggs under eight hens. The produce was 46 chickens; 14 were dead in shell, and crushed by hatching hens, and 12 eggs were added. Instead, however, of having only 17 chickens from three hens, which were set at the same time, he did not hesitate to say that he ought to have had 21; but, in consequence of two of the hens deserting their nests seven days before the chickens were hatched, he had to get another broody hen, which had only set a few days. The other eggs he had to divide among several hens which were sitting; and, as they chipped, ho
had to take them out and place under one hen, and some in flannel on a stove. So that, in fact, it might be said that one hen and the stove hatched these 17 chickens—which were perfectly strong and healthy.

The only sickness he had with chickens was caused by lice, which destroyed great numbers. The bad hatching of eggs was not confined to hens, but extended also to ducks; for out of 24 duck-eggs, he had only five ducklings. He reared 29 chickens over nine months old. For his breeding stock he had two cocks, with five hens each. Only one case of roop occurred; and as the hen was not a valuable one, he destroyed her. One hen died from paralysis, and another from diseased liver. The number of eggs he had was nearly 2,000; and he knew, with the exception of 17, to what purpose every egg was applied. A stock consisting of 17, increased to 60 by chickens in the spring, and purchases, consumed—

\{ 19 loads, at a cost of £12 13s. 6d. \}

The expense of rearing fowls, as we have said, is subject to great variation; but let us suppose that there were but one kind of cereal on which poultry could be fed, and that it maintained one invariable price throughout the kingdom; "still, the proportional amount of hand-feeding, required by an equal number of fowls, varies greatly, according to the circumstances of their owner. A head of fifty birds, kept at a suburban villa, with high-dressed gardens, and little other elbow-room, will not be able to obtain for themselves the same amount of unpurchased food as the fifty which belong to a small farmer, who has a common in front of his yard, and a young plantation at the back. The fifty that are kept on a dairy-farm will fare differently from another fifty, in whose master's barn the flail is perpetually going. Cochin-China fowls, too, and Malays, will consume a different amount of food from what bantams do; and to strike an average on a miscellaneous col-

lection, gives, in truth, but the phantom of a precise result."

The writer from whom we have just quoted, suggests, as the only way to obtain a safe calculation, to shut up a given number of fowls of the same breed and age, and mark what they consume in a given time. "But the experimenter should be warned, that the birds, when first confined, will probably sulk, and not eat nearly so much as their brethren at large; and so an error will be admitted that would prove of considerable importance, if the calculations founded thereon, were of equal consequence with those on which astronomy, navigation, or even large mercantile enterprises rely for satisfactory results. It is better, therefore, not to attempt giving any account of the quantity of grain each bird may be expected to consume, than to give such an account as must necessarily mislead, if it is made the groundwork of any calculation intended to be generally applicable." Instead, therefore, of aiming at anything like exactness in this matter, we will quote, from the Agricultural Gazette, a tolerably full account of the miscellaneous collection of an amateur, and of the way in which they were fed and managed.

"It may be premised," says the writer, "that my object in keeping fowls is not mere money profit. If it were clearly proved to me, that, at the end of the year, I lost a small sum by them, I should still go on keeping them, for convenience and amusement sake; and so would many other country ladies, gentlemen, and clergy. If it could be demonstrated to me that the eggs laid at home cost more, per score, than what eggs can be bought for in Leadenhall market, I would still indulge in the home-produced article, instead of French eggs, twenty-four for the shilling—just as I would prefer a joint of home-fattened pork; although meat, spelt with the same four letters, might, perhaps, be bought in a neighbouring city one-eighth of a farthing cheaper per pound. If men want to enter on the business of fowl-dealing and fattening on a large scale, as a trade to live by, let them serve a short apprenticeship, and they will soon discover the most profitable way of proceeding, according to the produce and the demand of their own special locality. This class of very useful persons are, in general, too acute and too
POULTRY.

practically experienced, to need much instruction of the kind from books.

"Another point in view has been, not to attempt the formation of anything like a complete collection or menagerie of poultry—though we have always wished to have plenty, both to observe and to eat—but rather to have a succession of breeds and species continually passing in review through our premises; to have their peculiarities noted; a pen-and-ink sketch of their portraits taken; and then, when we fancy to be the secret of their life has been coaxed out of them, or shrewdly guessed at, to dismiss them as inconvenient supernumeraries, and to replace them with less familiar faces. This mode is better suited to the income, the establishment, and the brains too, of most naturalist poulterers, than to have a vast, overcrowded, unwieldy aviary population, which distracts and perplexes the student as much as it pleases the common starter. There are minds capable of threading their way continuously through such a wilderness of interesting objects, and of carrying along with them a collection of clear and conclusive ideas; but such minds are not the majority. It is wiser to attempt the performance of a feat a little below, rather than a little above one's powers.

"Our collection, then, consists of turkeys, geese, ducks, various breeds of fowls, pigeons, with their several young, besides guinea-fowl, guans, a stork, a brood or two of pheasants and partridges, and a few pair of cage birds; altogether about a hundred and fifty head. At seven in the morning, during summer, those birds which had been shut up in their respective houses the night before, are let out for the day. A sprinkling of barley is thrown on the floor of each house the previous evening. The geese (to begin with them) are driven into a large, well-screened orchard (nearly an acre), that slopes slightly to the south, and contains a good-sized pond. There they have thrown down to them a few handfuls of barley, as much as is thought sufficient for their gradually diminishing numbers—i.e., about half of a quarter of a peck for ten or a dozen geese. This, however, is shared with them by such fowls as choose to fly over the fence and join the breakfast party; the ducks, too, will frequently creep through and under the palings; so that, although two or three additional handfuls may be given on such occasions, still, if every handful, or even every grain were counted, no true account could be exactly rendered of the quantity of corn appropriated to the geese. Their principal maintenance is the grass in the orchard; and we find that, during summer, they are thus kept in sufficiently good condition to kill for the house. During autumn and winter they require to be shut up, to fatten in the regular way. About half this quantity of barley is given at noon, and again at sunset, in the court-yard, when they are driven up for the night about eight o'clock.

"Our ducklings are kept pretty nearly in confinement—i.e., in coops with small enclosures in front—from the time they are hatched till they are about a quarter grown. During this infantile state they are entirely dependent on the food brought to them, consisting of bread-crumbs, mixed barley-meal, worms, &c. As soon as they are judged sufficiently robust to take to the water—of about an acre of which they have the range, besides open drains and ditches—they are turned loose with their nurse, but are always got home at night. Previous to this complete enfranchisement, they are, of course, disciplined by a few preliminary swims in a large milk-pan sunk in the ground. If their nurse be a hen, they very soon desert her, and eat for themselves; if a duck, then, under her guidance, they pick up by far the greatest part of their maintenance, costing nothing but the few kernels of barley that are thrown to them three or four times a-day to keep them in the habit of returning home with tolerable frequency. Now it is impossible to make any calculation of what these birds consume or are maintained by, that can afford any real instruction. I cannot properly enter into my balance-sheet, the insects, worms, seeds, and water-weeds on which my ducks grow, get flesh, and even fat, although they are all the produce of my own premises. De minimis non curat lex. The law careth not for crumbs and atoms. A farmer who wants to know the exact profit and loss on each duck and hen, would, we take it, be penny, or rather farthing wise and pound foolish; that is, if his time and thoughts are worth money to him. And what most baffles us is, that these
POULTRY.

[FEEDING.]

savings, which poultry get from off their walk, to the sparing of the barley-sack, perpetually vary. Thus, from Midsummer to Michaelmas, ducks cost very little to keep, where they have a proper range; and so do other poultry. Nature is then in her most liberal mood. But when the ground is petrified by frost, and covered with snow, it becomes quite a different affair. Fowls are then at their most costly time. A calculation of the expense of keeping them, at either period, cannot but mislead. And as the greater number of ducks do not live six months, their yearly average consumption cannot be taken.

"In the same way, turkey-chicks and common chickens are, with us, assiduously fed on their proper diet, their mothers being cooped, and dependent on the grain given to them. As the younglings gain strength they are gradually released; and, when finally turned adrift, have the range of more than eight acres of lawn and grove, where their mothers and themselves find abundance of nutriment, which, though valuable, cannot be charged in any bill for the maintenance of the growing families. During the time the mothers remain cooped, a person goes round to them as often as is thought needful (that point being much regulated by their respective ages), with a supply of suitable food. It mainly consists of hard-boiled eggs chopped up with lettuce and onions, bread-crumbs, boiled rice (costing 1s. 4d. the stone of 14 lbs.) as a variety, barley-meal, and fine pollard, either mixed with parboiled rice, or by themselves, with as little water as is sufficient to bring them to a consistence. Little chickens are treated to a few kernels of wheat. The most economical way of distributing grain is to scatter it on the bare ground, and to give no more at a time than the fowls will quite consume; and we find that the only mode of preventing the sparrows from getting much more than their fair share (their really fair share should be none at all), is to remain with the birds and chickens while they are eating, till they are quite satisfied, and to repeat the visit after a short interval. Young chickens never should go more than two hours at most without a supply of food; for adult birds, three times a-day is plenty. It does not appear to me that extreme precision in stating the weights and measures of the articles used as food for live stock, is so very necessary or expedient. For creatures that have either to work hard, or to grow, or to get fat, a little too much food is better than a little too little. We should prefer even some waste by sparrows, to seeing our poultry stunted in their growth, or checked in their moulting, or moping about in ill-conditioned plumage. Full-grown guinea-fowl, that have a range (and they should not be kept otherwise), require no more corn for their maintenance in health and in full laying powers, than what they will have when the poultry is assembled by the rattling of the corn-measure at morning, noon, and night. With us, the least profitable birds are, we believe, the pigeons, of which there are about forty. Besides the corn which these get at the general mess, they are entertained with peas, at the rate of about a peck a-week, in their private apartment, the pigeon-loft, to which, however, they are not at all confined. They are fed at an extra rate to prevent them trespassing on our neighbours' fields. Pigeon-pies, in sufficiency, could be had at a less cost; and the sale of choice pairs is not resorted to as a means of lessening the expense of keeping the flock.

"The commissariat department of every rearer of a general stock of poultry, must be arranged, not as for a regular army, where the men are all of a certain equal height, and are supposed to be of a certain equal capacity of stomach; but as for a mixed multitude or rabble, such as the followers of Peter the Hermit; or a disorganised riotous populace, consisting of old and young, male and female, healthy, sick, and lame. To the entire mass of this feathered band of insurrectionists (and very riotous they do become as the pangs of hunger continue to pinch them), it may be advised that three feeds of corn a-day be administered till they are tolerably satisfied. It is an error to believe that poultry will eat corn to repletion; they will turn from that, when they feel they have had a sufficiency, to pounce upon the fly, drag out the half-hidden worm, or crop the sprouting grass. Wastefulness in giving corn to fowls, consists in throwing them down a large quantity at once—more than they care to have—and then leaving them to themselves, instead of doing it out, handful by handful, and stopping the distribution as
soon as appetite begins to flag. They should not be allowed to leave a grain. The juniors, the prisoners, and the invalids must have separate attention, which we shall not be expected to particularise here. For poultry that is put up to fatten loose in a small shed—really a good and more healthy way than fattening-coops with separate compartments (for we never see a return of the number of birds which die, instead of fattening, from this incarceration)—for poultry so confined, no feeding-trough is better than that figured as for turkeys in Dixon’s Ornamental Poultry; but even the degree and kind of fatness expected in poultry, is a matter of local taste and fashion. Most country-people like a fowl, or a duck, that has been kept at large in high condition, either at the barn-door or in the pond, without any confinement at all—thus making an approach to the edible qualities of game. Londoners prefer birds that have never stirred, except in a dark cellar, nor used their wings, unless to help them to a perch three feet from the ground at most. This inaction of the muscles gives a peculiar tenderness to the flesh, andunctuousness to the fat, which is much valued by metropolitan purveyors. As far as the digestion of the eaters is concerned, it would be well if the parties could change their taste. The capon-like and luscious peculiarity of the fowls supplied by the best London poulterers, requires a little fresh air and exercise to settle comfortably; while the lightness of the barn-door flesh, if not eaten too soon after slaughter, is more suitable to a sedentary stomach. How hard, then, is it to dictate which is the best mode of feeding and fattening; when connoisseurs differ so widely as to the result most worthy to be aimed at!”

FATTENING.

Poultry intended for the table, like every other living thing raised to be eaten in an artificial state of society, must pass through a certain change previous to its being subjected to the masticating process of the mouth of man. In order to have a chicken fat, the best thing to do is never to allow it to get thin. To “fetch them up,” however, for the table, they should either be absolutely cooped up, or, at all events, inclosed in a very small space. If they are put into coops, these should be warm, rather dark, and placed under cover. They should also have sufficient height, and be large enough for each fowl to be comfortable, without being forced to move about; and each should have a portion of the coop partitioned off to itself, so that it may see its neighbour, without touching it. At the front of the coop, there should be a large trough to hold the food, with a compartment for water, raised fully an inch from the ground. What this convenience is to be made of is a matter of taste; but, instead of wood, either pottery or glass is recommended as even more suitable, on account of their being more easily kept clean; whilst they look equally well, and are by no means expensive. The back part of the floor ought to be grated, so that the droppings of the fowls may readily pass through. The birds should be starved for a few hours after cooping, and then supplied regularly, three times a day, with as much food as they will eat, and no more. The trough should be cleaned out each time after they have been fed. Very little water should be given them. In this manner, steamed potatoes alone have fattened chickens in eight or ten days. Boiled dry rice, moistened with milk or water, is also a very fattening diet; and if accompanied with a portion of treacle, the process is greatly quickened. By great attention, and giving a constant variety of food, in order to excite the appetite of the fowls, they ought to be ready for the table in a fortnight. Vegetables of every description, and grease of every kind, they will eagerly devour and fatten on; and the most economical plan is to boil everything given to them. Upon this subject Mr. Bailey has written a practical little pamphlet, called The Dorking Fowl: Hints for its Management and Feeding for the Table; from which we extract the following passage:—

“I advise, from the first, to feed the hen and her chickens well, in the following manner. Instead of throwing down handfuls of whole corn, let it be ground, and skated with lukewarm milk, to such consistence, that when a ball of it is thrown on the ground it will break, and scatter about in particles. If there be green-meat, such as onion-tops, chopped fine, and mixed with it, so much the better. The chickens should be fed in this manner three or four times per day, and the little extra
HOUSING.

In choosing a hen-house, as in many great events of life, most persons have to consider what they can have, rather than what they would prefer. The house must be weather-tight and well ventilated; it should occupy a sheltered spot, and enjoy a warm, sunny aspect. Crowding should be carefully avoided: a dozen fowls is enough for a house ten feet square, and so in proportion. The talented author of the Poultry Pentalogue, says the house "should be composed of non-conducting materials, that it may be comparatively warm in winter, and cool in summer." This would promote laying in cold weather, and mitigate distress from heat. "My own fowls, however," he continues, "never did better than when kept in a rough weather-boarded place; but then it was but loosely parted off from the end of a large cow-house, which was always filled with cattle in the winter, and empty in the summer."

It sometimes happens that mortality, for which we can assign no reason, makes most un-welcome inroads on our poultry; and when we reflect upon the manner of life of our favourites, it is difficult to find a solution of the discouraging enigma. The fowls had access to gravel, lime, grass, and also had a liberal supply of food properly varied; yet sickness and death were of frequent occurrence. As wholesome air is necessary to the well-being of every living animal as wholesome food, the breeder of stock, of every description, will find it advantageous, occasionally, to visit the sleeping-places at night. When fowls follow their own instinct, they seek a lofty place to roost upon. Now that we bring them to a weight and bulk which they would never attain in a state of nature, we counteract this instinct; and, as the wings of such heavy birds are incapable of saving them from injury in a great descent, we oblige them to roost near the ground. By this means we bring them nearer to the carbonic acid gas, which, from its specific gravity, falls to the ground. Many useful hints, on different subjects connected with the rearing of stock, may be found in a work entitled Agricultural Chemistry, by J. C. Nesbit, F.G.S., F.C.S., &c.; to which we refer the reader.

A piece of any convenient part of the hen-house may as well be left unfloored, to be divided off into nests, leaving the bare earth for the bottoms of them. They will do either with or without straw. If baskets or boxes are used for nests, for the safety of the eggs, they had better have an abundant supply of straw.

We have just observed that large fowls should never roost high; for if half-a-dozen hen-ladders are placed for their convenience, they prefer to use their wings, which were never made to poise, in mid-air, from seven to eleven pounds of fatted, feathered flesh and bone. The best practical judges reckon that the perches should be within two feet of the ground, and made of poles from four to six inches in diameter.
We would never leave fowls dependent on the
hen-house alone for shelter. In addition to
that, they should have a shed, under which
they may find protection from rain and hot
sun, and a dry spot for a dust-bath, which
must be always supplied with plenty of dry
dust, in the use of which the fowls will require
no teaching. If a good potting-shed, or any
shed of the kind, be included within the
precincts of the hen-run, nothing can be better
for the fowls; and they can do no harm by
having a corner for a scratching-bit. If there
be no such shed ready to hand, a slight one can
be constructed at small expense. A few lengths
of carpenter's quartering, made into an oblong
frame, fixed upon a sufficient number of legs
(according to its length), and covered with
rough board or patent felt, will answer the
purpose very well.

There are numerous kinds of fencing for
forming the boundary-line to the run. Gal-
vanised iron wire, stretched on a framework,
is neat and durable. Galvanised iron netting
may be set up, with the support of upright iron
rods only. A firm rod along the top of a low
fence had better be avoided, for it will be used
by the fowls to lodge on in getting over.
As they are less likely to rest on an edge
which is shaky or uneven with spikes, some
manufacturers make their wire-work for poultry
without the finish of a wire at the edge which
is intended for the top of the fence. The cost
of a wire fencing is from one penny to three-
pence per square foot.

In Suffolk, an excellent warm fence is made
by bracing fagots of fern, gorse, &c., close to-
gether upon iron hurdles.

Common sheep hurdles, in the usual position,
will make a good fence for poultry; but placed
on end, fixed together, and made firm with
stakes, they afford a fair high fence, where
appearance is not an object of consideration.
If thatched, they will make a very tolerable
hen-house. Simply fixed with the spikes in
the ground, they are not high enough to keep
in any poultry, nor firm enough after two years'
wear and tear; but these defects may be reme-
died, and a good lasting fence made of them,
at the expense of a little labour. If the poplar
or the willow grows in the neighbourhood, it
is not a bad plan to cut large sprays of either,
about six feet high, and stick them into the
ground so close together, along one side of the
hurdles, that the twigs meet and cross above
them, so as to form a tolerably close screen.
They will take root, become firm supporters to
the hurdles, and form a lasting, and not an
unsightly fence.

A lattice of laths is quite as dear as wire
netting, and not so pretty; neither, we think,
will it be found so durable.

With the addition of drinking-pans—of
which the best are those which can be kept
clean most easily—the home of the fowls may
now be reckoned ready for their reception.

All pans for food, and divers contrivances for
inducing the fowls to stuff themselves imme-
dately, we repudiate.

As a suitable conclusion to this part of our
subject, we subjoin a description of the cottier's
poultry-house, as given by Mr. Richardson.

"One of the best modes of rearing fowls, is
the old custom of suffering them to roost on
the rafters of the room in which the cottier
keeps his fire. It is, perhaps, owing to the
warmth thus afforded to the birds, that
during winter, when eggs are scarce, and con-
sequently at a high price, they will be procur-
able from the humble cabin, when they have
long vanished from the elaborately constructed,
but less warm poultry-house of the more
affluent breeder.

"Should circumstances, however, render the
keeping of poultry in the cabin objectionable
or unadvisable, a very suitable place may be
erected for them against the outside of the
cabin wall. If possible, the part of the wall
against which the little hut is erected, should
be at least opposite to the fire-place within; thus
securing the necessary warmth. If shelter be
required, it can be obtained by means of a
few bushes, or a wall of sods. The neighbour-
ing roads will serve as an ample walk; and
the nearest stream will slake their thirst. A
few laying-nests may be placed in a warm
corner of the cabin. By these means, the
poultry of the poor cottier will thrive as well,
and yield as great a profit, as those kept in
the best-appointed establishments in the
kingdom."
CHAPTER V.

THE TURKEY; GUINEA HEN; PEA-FOWL; PHEASANT, ETC.

THE TURKEY

Under the singular impression that this bird and the Meleagris of the ancients are identical, Linnaeus, and some other naturalists, have designated the Turkey as the Meleagris Gallipavo. This error was first observed by the French academicians, who pointed it out; and it is now generally accepted as correct.

The common turkey is a native of North America, and was introduced into England in the reign of Henry VIII. According to Tussor's Five Hundred Points of Good Husbandry, it began, about the year 1585, to form an article in our rural Christmas feasts:—

"Beefe, mutton, and porke, shred pies of the best, Pig, veale, goose, and capon, and turkie well drest; Cheese, apples, and nuts, jolly carols to heare, As then in the countrie is counted good cheere."

The turkey is one of the most difficult birds to rear of any that we have; yet, in its wild state, it abounds in the forests of Canada.

The origin of the name appears to have arisen from the confusion that, at first, subsisted relative to the identity of the bird with the Guinea fowl, which is really a native of Turkey, and was introduced into England from the Levant. Athenians, and other classical writers, with the most minute accuracy, refer to this fowl; and in scarcely one particular, can any resemblance be traced between it and the turkey.

The disposition of the female turkey bird is, in general, much more mild and gentle than that of the male. When leading out her young family to collect their food, though so large, and apparently so powerful, she gives them very little protection against the attacks of any rapacious animal that may approach them. She rather warns them to shift for themselves than prepares to defend them.

The best mode of keeping turkeys, is to allow them a large open shed, sufficiently protected from the weather, and, above all, from moisture, to the destructive effects of which the turkey is singularly liable. The perches should be high, and a hen-ladder is very necessary to be placed in their habitation. The reason for suggesting this is, that although turkeys may fly very well in their natural state, yet when fattened by the arts of domestication, they become by far too weighty for the strength of their wings. The consequence of this is, that they often injure themselves in their descent from a lofty perch, more particularly if kept in a state of confinement. When enjoying the fulness of their liberty, they are enabled to take better care of themselves, and also to take such an amount of exercise as will preserve them from assuming aldermanic proportions. In warm weather they should be allowed to choose their own roosting-places, whether on the trees or about the farm; but if frost be expected, this liberty must not be granted them, on account of the tenderness of their toes, and their susceptibility to be frostbitten. To these birds, although originally the inhabitants of an extremely cold climate, it is now found that summer is the only season of the year when they may, with safety, be permitted to roost out of doors.

In a wild state turkeys are gregarious; and associate in flocks, sometimes to the number of five hundred. They frequent the great swamps of America to roost; but leave these situations at sunrise, to repair to the dry woods in search of acorns and berries. They perch on trees, and gain the height they wish, by rising from bough to bough, and generally mount to the summits of even the loftiest. They are very swift runners, but fly awkwardly; and, about the month of March, become so fat that they cannot carry themselves beyond three or four hundred yards, and are then easily run down by a horseman.

The females lay their eggs in spring, generally in some retired and obscure place; for the cock, enraged at the loss of his mate while she is employed in hatching, is apt to break them. They sit on their eggs with so much perseverance, that, if not taken away, they
POULTRY.

will almost perish with hunger before entirely leaving the nest.

The morning is the time when the hen turkey usually lays; some performing this operation daily, and others only every second day. From fifteen to twenty eggs is the number generally laid; but this varies according to the age of the bird—a hen of a year old laying fewer eggs than one of greater maturity. When the turkeys are about to be let out in the morning, the hens should be examined, and those which are about to lay should be kept in until that process has taken place.

The eggs, as we have said, are to be taken away as soon as laid, lest they be broken, through the awkwardness of the hen, or sucked by vermin; and if put into a basket, and suspended in a dry place, they will keep till the hens have done laying. As the hen turkey has no very refined feelings of exclusiveness, there is no necessity for keeping the eggs, belonging to each, in a separate place. Her disposition manifests no wonderful excess of maternal love towards her eggs; neither are her discriminative qualities very great; for she will, with equal kindness, care, and attention, rear a batch belonging to another, as if they were her own. Even in the nest, such eggs as those of geese, ducks, and common fowl, do not come amiss to her. In the second laying, the eggs are fewer in number, and rarely exceed from ten to thirteen; but, on this occasion, more than ordinary care is requisite.

We have observed that the hen turkey is a most persevering incubator; and Mr. Richardson says, that "if her eggs were not taken away, she would sit upon stones, if she could not procure the eggs of another bird, and would perish before quitting the nest. Eggs should, therefore, be left with her, not only to tranquillise her, but because sitting upon eggs fatigues her less than sitting upon an empty nest. These eggs, however, should be marked, in order to distinguish them from those the poor bird continues to lay. Any eggs that seem to her to be slow of hatching will be abandoned, as she will quit the nest as soon as she perceives the chick. Consequently, as soon as the eggs you have placed under her are hatched, she will leave the nest, and the eggs of her own laying will be sacrificed. Remove, therefore, the former. It is for this reason that I recommend them to be marked. Keep the nest clean while the turkey hen is sitting, as dirt will injure the eggs. No person should go near a hen when sitting, except her keeper; and none should turn the eggs, or meddle with them further than I have already indicated. The bird will turn her eggs with more judgment than you can."

The time of sitting varies. Sometimes it is twenty-seven, and at other times thirty-one days. When the latter takes place it is at Midsummer. As some of the chicks come forth more slowly than others, these should be removed to a place where they may get greater warmth; but, generally speaking, all interference should be avoided: where, however, they have been removed, they may be returned to the hen for six or eight hours before feeding them. As in cases with more common fowls, assistance is sometimes necessary to enable the chick to leave the egg; and if so, the utmost caution should be observed, lest any injury be the result. A too great eagerness to render aid, on these occasions, often does far more harm than good.

Many writers recommend a vast deal of what may well be denominated quackery in the treatment of the young chicks; but they generally thrive much better when left to themselves.

In feeding poults, after the second month, it will be sufficient to supply them with such boiled herbs and plants as are esteemed nourishing. Those which in their natural state they would feed upon, are, as a matter of course, the best. Among these may be enumerated wild succory, nettles, milfoil, turnip-tops, cabbage-sprouts, or the outside leaves of greens, well macerated by boiling. Potato skins, or a few potatoes themselves, may be given; and, if beans, oats, barley, or buck-wheat be amalgamated with them, the poults will rapidly fatten. Besides these, the meal of Indian corn is advantageous; but, as this requires to be boiled three times more than that of oats, it is proportionally more troublesome to be used as a food. If, however, the market has to be met, the sooner the poults can be "got up" the better; and, although the feeding required for this may be a little more expensive than usual, the results will, nevertheless, prove satisfactory. When approaching their sixth month, especially if there be an appearance of cold
weather setting in, give them boiled potatoes, mashed and mixed with meal, and then chopped small. This should be given them fresh and fresh, in a vessel perfectly clean, and always to be kept so, lest it contract a disagreeable smell. It must be remembered that turkeys are particularly nice in their appetite, and are also very cleanly in their habits. After a month of this kind of feeding, morning and evening, the poults will be in a condition to be made use of; and, if of a good sort, they ought, at least, to weigh eighteen pounds. During this process of fattening, they should, after their meals, be kept pretty much in the dark; indeed, a great portion of their time should be spent in darkness, and their exercise much curtailed.

In considering the advantages in connection with the expense which attaches to the raising of turkeys, it must be borne in mind, that until they are wanted to be fattened for sale, there is no necessity for nourishing them to the extent we have just indicated, as, of all our domestic fowls, they are the best providers for themselves. They are also blessed with a good digestion; therefore, nothing comes amiss to them in the way of herbs, grass, berries, fruit, corn, insects, and even reptiles. This universality of appetite, so to speak, generally enables them, in their wanderings, to find plenty to satisfy themselves, almost without the artificial assistance of man. In its native forests, a favourite food of the turkey is the seed of a kind of nettle, and a small red acorn, on which latter food they soon become so fat as not to be capable of flying, when they are easily run down by a dog. The weight to which the bird attains, in this country, has been much exaggerated; but twenty pounds is a fair weight for a fat yearling bird. For one only six months old, this is a very great weight. A turkey weighing thirty pounds, of any age, is a fine bird; and few, save the Norfolk, ever exceed forty.

Cold, or damp, being fatal to turkey poults, it is necessary that the weather should be watched before allowing them to stray far from their habitation. Intense sunshine is also fatal to them. In such weather, therefore, they must not be led to pasture, unless this can be done under shade. Should rain fall, they must be at once housed.

To the peasant the turkey is a bird of considerable profit; as, among the hedgerows, and upon the roads, it can find almost as much food as suffices for its maintenance. Worms, snails, and slugs are amongst its most favoured repasts; and any stream suffices to quench its thirst. From its great partiality to grain, however, it is a pest to the farmer, who should circumscribe its roaming propensities to the boundaries of his yard, until his crops are so strong in their roots as to offer no temptation to its depredations.

THE GUINEA HEN.

It is difficult to ascertain the precise time when the Guinea fowl was first brought into Great Britain; but its introduction must, at all events, have taken place at a remote period; for, in Kennet's *Parochial Antiquities*, it is stated that it was well known in England as early as the year 1277. Its original country is Africa. The Guinea fowl is a little larger than our ordinary barn-door fowl; but it is inferior in size to the larger foreign breeds, as the Malay and Spanish. In both aspect and character, it appears to occupy a position between the pheasant and the turkey. Although long familiarised, the Guinea fowl has never been fully domesticated. It still retains much of the restlessness and shyness of its primitive feral habits. Its courage is very great, as it will not only attack the turkey, but frequently conquer him.

The cock and hen are so nearly alike, that it is not easy to discover which is which. Sometimes there is a difference of hue in certain parts; but this difference only occurs occasionally; and it is rather on the distinction of voice and demeanour that we must chiefly depend, in order to distinguish the one from the other. It must be remarked that they pair; therefore, a second hen will be neglected and useless, except for eggs.

As a source of profit these fowls are not much to be recommended. The eggs are very small, three of them being scarcely equal to an ordinary hen's egg; and the flesh of the bird is not relished by every palate, though it is in tolerable request in the London markets, when the game season closes. Its flavour resembles that of the pheasant.

This bird dislikes confinement, and will not thrive unless it has perfect liberty; where such,
POULTRY.

therefore, cannot be afforded, it is useless to attempt to keep it.

The hen commences to lay in May, and continues throughout the entire summer. For the table, the birds are in season from February to June. The period of incubation is twenty-eight days. The chicks, while young, require careful management, and must be constantly fed. In a short time they become perfectly hardy. At nine months they are fit for the table. The hen is prolific.

THE PEA-FOWL.

A peacock, in all the pride of his "Argus-eyed tail" spread before the rays of the sun, parading on a green lawn, or from the extremity of a terrace wall, is one of the most beautiful of living objects which can adorn the garden landscape. Of fruit, however, he will be found a devourer, not to be guarded against; and both him and his mate are not infrequently the veritable assassins of the young of other fowl. The cock does not attain the full splendour of his plumage until he is three years old; and the hen does not lay until she is of the same age. She lays from five to seven eggs, and sits twenty-nine days. If the first batch of eggs is taken away, she will lay a second; so that, by having a hen turkey as foster-nurse, two broods in one summer may be obtained.

The pea-hen generally chooses a very retired spot, quite out of the way of the peacock, which is often a cruel, unnatural father.

The young of this breed must be tended like Guinea fowl and young turkeys; and without they are abundantly and regularly fed, they are apt to wander. When fat, and hung long enough, they make a delicious and enviable roast. They should be larded over with slices of fat bacon; the head and neck, with the feathers on, carefully wrapped in paper, and tucked under the wing, away from the fire; and, when ready, set up in purple glory, to match the tail adorned with feathers, neatly stuck in at the last moment.

THE PHEASANT.

We have already treated of the Pheasant in the division on "The Gun;" but here it is necessary to say a few words upon it, in what may be called its domesticated state.

To hatch the eggs of this beautiful bird, a Bantam hen is the best. The young ones should be left with her for twenty-four hours after being hatched, without being disturbed; and then they should be fed every hour with hard-boiled eggs, bread and milk, bread crumbs, young nettles, or lettuce, chopped fine, and eggs from ants' nests. They should be kept in a dry, warm place, and be allowed plenty of fine soft sand. A piece of meat may be put in a convenient spot, and kept there till it becomes fly-blown, when the maggots, thereby generated, should be given them every day. When moulting, supply them with a little boiled rice. The vessels in which they are fed must be kept quite clean; and as they are subject to various diseases, alum-curd, made by boiling new milk with a lump of alum, until it is of the consistency of custard, may be given them. If vent-bound, clip off the vent feathers carefully, and apply some sweet oil to the part.

Although we have recommended a Bantam hen for a sitter, there are many circumstances under which it may be found necessary to hatch and rear young pheasants by means of common hens. In Stonehenge's Manual of British Rural Sports, the author says—"The old hen of each hive or nido is always anxious, if alive, to retain her old nest, and to drive the young hens away from her neighbourhood. If the keeper is not on his guard, the hens stray far off his beat; but if watchful, he can easily detect the nest of almost every pheasant. If the eggs are likely to be taken, he may then, and then only, as soon as the hen has laid her full number, remove them. Hen pheasants will spread themselves abroad, and no art will keep them closer together than they like; but the above plan may save a great many eggs. There are many situations in which nests should be disturbed, if found early enough, or the eggs taken if found late: for instance, in situations likely to be flooded; in ditches or hollow water-ways, or in clover-fields or vetches which will be mowed over before the time of hatching."

As the hen pheasant never rears her full number of chicks, five or six eggs should be removed from every nest which is found. A moderate-sized hen will cover thirteen eggs. She should be set in a box without a bottom,
so that the nest shall be on the ground; and the box should have a lid, that the hen may be shut in. The boxes should be eighteen inches high, and perforated, to admit of ventilation. The hens must be let off to feed, and shut up again. Boxes are only necessary where a number of hens are set together. When the hens have sat for five or six days, the eggs may be tried, and all which are not good, removed, making up each hen’s nest, and giving fresh eggs to those that may be left without any.

After the pheasants have been hatched about ten hours, the hen should be put under a coop, solid all round, except two bars in front, just wide enough to allow the poults to run in and out. In other respects it is the same as a common rip for hen and chickens. This should be placed on the grass, on a sunny spot, with a west or south-west aspect.

While the chicks are quite young, a run should be made for them, by three boards a foot and a-half wide, to be supported by pegs driven in the ground, to fence in a square piece before the coop. This piece to be made safe by a network covering.

If the chicks are strong at the end of a week, the little enclosure may be removed, and they may run at large. When the chicks are a month old, some breeders recommend that the hen should be tethered by day, and placed in the coop again at night. A constant supply of clean water is very important.

The greatest difficulty is to hatch the eggs, for they are very easily spoiled by being shaken. In the early days of sitting, the embryo chick is so delicate, that a very slight blow or shock destroys life, and the egg becomes addled. If a hen can be reckoned on, it is far better to wait till within a week of the time of hatching, as the eggs will bear removal very well at that time, if placed in a basket full of warm, dry wool. In this way we have known eggs removed more than twenty miles, and afterwards nearly all hatched.

For a coop, some make a box, nearly three feet long, two feet wide, and two feet high in front, sloping off to one foot high at the back, and give it a boarded floor. This box has a lath front, with intervals to allow the young birds to pass out. This is the coop for the hen; but the young birds ought to have a further space of about two yards square to run in, fenced off by some means. In rearing young pheasants and partridges, success is more likely to crown our care in a walled garden, as they are then almost safe from the attacks of the weasel, stoat, or rat. If this cannot be procured, we should be careful to select a good aspect, sheltered from the east and north, and open to the morning sun. It should not be exposed to the incursions of poultry. For food, ants’ eggs are the best, if they can be got in sufficient quantities; or maggots, secured by keeping them twenty-four hours in bran. Mix oatmeal and eggs together carefully; tie them up in a cloth; boil them until hard; and this, broken up, makes excellent food. When the young ones are a fortnight or three weeks old, soaked bread, or bruised barley soaked, may be given, and, soon afterwards, whole barley; but ants’ eggs and maggots should be continued even until the birds are turned into the woods. The feeding recommended by some is—first, hard-boiled eggs chopped fine, crumbs of bread soaked in milk, curd pressed in a cloth until dry, and ants’ eggs; afterwards, dough, of oatmeal and water. This must not be thrown down to them, but they must be fed with little balls of it as long as they will eat. For change, give barley and wheat.

THE DOMESTIC DUCK.

In keeping ducks, one of the first considerations to be attended to is, to see that they have plenty of water; for, although a small quantity of this will suffice for them, still, to have it always in such a situation as will admit of easy access to it, is one of the most essential points of duck-keeping. As the flesh of this kind of fowl always, more or less, partakes of the flavour of the food upon which the bird has been fed and fattened, it should be confined, at least, for not less than a week before it is killed, and put upon a more choice kind of food than the duck will feed upon when left entirely to provide for itself. This bird is by no means very particular as to what it eats; whilst its capacity of gormandizing is, where opportunities offer, carried to an enormous extent. We have seen some of them admitted into a field to follow the plough
POULTRY.

while at work, when they have so stuffed themselves with the exhumed worms, that they have actually been unable to rise after lying down. For the purpose of fattening, and bringing their flesh to a good flavour just before killing, boiled potatoes are excellent, and, if mixed with a little grain, the feeding is greatly improved. Indian meal is also good, although, at first, it should be given sparingly. If ducks are allowed to enter a garden, they will not do much harm, while they will help greatly to free it from slugs and insects; but, as they are rather ungainly walkers, and by no means remarkable for any extraordinary beauty of plumage, we, ourselves, would rather put up with a few extra slugs in our flower-beds, than permit a few of these unhandsome creatures to walk over them at their pleasure. Ducks lay a large number of eggs; and we have heard of the case of one laying upwards of eighty in succession. This is prodigious; and when we consider that three duck-eggs are, in culinary estimation, of the value of six hen-eggs, a bird possessed of such prolific powers is not, even in a commercial point of view, to be lightly estimated. It is mostly by night, and not by day, that the duck lays; and while producing, she requires a greater degree of attention than the hen, until she has acquired the habit of resorting to a regular nest. When she has done this, attention is no longer necessary. In hatching, the eggs require thirty-one days; and after the ducklings have come forth, they should have, for their first food, boiled eggs, nettles, and a little barley. For the first day or two they should be kept from water; but after they have seen the light for a few days, they may, with the greatest safety, be left to shift for themselves. The drake should have from four to six females, as he does not pair like the wild duck. Of the domestic duck there are many varieties; the white having a preference by some over all the rest. Of this variety, the Aylesbury is the favourite. It is very easily tamed; and, in Buckinghamshire, it lives with the cottager in a state of domestic familiarity, similar to that which characterises the sociable qualities of the pig in the cabin of the sister isle. In this county, many of the cottagers add to their little incomes by rearing the Aylesbury duck for the market; and the interior of the cot-
tagers' dwellings sometimes presents a singular appearance to the eye of the stranger. They are supplied with boxes and pens, ranged round the walls, for the purpose of protecting the early broods, which may be said to be brought up by hand. This duck is a large, handsome bird, with unspotted plumage, yellow legs and feet, and flesh-coloured bill. It is a most assiduous mother, and very productive.

Until the introduction of the Rhone, or Rohan duck, which is very prolific, and lays large eggs, the Aylesbury variety was held to be the most valuable of all the species. The latter, however, still fairly divides the honour with the former, and is by some regarded as superior. Its flesh is of a most delicate flavour, being by many compared to that of the chicken; but it is said, that a cross between it and the Rhone is superior in flavour to all others.

In France, ducks are both excellent and abundant, especially in Languedoc and Normandy, where duck-liver pies are considered a great delicacy.

THE MUSCOVY, OR MUSK DUCK.

This bird does not, as some suppose, take its name from having been imported from that country, but from the flavour of its flesh. It is easily distinguished by a red membrane surrounding the eyes, and covering the cheeks; and the Musk name, by which it is distinguished, is both a contraction and a corruption of the term Muscovy. It is a distinct species from the common duck; and the hybrid race will, therefore, not breed again between themselves. They are, however, capable of doing so with either of the species, from the com- miture of which they sprung.

THE BLACK EAST INDIA DUCK.

This species of duck is all black, except the bill, which is deeply tinged with a rich green. When floating on the bosom of a pond, mingled with the pure white Aylesburys, they present a beautiful contrast. The varieties of waterfowl may, perhaps, be as well studied in the inclosure of St. James's Park, London, as anywhere else.

THE CALL DUCK.

This is the Bantam of its race, usually coloured like the wild mallard, but often white—a colour
preferred by fowlers, who use it in the decoys, on account of its being so easily distinguished from the others. These birds are a Wiltshire breed, with compact and elegantly rounded crests, and are very handsome.

CAPONISING.

The practice of converting fowls into capons has been long followed by the Chinese; but it does not appear to have been early practised in Europe. Some years ago the French began to use it extensively; and now, both on the male and female fowl, the practice is quite common. The object proposed in making a cock a capon is the taming of his natural fierceness, so as to render him of a more placable disposition; and assuredly it has this effect. His pugnacity entirely desert him. He no longer seeks the company of the hens; he grows to a far larger size than he otherwise would have done; acquires flesh with far greater rapidity; and that flesh is peculiarly white, firm, and succulent. Even the fat is perfectly destitute of rankness. The process which effects this singular metamorphosis in the disposition of the bird is extremely simple, and one which the rural hen-wives of France perform with facility and certainty. The practice of these is to select the close of the spring, or the beginning of autumn, as well as fine weather, for operating upon their fowls. The parts necessary to be removed being fixed in the abdomen, and attached to the spine at the region of the loins, it is necessary that the abdominal cavity should be opened for the purpose of their extraction. The bird should be healthy, fasting, and about three months old. He must then be secured by an assistant, laid upon his back, with his belly upwards, and his head down, that the intestines, &c., may fall up towards the breast; the tail is turned towards the operator. The right leg is then carried along the body, and the left brought backwards, and held in this position, so as to leave the left flank perfectly bare. Here the incision is to be made; and this is to be directed, from before, backwards, transversely to the length of the body, at the middle of the flank, and slightly to the side, between the ends of the breast-bone and the vent. Having plucked away the feathers from the space where the cut is to be made, a fine-
tempered pen-knife is taken, and the skin, abdominal muscles, and peritoneum incised. This is best done by two or more cuts, in order to avoid the possibility of wounding the intestines—a casualty which would, in most cases, be attended with fatal results. The intestines will then present themselves at the orifice; but they must not be allowed to protrude. On the contrary, they must be pressed gently aside, so as to leave room for action. The incision should be sufficiently large to admit the fore-finger, previously well-oiled, to pass into the abdomen, and to be carried carefully towards the lumbar region of the spine. There will be found what is wanted. You first reach the left substance, which is to be detached with the nail, or with the finger bent hook-fashion. The right is treated similarly. Bring both substances forth, and return the intestines; sew up the wound with a silk thread—a very few stitches will suffice—and smear the place with a little fresh butter. Some persons recommend the amputation of the comb, close to the skull of the newly-made capon; but this is an unnecessary piece of torture; though, of late years, it has been exclusively adopted on the continent: the proposed object of this amputation being to insure the recognition of the capon among his co-mates of the poultry-yard.

DOMESTIC GEESE.

Amongst the varieties of our common domestic goose, there is one which has, not a great number of years, been introduced to our island; and which, from its great size and capacity of carrying flesh, has taken a very high place in the estimation of the breeder. This bird is designated—

THE TOULOUSE GOOSE.

Originally, this fowl was imported from the Mediterranean by the Earl of Derby, and is known indiscriminately by the names of Mediterranean, Pyrenean, and Toulouse. It is principally remarkable for its vast size, being perfectly gigantic, and therefore to be regarded as a most valuable addition to the poultry-yards of Great Britain. Its prevailing colour is a slaty blue, marked with brown bars, and occasionally relieved with black. The head and neck, down to the beginning of the breast,
and the back of the neck as far as the shoulders, are of a dark brown; the breast is slaty blue, and the belly and under-surface of the tail are grey. The bill is orange-red, and the feet are flesh colour. This bird is supposed to be the unmixed and immediate descendant of the grey-lag. In its habits it resembles its congener, but appears to possess a milder and more easy disposition. Of its other peculiarities, it may be remarked, that the curl of plumage on the neck comes closer to the head than in the common goose, and that the abdominal poult, which, in other varieties, is attendant only upon age, exists in these birds from the shell. The white Irish goose is fully larger than the Toulouse.

THE CHINESE GOOSE.

A Cygnoides.—Of the Chinese goose there are three sub-varieties, each presenting striking points of difference, and yet sufficiently alike to justify their being classed together. These are—The Hong-Kong, which has a large horny knob on the bill and forehead. Its prevailing colour is grey, with a longitudinal stripe, of a deep brown, running above the back of the neck. The legs are of a red colour, whereas it is sometimes distinguished as the "Red-legged China goose;" and has long been known amongst us as the "Poland goose." The Black-legged Chinese Goose.—Also knobbled, and usually with a white edging round the knob, somewhat similar to that of the wild breed called the "White-fronted goose." The White Chinese Goose.—A very handsome bird, knobbled like the rest, of snow-white colour, and with legs of a bright orange-red. These geese are all smaller than the Toulouse; but they are, nevertheless, very fine birds. The white variety, especially, with red legs, is very beautiful, and forms an appropriate ornament on a piece of water. The flesh is also good, and they feed well, fatten easily, and are very prolific. Of our ordinary domestic geese there exist but two sorts, the only distinction of which seems to rest in their relative size. They are divided into the large and small; and by some, according to their colour, into the white and the grey. These divisions are, to a certain extent, arbitrary; as out of one clutch, several varieties, both as to size and colour, will generally be found. The best sorts of geese, however, are those which vary least in colour. Those approaching most nearly to the primitive stock, are the birds which every good judge will prefer breeding from. Grey is the best colour, as coming nearest to the original grey-lag; white is not quite so good; but mixed colours are not so prolific, and the young are more difficult to feed up to the required standard. Markham says, "the largest is the best; and the colour should be white or grey, all of one pair; for paid geese are not so comfortable, and black are worse."

In reference to mating the gander, it is observed by Mr. Richardson, "that this entirely depends upon the object which the breeder has in view. If eggs are wanted, one gander is plenty for six or even eight geese; or he may abandon the unnecessary trouble of keeping a male at all, and only occasionally send his geese to his neighbour's. It so happens, however, that keeping geese for the produce of their eggs alone is not profitable; and hence these must be rendered duly fertile. To effect this, one gander to a large number of geese will not answer. For the purpose of hatching, a gander should be mated with, at most, four geese. If of the ordinary kind, amongst which colour varies, he should be of a pure white, or ash-grey colour; but not at all of two colours. His dimensions should be large, his gait active, his eyes lively and clear, his voice ever ready and hoarse, and his demeanour full of boldness. The goose should be chosen for her weight of body, steadiness of deportment, and breadth of foot—a quality which indicates the presence of other excellences. In one season the goose lays from ten to twenty eggs; and, should she not be desired to sit, by removing the eggs as fast as she lays them, and at the same time feeding her highly, she may be induced to continue laying to the number of forty-five, or even fifty. This is, however, unusual, as well as unprofitable. When tolerably well looked after, geese may be made to lay, and even hatch, three times in the year. When this is desired, the plan to pursue is only to feed highly, and house them well, and early in the spring, so as to have the first brood soon in March; but we would rather have two good clutches reared than three bad ones; and therefore recommend patience and moderation."
The goose will begin to lay about the latter end of February, or the beginning of March. The commencement of her laying may be readily discovered, by noticing her running from one place to another, carrying straws in her mouth. This is for the purpose of forming a nest, when she should be watched, lest she drop her eggs where they cannot be found. On this account Mascall recommends trying the geese manually over-night, and confining such as are ready to lay. When a goose is shut up, and lays her first egg in any particular nest, no further trouble need be taken with her, for she will continue to lay in that spot, and will not be likely to stray elsewhere.

When the inclination to hatch discovers itself, the nest should be made of straw, with a little hay as a lining, and should be so formed that the goose will not throw the eggs over the side when in the act of turning them. There is no necessity for banishing the gander. On the contrary, he may be suffered to remain as near the nest as he chooses, and he will act the part of a guardian. Fifteen eggs will be found sufficient for a fair-sized goose to properly cover; and they should not be touched during incubation, or the goose interfered with. As she is heavier than the hen, her food and drink should be left rather nearer to her than is necessary with common poultry, because, if she chance to absent herself from her eggs so long as to allow them to get cool, she may abandon the process of incubation altogether. It is, however, not necessary to mix either vinegar or pepper with her food or water, as some recommend, or in any way to meddle with her. The necessary period of incubation is one month; but the early-hatched goslings must be removed, lest the more tardy be deserted. About the twenty-ninth day these begin to chip the shell; and, should their own capabilities prove inadequate to their liberation, aid should be rendered them. The eggs should all, as nearly as possible, be of equal freshness, that they may be hatched at one time. On the appearance of the goslings they should be turned out into a sunny walk, if the weather will permit; but they should not be made to feed for twelve hours, at least, after leaving the shell. Their food may then be bread soaked in milk, boiled greens, curds, porridge, or even bran, mixed with boiled potatoes; and care must be taken that the food is not given in too hot or too cold a state. Avoid exposing them to rain or cold breezes; and be particularly careful that the walk into which they are turned is sheltered both from wind and weather. The goslings should also be kept from water for at least two days after hatching, lest they become affected with cramp—a disease which frequently proves fatal to them.

Geese should be confined as little as possible, and should be kept in an inclosed yard, sufficiently large to admit of their having plenty of room for walking about; and if there is a common in close proximity, they should be allowed to stroll about and shift for themselves. This will considerably lighten the expense of keeping them. They require water, and cannot be advantageously kept when they are deprived of it; still, however, they may thrive without having access to any pond or river, if they have only a small artificial pool in which they may bathe themselves. When geese are within range of water, and suffered to roam at large, they usually discover it, and afterwards daily resort to it. Though they are so fond of water, their sleeping-places must be kept perfectly free from damp. Grass is as necessary to them as water; and the rankest, coarsest kind, such as cattle reject, constitutes their delicacy. Such grasses as they prefer will be found on swampy lands, of which, perhaps, no more profitable use could be made. The stubble-field is, when it can be obtained, also an excellent walk for geese; for they not only find the young grass and herbage springing up amongst the stubble, but likewise pick up much corn that would otherwise be lost.

Goslings, produced in June or July, will fatten without other food than such as the stubble-field may yield, as soon as they are ready to consume it; but if required to be brought up by a given time, potatoes, turnips, or other roots, bruised with meal, should be given at least once daily. The goose is very voracious, and only requires to get plenty to eat in order to accumulate fat. Geese, fed principally on grass and corn, do not, perhaps, attain the same bulk with such as are crammed; but their fat is much sweeter, and they are altogether much more desirable.
POULTRY.

for the table. Early geese require home-feeding, as they have no stubble-fields. London feeders, therefore, when they receive goslings from the country, about March or April, feed them first with meal from the best barley or oats, made into a liquid paste, and subsequently with corn, to give greater firmness and consistency to their fat.

Geese are fattened in large numbers in some places of the European continent. This is especially the case in the neighbourhood of Strasburg—a place celebrated for its pies. There geese have a shepherd to tend them as sheep have. The birds are reared by the peasantry, every one of whom is possessed of some stock of these valuable fowls; and the shepherd, every morning, wakes the echoes of the village by the sound of a trumpet, with which he assembles his feathered flock, which, in the company of a herd of pigs, repairs to pasture on the common devoted to that purpose. In the evening, the shepherd leads back his flock; but, before they arrive at the village, almost all the geese take flight, rise above the roofs, and settle down in their respective homes. They flap their wings, cross, and fly against each other in the air, uttering a cry not unlike the note of a hoarse trumpet, and presenting an animated scene to the delighted villagers.

Towards autumn the peasants carry to town their finest birds, and occupy a place in the market, which is so large as to furnish a very great number with plenty of accommodation. One hundred and fifty thousand geese annually pass through the market of Strasburg. The woman who fattens them is acquainted with those peasants who come from where the best geese are produced. She fingers the bird to assure herself that the body is well formed; examines the foot and beak, to determine its age; then makes her bargain, and carries home her purchase. When she returns, she places the goose in a separate compartment, and feeds it with marsh-beans. As soon as it is considered sufficiently strong to undergo the process of fattening, this is begun. The pupil passes into a higher class, and is fed with maize, steeped in salt water. From this time the feeding is regular and forced. It is admitted, now-a-days, that geese ought to be fattened without exercise; therefore they are packed, about thirty together, in a stable, and, during the last eight days of the fattening, they are placed in a cage open at the top. It is the skill of the trainer, in this latter period, that determines the success of the operation; and as it is necessary to kill the bird just at the time when the liver will remain white and firm—night and day must this favourable moment be watched for.

The following is the manner in which the fattening process is carried on:—The feeder places the goose between her knees, and holds the wings fast, whilst the feet are left free. With one hand she holds the beak open; with the other she drops the grains of maize into the throat, and pushes them home with her forefinger. This operation is gone through regularly thrice a-day. One woman alone cannot cram more than twelve geese an hour. An estimate of the labour may be made from the fact, that 200 geese are often trained by the same feeder. The bird being killed, plucked, and disjointed, the feeder hangs it up in an airy place; and not until twenty-four hours have elapsed can she judge of the condition of her treasure. She then takes down the bird, and carefully effect the extraction of the much-esteemed liver, which is immediately taken to the pie-makers, who make of it the well-known pies. Matthieu, the cook of Cardinal de Rohan, was the first who suggested the use of the liver of the goose for pies. Success crowned his efforts; and from that period the fattening of geese became a trade. It is by the feeding of geese, that the wife of the mechanic, who is deprived of work in the winter-time, supports her family. Other women, who have a little capital, carry on feeding on a larger scale. The business is a very arduous one. The woman has to rise two or three times in the night, and inspect her stock; goose, during the latter period of their feeding, being subject to apoplexy. This dreadful watch-woman marches about with a sharp knife, to cut the throat of the first which shows symptoms of suffocation. Every goose that dies against rules, occasions to its owner a clear loss of more than 6s., besides labour and time. A goose costs from 2s. 6d. to 3s. in the market; and, on an average, it consumes, in food, about 2s. 6d. Killed in good condition, it ought to weigh from 6 to 7 lbs., and is worth about 6d. per lb. It yields, besides, 1 lb. of fat, worth
POULTRY-HOUSES.

POULTRY.

About 10½d.; the offal fetches 3d.; the feathers and down about 1s. 2d.; making a total of 5s. 8d. All the profit, consequently, is derived from the liver, which is sold, according to its size and quality, from 2s. 6d. to 4s. 6d. The value of the liver is said to depend, like beer, chiefly on the quality of the water.

POULTRY-HOUSES.

Previous to the laying-in of a stock of poultry, a house must be made ready for their reception, or more harm may be inflicted on them than will ever be repaired, by setting them to roost in a cold place, or cooping them up in what may be called little better than a hole, where the heat of their bodies engenders an atmosphere at once deleterious and destructive. A poultry-house may easily be erected, and at very little cost. In nine cases out of ten, some outhouse, without preparation or alteration, is appropriated to the poultry; but, if consistent with the owner’s means and position, a proper house should be constructed. If this be done, a piece of gravelly soil, well drained on a slight declivity, near trees which will afford shade from the sun, and shelter from winds, should be chosen. The building must be sufficiently high to admit the poultry-keeper without stooping, and the roof should be kept weather-tight. Thatch is warm and ornamental, but apt to breed vermin. If, therefore, slates or tiles are employed, the house should be ceiled, in order to protect the fowls from draughts and sudden changes of temperature. In the absence of lath and plaster, a piece of patent asphalted felt, closely nailed, forms both a cheap and efficient protection.

The best perch is made in the shape of a broad double ladder, and in such a way as to form a wide angle—the bars being placed so far apart, that one fowl shall not overhang another. If roosting-bars are so placed as to run across the fowl-house, care should be taken that a convenient hen-ladder is attached to them, and that they are not placed too high. Perches, if lofty, and unaccompanied with a ladder, are dangerous to the heavier fowls, as they frequently break their breast-bones in descending by flight from them. After the fowls have taken up their roosting-places for the night, the poultry-keeper should see that they are all comfortable, and not too crowded, with sufficient room for the weak ones to remove themselves from the strong, which are apt to peck them. The floor must be sound, dry, and strewed with fine gravel or sand, and it should be swept clean every day. Nothing injures the health of fowls more than bad smells. A basket of slaked lime or cold mortar ought always to be kept in a corner, with a shovel, so that it may be shaken over any droppings. For the same reason, the interior walls should be frequently whitewashed, and the window opened in fine weather. The door should have a hole at the bottom, with a sliding panel to admit the poultry during the day; and if there are no windows, movable loose boards, fitted to the door, may be useful to admit air. As warmth is very requisite to poultry, one side of the poultry-house, if it can be done, might stand against the outside wall of a kitchen or boiler-house; or a hot-water pipe, running through it from the hot-house, will well repay the outlay. With a sweet, warm, clean poultry-house, a good supply of eggs may be expected as the result.

In reference to the nests, the great object should be to have them near the ground, that they may be easily cleaned, and of moderate size. If they are too large, two fowls will often try to sit in one nest at the same time; and if there is any difficulty in getting at them, hens are apt to drop their eggs on the ground. Nests may be made of wood, unglazed earthenware, or basket-work. If of the first, there should be a small ledge to prevent the eggs from rolling out. A little old mortar, or woodashes laid at the bottom, will tend to keep the nests clean. Straw and heather both make good lining for nests; but the latter must be cut into short lengths. Should the nests be arranged in two storeys, there ought to be a broad ledge, sufficiently wide for a hen to walk on, in front of the top row, and a hen-ladder should be placed at each end; but nests are better on the ground. It is of some advantage to have fowls that are sitting placed in a retired situation, where they will not be annoyed by the others, and where, when the hatch takes place, they can be cooped with their young, out of danger, with a dry yard, or close-cropped lawn in front to run on. Many hens, as well as pea-fowl and turkeys, are
POULTRY-HOUSES.]

POULTRY. [POULTRY-HOUSES.

vicious, and will try to destroy a rival brood. A small brick hutch, about a yard square, with a hard dry floor, and a movable wooden top, is excellent as a sitting-room for hens. Before a bird is put to sit, the nest should be made perfectly clean; for if the hen becomes infested with vermin, she pines, and cannot sit close. Should the stock comprise more than one breed of fowls, and should the races be intended to be preserved pure, they must, as a matter of course, be kept separate.

"Where this is attempted," says Mr. Richardson, "an inclosure adjoining the poultry-house, with three divisions of iron wire, if the space can be spared, will be found useful. In these inclosures, in wet cold weather, the poultry can be confined, with room to scratch and feed. The largest division will be for laying hens and turkeys, and miscellaneous stock. In this space you can muster them, accustom them to be fed, see that all are in health, and make the close observations which are needful for success. In the second, you can place hens with young broods, before they are strong enough to mix with the other fowls. In the third, and smallest, you can keep poultry for fattening. If the accommodation is large enough for them to enjoy the air without being able to run about much, with shade, sun, plenty of clean water and food, they will generally thrive better than when cooped. A few good coops, either of wood and wire, or wicker, with the top thatched, should always be at hand. These may be made so as to shut up the chickens, if necessary, as well as the hens. If the fowl-house is large enough, have a small hollow sunk in one corner where there is light, and fill it with fine sand or ashes, slaked lime, or burnt oyster-shells, as a dust-bath for the fowls. If it is not, place in the yard, under cover, a large glazed earthenware pan. By placing the dusting material in a pan, it is easily changed from time to time. If you are obliged to put up with a small lean-to, or other confined place, for your fowl-house, at any rate take care to keep it clean; for warmth, cleanliness, and judicious feeding are the cardinal maxims for poultry management."

THE COTTIER'S POULTRY-HOUSE.

Under the head of "Housing," we have already observed, that the best mode of rearing fowls, is the old plan of allowing them to roost on the rafters of the room in which the cottier keeps his fire. Owing to the warmth thus afforded during winter, when eggs are scarce, and consequently at a high price, they are to be obtained from the humble cabin, when they are not to be got from the less warm poultry-house of the more affluent breeder. Let us repeat, however, that should circumstances render the keeping of poultry in the cabin unadvisable, a comfortable house may be erected for them against the outside of the cabin wall. If possible, the part of the wall against which the little hut is erected, should be that opposite to the fire-place within. If shelter is required, it can be obtained by means of a few bushes, or a wall of sods; and the neighbouring roads will serve as an ample walk; whilst the nearest stream will slake their thirst. A few laying-nests may be placed in a warm corner of the cabin. By such means as we have stated, the poultry of the poor cottier will thrive as well, and yield as great a profit, as those kept in the best-appointed establishments in the kingdom. Indeed, we are not certain that they will not thrive better; simply because the artificial means adopted to nourish and preserve them, is of a less complicated kind than such as are employed by the more affluent. Nature is left much more free to carry on her own operations; and as she is usually the best nurse of the bird, she generally performs her duties with an unerring certainty as to results.

879
As the poet Burns has affirmed that the best-laid schemes of mice and men "gang aft a'jee;" so may it, with equal certainty, be affirmed, that the strongest, as well as the weakest of animated beings, are the subjects of occasional disease. From this penalty incident to life, fowls are no more exempt than other animals; consequently, when the poultry-keeper sees one of these beginning to droop, or to fail in appetite, it is better, at once, to have it dressed for the table. If, however, it is of great value—perhaps a Spanish cock, worth more than a sovereign—a trial to save its life should be made.

The most common diseases to which fowls are liable, are the following:

ACCIDENTS.
When these show themselves in bruises, loss of feathers, fractures, ulcers, &c., they may, in most cases, be left to nature. When bones are broken, however, the patient had better be consigned to the cook; but in less severe cases of accident, common sense will generally dictate the remedy.

ASTHMA.
This disease is accompanied by panting, gaping, and difficulty of breathing, and is usually caused by the sudden and frequent change of weather which takes place in this country. Poultry, having originally been brought from warm climates, still inherit the natural love for heat, transmitted to them by their progenitors, and are, notwithstanding the feathery covering with which nature has provided them, easily affected by climatic influences; and hence the colds, catarrhs, coughs, and consumptions to which they are subject. For asthma, the treatment recommended is warmth, with small doses of hippo powder, frequently repeated, and sulphur mixed with butter.

CONSUMPTION.
This disease is pronounced incurable; but a change of air and warmth is recommended.

Corns.
These may generally be extracted with the point of a penknife. Should weight have brought them to an ulcerated state, a little lunar-caustic may be applied to them with success.

COSTIVENESS.
When this occurs, change the diet, and let it be given more sparingly than usual. Thin porridge is good. For a cure, give a little castor-oil with burnt butter.

DIARRHEA.
This disease is usually caused by damp and improper food. Therefore change the diet, and have the fowl taken into a dry place. Should the disease become very severe, administer chalk, and a little starch, mixed with cayenne in porridge, and give it a little warm.

FEVER.
In all febrile afflictions to which fowls are frequently subject, give castor-oil, with a little burnt butter. Also, let the birds have a change of air, if possible, with light food, and not much of it.

GOUT.
Administer pellets of colchicum. Sulphur may also be found useful.

INDIGESTION.
This is caused by over-feeding and want of exercise. Administer powdered gentian and cayenne in the food, of which the usual quantity should be lessened. With this regimen let the fowls have an open walk to run in.

INFLAMMATION OF THE TRACHEA.
The disease to which this term is improperly applied, is an inflammation of the tail-gland. The symptoms are—difficulty of breathing, dizziness of sight, constant gaping, and total loss of sight; a discharge from the nostrils, that gradually becomes purulent and foetid;
also loss of appetite; but thirst remains, to the most aggravated extent. Sometimes this disease appears to occur independently of any obvious cause; but dirt, too hot feeding, and want of exercise, are amongst the most usual.

The remedies recommended are various. Mr. Martin prescribes one grain of calomel, made up with bread into a pill; or, if preferred, two or three grains of Plummer's pills (pil. hydr. Subnitric. co. Lond. Pharm.); after which let flower of sulphur be administered, to which add a little ginger, with mixed barley-meal reduced to a paste, and the mouth well washed in a weak solution of chloride of lime. In the meantime, let the bird be kept in a dry, warm, well-ventilated apartment, separate from the other fowls. When the bird dies of this disease, the trachea will be found swarming with narrow worms about half an inch in length, imbedded in slimy mucus. The worms are the distoma lineare—a long and short body united; the long body being the female, the short the male. They are permanently united; otherwise they are quite perfect in themselves. Mr. Martin is uncertain whether these worms are the cause or consequence of the disease; but it is certain that when they have once established themselves, their removal is necessary to give the bird a chance of recovery. This is sometimes done by means of a feather, neatly trimmed, and introduced into the windpipe. It is there turned round once or twice, and then drawn out. This will dislodge some of the worms if dexterously performed, and with some knowledge of the anatomy of the parts. A cock, in the last stage of roup, was cured by washing its mouth and nostrils with soap and warm water; its eyes with warm milk and water; and the internal application of pellets, consisting of "barley-meal and flour (equal parts), with mustard and grated ginger (equal parts), and half the above." Its drink consisted of lukewarm water sweetened with treacle. An acquaintance of the Rev. Mr. Dixon gave spirit of turpentine in rice, and afterwards a little salt in the water given them; he thus saved sixteen out of twenty chickens attacked with this disease. Mr. Richardson's treatment is, for pellets—Powdered gentian, one part; powdered ginger, one part; Epsom salts, one-and-a-half part; flower of sulphur, one-half part; made up with butter, and given every morning. If the discharge should become fetid, the mouth, nostrils, and eyes may be bathed with a weak solution, composed of equal parts of chloride of lime and acetate of lead. Fomentation with an infusion of camomile flowers is also highly beneficial. The other affection—that improperly passed under this name, viz., swelling of the tail-gland—may be treated as a boil. If it become inconveniently hard and ripe, let the pus or matter out with a penknife, and it will soon get well.

Mr. Tegetmeyer first announced, in his writings, the efficacy of certain local applications, in some stages of roup; and a person of the name of Homer, we think, first gave the solution of copaiba. This was administered through a quill; for where so given, it becomes, to a certain extent, a local application also: inasmuch as the fowl usually makes a coughing or a sneezing effort after it is given. The caustic potash, spirit, &c., used in forming the solution, seems to increase its efficacy as a local agent. For this purpose, Faulk's solution of copaiba is as good as any. It is readily given by means of a quill; which should be shaped like a blunt-pointed pen, or rather a scoop, for the facility of pouring the solution into it. The plum, or top of the quill, should then be cut off, leaving a circular aperture. On this end the fore-finger should be placed; the solution poured in at the scoop end, and well inserted in the bird's mouth above the tongue. The fore-finger should then be raised from the other end, when the contents of the quill quickly flow into the fowl's throat. As all are not equally informed, we shall be pardoned for stating, that there is a difference between balsam of copaiba and solution of copaiba; the latter being, in some respects, weaker, as it is prepared from the former. But the ingredients used in preparing the solution are, themselves, of efficacy, especially from their local action. But we must warn fowl-keepers not to expect that catarrh or roup in fowls is now to be "cured in one minute," as some peripatetic "doctors' vouch for the tooth-ache. These diseases seem often to be as depressing and lingering in fowls, as influenza or inflammatory sore throat is with ourselves.

The treatment frequently found most speedy and beneficial, is, first to give a dose of
powder jalap, made into a bolus, the size of a filbert or nut. The dose may be repeated twice or thrice every third day. Give a large quillful of the solution of copauba every night; that is, about a teaspoonful. In bad cases, we should give it night and morning, especially to large fowls. When the eyelids are swollen and gummed up, besmear them with an ointment, made from half an ounce of spermaceti and five drops of Goulard’s extract. If this cannot easily be procured, or is not at hand, a little softened tallow from a candle, spread on the eyelids, greatly prevents their being gummed up. Such is good treatment. Everybody knows that the birds should be kept warm and dry; and we cannot too strongly protest against all effluvia and want of attention to cleanliness and ventilation. Let it always be remembered, that when these are not attended to, they are more frequently the cause of what are usually termed colds, and roup'y attacks, than even cold and rain.

INFLAMMATION OF THE LUNGS.

Is attended by quick breathing, with a rattle, an audible dulness, disorder of plumage, vacancy in the eye, and general indisposition. We know of no cure recommended for this disease.

INFLAMMATION OF THE HEART.

A fatal disease among poultry, and only detected by examination after death. The patient appears to droop; refuses to eat, retires to roost, and is found dead in the morning. In this case, the peritoneal membrane exhibits indications of active inflammation. This complaint is more peculiar to parrots, and caged birds of that description.

INFLAMMATION OF THE MUCOUS MEMBRANE.

This generally proceeds from aggravated diarrhoea. Damp and improper food is the cause of the disease. The remedy, to be successful, must be administered early. First, give a small quantity of castor-oil; afterwards, give doses of hydragryrum cum creta (Lond. Pharmacopoea), with rhubarb and laudanum, as follows:—Hydr. cum creta, three grains; rhubarb, two or three grains; laudanum, two, three, or four drops; mixed in a teaspoonful of gruel, and given twice a-day.

MOULTING.

Moult ing can hardly be called a disease, but, as it takes place annually in birds, and is very dangerous to young chickens, it is necessary to notice it. With full-grown fowls, warmth and shelter from the inclemency of the weather, are usually sufficient to preserve them from any evil consequences, if fed with an extra degree of nutritive and stimulating food. This treatment is recommended, from the fact of Nature causing the wild birds to moult at the very season when they have food in greatest plenty; which may be safely taken as a sign that good food is necessary to them at this time. After the third year, the time of moulting becomes later and later; and in proportion as this happens, so the degree of warmth should be supplied. Two or three grains of Cayenne made into a pill, with bread, may be given them. Sometimes the feathers will fall off fowls when they are not moulting, which is caused by a cutaneous affection similar to the mange in dogs. The treatment for this disease is such as we have recommended for animals so affected, in the preceding divisions of this work: and which are alteratives; such as sulphur and nitre, in the proportions of one quarter each, mixed with fresh butter; a change of diet, cleanliness, and fresh air in addition to this, will generally be found sufficient to effect the cure. Care should be taken not to confound this infection with moulting. The distinction is, that in the latter case, the feathers are replaced by new ones as fast as they are cast; in the former, this is not so, and the animal becomes bald.

PARASITES IN FOWLS.

The insects which infest poultry are particularly obnoxious, and the utmost possible cleanliness, and frequent lime-washing and fumigation, are necessary to keep them away. Mr. Richardson says, that “a correspondent of the Agricultural Gazette, had a beautiful brood of black Spanish chickens hatched. Taking one in his hand on the second day, he was much struck by observing on his poll five or six full-sized lice (Goniocotes holagaster), evidently caught from the mother. All the brood were
similarly affected. Some white precipitate powder, applied with a small camel-hair pencil, was sprinkled over them, and the day after the parasites had disappeared; nor could he discover one during their after-growth. This powder must be used in very small quantities.

Like the domestic fowl, the peacock has also its parasites in the Goniodes pulcriornis. "After the death of the bird," says Mr. Denny, in the Monograph Anaplavorum Britanniae, "the insect may be found congregated in numbers about the base of the beak and crown of the head." This gentleman was afterwards induced to examine all the genera of domesticated birds; and he found on the turkey, Lipurus polytrapozius as a common parasite; the Goniodes stylifer is also frequently in the head, neck, and breast. Over the domestic fowl he found three species of parasitic Goniodes dissimilis, of rare occurrence. Lipurus variabilis preferring the primary and second feathers of the wing, among the ribs of which they move with great celerity. Menopon pallidum he also found in great abundance; and, as a general rule, he observed, that when two or more species frequented the same description of bird, each had its own locality. The remedy in all cases is cleanliness (when the fowls are over-infested), fumigation, and a plentiful bath of clean, dry, and rough sand: for the white precipitate powder, named above, is poisonous, and only fit to be used on very young birds, which have not yet learned the art of preening their feathers with their bill.

This disease, to which young fowls are extremely subject, exhibits its symptoms in the affected birds having a thickening of the membrane of the tongue, especially towards its tip, and, by-and-by, a gasping for breath, when the beak will often be held open. The plumage becomes ruffled and neglected, especially about the head and neck. The appetite gradually lessens; and the bird shows its distress by piping, moaning, and seeking solitude and darkness. The cause of all this is want of clean water, and from feeding too much upon hot exciting food. Dr. Brecht considers it to be analogous to the influence of human beings. In treating for it, most writers recommend the immediate removal of the thickened membrane. Mr. Martin has suggested that the tongue be cleansed by applying a little borax, dissolved in tincture of myrrh, by means of a camel-hair pencil, two or three times a day. Mr. Richardson would rather anoint the part with fresh butter or cream. Prick the scab with a needle, if you like; and give, internally, a pill about the size of a marble, composed of equal parts of scraped garlic and horseradish, with as much cayenne pepper as will outweigh a grain of wheat. Mix this with fresh butter, and give it every morning—keeping the fowl warm. Keep the bird supplied with fresh water; preserve it from molestation, by confining it to itself, and you will generally find it get well, if you have taken the disease in time.

ULCERS.

These may be kept clean by being dressed with a little hard, or washed with a weak solution of sugar of lead, as they appear to require it. If the ulcers seem sluggish, they may be touched with bluestone, in order to accelerate their action, and bring them more speedily to a healthy state. Such are the principal diseases to which poultry is subject; and which, whenever they make their appearance, should be attended to with as great promptitude as those which affect animals of much higher value to mankind. If fowls are kept, they should have every attention their condition requires. Humanity, if not interest, demands this; and it is very frequently the case, that precisely in proportion to the attention given them, their beauty is developed, and their value enhanced.
DIVISION VIII.

PRINCIPLES AND PRACTICE OF MODERN ENGLISH FARMING.

CHAPTER I.

LINES OF COMMUNICATION; NECESSITY OF LABOUR; THE FECUNDITY OF WEEDS; AGRICULTURAL EDUCATION; THE LITTLE SMITHFIELD CLUB; TURNIP CROPS; THE ROTATION OF CROPS; ARTHUR YOUNG; THE EARL OF LEICESTER; ARTIFICIAL FATTENING.

LINES OF COMMUNICATION.

"Of all inventions," says Lord Macaulay in his History of England, "the alphabet and the printing press excepted, those inventions which abridge distance have done most for the civilisation of our species." Every improvement, he adds, of the means of locomotion, benefits mankind morally and intellectually, as well as materially. Of the truth of this remark, every one who has, whether from pleasure, choice, or business, had to traverse the primitive cuttings of a British colony in its semi-infantile state (as the present writer has had to do), must be conscious. There, as a general rule, there is nothing but difficulty to the traveller. If his excursion is commenced in love, he soon finds that it must be prosecuted with toil; and if he set out with the intention of viewing the country, he discovers that he must first see through the wall of an interminable forest, the immediate trees of which extend their branches over his head, and, for the greater part of his journey, shade the narrow way upon which he is proceeding, even, in many instances, to the shutting out of the light of the sun. He does not proceed easily and gaily over the smooth and level surface of a macadamised road, but over a sort of mud swamp, hardened—when it may happen to be hard—by the broken and decaying branches of the neighbouring trees; presenting no other sign of an approach to civilisation than that of its having been rudely cut by the hand of man. It is evident that where there are difficulties of this kind in the way of communication between different parts of a country, its progress must be slow indeed towards the goal of an advanced civilisation.

The earliest maker of roads, of which history has given us any information, was an Egyptian Pharaoh, who, by forced labour, constructed a gigantic causeway, to enable his workmen the more easily to convey materials for the erection of a useless pyramid, which has certainly immortalised his folly, notwithstanding that the name of the founder is a subject of doubt. Herodotus has handed down to us the cruel edicts which this despot passed for the purpose of compelling the unfortunate creatures subjected to his power, to carry out his fanciful caprice, and the curses with which they loaded his memory. On this remote effort at road-making, however, it is here unnecessary to dwell, when even road-making, especially through the most populated parts of Great Britain, has, in a measure, been put out of fashion, in order that railway-making may apparently take its place. But it must be long, if it is ever to take place, before the railway can be made subservient to the requirements of every portion of an agricultural district. There, if farming is to thrive, good roads must still be preserved in a state of repair. "It is well known," says Sir John Sinclair, "that the best cultivated districts are those which possess the greatest facility of internal communication, without which agriculture languishes in the most fruitful soil; and, with it, the most ungrateful soil soon becomes fertile." The truth of the last clause of this sentence is remarkably verified when we look at the effect which the
HARROWING WITH OXEN.

COW HOUSE.
expansion of our railway system has had in stimulating the farming operations of the country. "For several years past," says a well-informed writer on this subject, "all the railway companies have agreed to convey live-stock free, and implements at half their usual charges, to and from the shows of the Royal Agricultural Society: the railway companies, at the towns where they are held, generally providing accommodation for the mechanical compartment. This, at Chelmsford, cost the Eastern Counties Railway Company upwards of £3,000. Railway fares and pace could alone bring the number of shilling-paying strangers who contribute to the enormous expense of these exhibitions. The population of the city of Salisbury, including men, women, and children, amounts to 10,000; but the visitors to the show, in 1857, were over 35,000. This is of itself a striking proof of the wide and eager practical interest which is felt in agriculture, for there is little to gratify the eye of mere holiday-gazers; and when, in addition, we consider the mountains of coal, iron, timber, artificial manure, lime, and chalk conveyed in the one direction, and live-stock and corn in the other, we cannot help coming to the conclusion, that George Stephenson's locomotive has been the great cultivator of the farmer's mind and the farmer's land—the great agent for the extraordinary advance which British agriculture has achieved in the last quarter of a century. Very significant were the figures given by the chairman of the above company at the Chelmsford dinner, when he told his farmer friends, that, in the course of the preceding twelve months, the lines over which he presided had conveyed 21,000 tons of guano and other portable manures; 700,000 quarters of grain; 550 sacks of flour; 71,000 beasts; 350,000 sheep; 13,000 tons of meat and poultry; and 48,000,000 quarts of milk!" This was ten years ago; and, as population has since greatly increased, and agricultural appliances considerably multiplied, we may fairly presume that these figures have increased in amount to a proportionate extent. Well may the writer exclaim—"Who can calculate the value of the many rewards held out to breeding, feeding, and corn-growing, in the shape of four thousand miles of railway! and how little are men, who live in the midst of these changes, conscious of their magnitude until the results are collected and put on paper!"

THE NECESSITY OF LABOUR.

If a person enters upon the operations of farming, he must not expect that he is beginning a life of idleness. In the mere fecundity of the weeds upon his fields, intermingling with his crops, he will very soon find the truth of the original sentence passed upon Adam, and thus written in Milton's Paradise Lost:

"Cursed is the ground for thy sake; thou in sorrow Shalt eat thereof all the days of thy life; Thorns, also, and thistles it shall bring thee forth Unbid."

Nothing can be truer than this, for ill weeds grow apace. As the crop ripens, so do they; therefore there is a constant vigilance, accompanied with labour, to keep them down, or rather to eradicate them from the soil, in which they seem to find such a congeniality of conditions, that they appear literally to love it with an enduring and inseparable affection. Sir John Sinclair, however, considers these wild and spontaneously-growing children of the soil as a positive advantage. Strange if this is really the case, when every farmer complains of them, and labours at their extirpation. No doubt Providence has supplied them for something more than merely that of cursing the ground. "What," says Sir John, "is the inference from the fact, that couch-grass and thistles can by no means be extirpated? Is it not perpetual exertion, following and agricultural labour? Some may be inclined to say, 'A melancholy reflection!' But I say, No! not at all. Providence could not have better contrived than that exertion should be perpetual, and that success should be in proportion. There is not a weed that we ought to wish out of our fields, unless we remove and destroy it; because if there were none, or very few, all fields would be clean, and no praise could light on superior modes of tillage. Some may say, again, 'So much the better!' But I say, No! Does any man think that our various soils would have been sufficiently pulverised and worked, had there been no enemies of this sort to challenge forth our labours? Sterility would have seized upon our turnip lands, which are only con-
tinued in a state to bear their rotations of crops, by the necessary periodical renewals of their fertility. The necessity of subsistence produces industrious hands for every department of labour; but the sluggish nature of man requires every stimulus to exertion. The weeds of the fields excite emulation among farmers; and soul fields are always a reproach to the occupier. Thus we are compelled, by an unseen hand, to better habits and more active industry."

This reasoning, we fear, is more specious than sound, as there are thousands of flower-gardens entirely destitute of weeds, and yet possessing soils perfectly pulverised. We have heard even of kitchen-gardens being so completely denuded of weeds, that it was deemed necessary to cultivate groundsel, for the humble purpose of feeding a solitary pet bird. Whatever may be the providential purpose of weeds, however, toil is as necessary to eradicate them, as tillage of the soil is necessary previous to its reception of the seed for a valuable crop. We profess to small knowledge, indeed, of the meanings of the ways of Providence; but that weeds will multiply rapidly and indefinitely, without they are rooted out, is a fact which comes within the experience of every farmer, and which, without any effort of memory, is daily brought within the range of his observation upon his own grounds. Pliny tells a story which will bear quoting, as it strikingly shows the value of labour when nicely applied to the objects of agriculture. "I cannot forbear stating," says he, "one instance from old times, from which we may perceive both that questions of culture were brought judicially before the people, and also how men of that time were in the habit of defending themselves. C. Furius Cresimus, a freeman, because the object of much ill-feeling on the part of his neighbours, in consequence of his gathering, from a very small field, much more produce than they could procure from very large ones. He was accused of attracting the crops from other fields by charms. Sp. Albinus appointed a court day to hear this charge; and Cresimus, fearing that he might be found guilty, when the tribe were about to pronounce their verdict, brought his live and dead stock into the forum; and he brought with him a stout wench, and Piso says that she was in good case, and well clad. His iron implements were exceedingly well manufactured; the spades were strong, the shares powerful, and the oxen in high condition. Then he said, 'These, Romans, are my charms; but I cannot show you, or bring into the forum, my mental labours, my vigils, nor the sweat of my brow.' " Here are some of the great secrets of good farming—strong and willing labourers, good implements, long watching, and hard labour.

THE FECUNDITY OF WEEDS.

What is a weed? is a question much more easily asked than answered. For example, every person at all conversant with fields and flowers in this country, would be loth to consider the dandelion as a specimen plant, suitable to take its place in the garden; yet has this very plant been lionised in Australia. It has there formed one of the attractions at a flower show, and was the means of drawing thousands to gaze upon its charms. Dr. Johnson defines a weed to be "an herb noxious and useless"—a definition more brief than true. In his Book of the Farm, Mr. Stephens says—"When any plant is found growing where it should not be, it is a weed. For example, a stalk of wheat in a bed of tulips in a garden, is a weed, and should be removed; and, in like manner, a tulip in a wheat-field is a weed, and should be eradicated." This is just saying that it is a fruit or a flower out of place. The author of the article on "Weeds," in Morton's Cyclopaedia of Agriculture, says—"Every plant different from the crop, and growing with the crop, to its hindrance, is a weed. Regarded in this light, most of our wild, and even cultivated plants, may take the place of weeds: thus potatoes, left in the soil, may completely smother a succeeding crop; or the shed seeds of a former crop may germinate amid a new one; and, in both cases, their removal by weeding will be necessary to success." This is sufficiently clear and comprehensible for the farmer's view of the subject; and as weeds are certainly greatly obnoxious to good cultivation, it may not be amiss to show here the wonderful fecundity with which they are endowed. Professor Buckland, in an article in the Agricultural Gazette, says
that "the Crow-garlic is a handsome plant, the scape or flower-stem of which is as much as from two to three feet high, rising from a bulb, which, especially in non-flowering examples, will be surrounded by from four to eight smaller bulbs or bulblets. The intended intention of the scape is to bear the flowers, after the manner of the garlic and onion of our garden; but it curiously happens that, instead of flowers, the scape is surrounded by from one to three compacted heads of minute bulbs, possessing the structure and characters of those at the base of the plant, and endowed with such a power of vitality, as to be, in most cases, viviparous; that is, growing or sending out leaves before they fall from the parent stem. These are sometimes, but very rarely, mixed with flowers; and as they readily and singly separate from the parent as its stem becomes dry, they become scattered around, and take possession of the soil. Thus a whole colony, in one season, results from a single plant.

"Thus, then, we see that the Crow-garlic, if allowed to seed, has a prodigious method of increase; but we must recollect that this increase is not, like the majority of weed-plants, by seeds which are agreeable to birds and insects, by which means many much more productive plants are kept in check. On the contrary, it would appear to be avoided by all classes of those creatures; but the bulblets themselves, which are seldom abortive, possess such wonderful powers of vitality, that they may be kept alive outdoors, or in the ordinary flowering bulb, for months, and, perhaps, even years, and still maintain their germinating power."

The importance of this subject must be our apology for the length of this quotation; but it makes it clear, that the farmer who does not know that the principal means by which the Crow-garlic is multiplied is through the bulbs, has done but half his work in the destruction of the weed, if he allows these still to exist. Facts of this sort necessarily suggest the value of a knowledge of botany to the farmer, especially when the operation of weeding alone, on an acre of arable land, costs the yearly sum of from five to twenty shillings. An old rural rhyme says that—

"One year's sowing
Is seven years' weeding."

And the truth of the maxim it embodies will be apparent from the following table, drawn up from several hundreds of observations, stretching over a period of five years, in different parts of England, and under the most varied conditions of geological formation and modes of farming:—

Table of the Fecundity of Weed-Plants.

</table>
Such is the astonishing fecundity of weeds-plants. Of 21,950 seeds of the following weeds, upwards of 6,000 have been found ripe in April, when hoeing is frequently carried on. The grey speedwell, ivy-leaved speedwell, shepherd's purse, hairy bitter cress, chickweed, and groundsel. In the very process of hoeing, then, these are scattered about under the most favourable circumstances for growing; and, if the hoeing is, for some little time, deferred, or not done at all, the 21,950 will, in all probability, by next season, have taken entire possession of the soil. The manner in which weed-seeds are propagated are, first, by the neglect of way-sides and waste places; second, from permitting weeds to be thrown on the manure heap; and third, from sowing weed-seeds with the seeds for the crop. To these circumstances, therefore, the farmer should be particularly attentive.

AGRICULTURAL EDUCATION.

Of the necessity of an agricultural education, independent of his other scholastic acquirements, for the young or rising farmer at the present day, no one of the slightest intelligence has the smallest doubt. The customs of our grandfathers are already old and effete; whilst those of our fathers are fast wearing out. In a lecture delivered by Mr. Morton, at the Royal Agricultural College, he laid down these three points as essential to the young farmer:—1st. That he should have practical skill. 2nd. That he should have business tact. 3rd. That he should have a liberal and scientific education. This gentleman showed that, if a man possessed a merely practical skill, and nothing more, he was little better than a labourer; that if, added to his practical knowledge, he had business tact, he might not only be a labourer, but become the manager of a farm; but that, without having, in addition to capital, a liberal and scientific education, he was not fitted to hold a large farm in the present day. This subject is a most important one. We ourselves are acquainted with several young gentlemen, the sons of farmers, who have been boarded out to receive what is called a liberal education; and they have gone home to follow the occupation of their fathers, with as much of the kind of knowledge necessary for such an object, as a watchmaker may be supposed to have for the manufacture of a steam-plough or a threshing-machine. Their case, however, is by no means singular. At a meeting of the weekly council of the Royal Agricultural Society, in April, 1861, the subject of agricultural education was introduced by Mr. Holland, M.P., and discussed. Among the authorities quoted upon this subject was Mr. Wilson, of Edington Mains, the author of British Farming; who, in respect to the rising young farmers, gives his opinion in the following terms:—

"The mere possession of capital," he says, "does not qualify a man for being a farmer; nor is there any virtue inherent in a lease to insure his success; to these must be added probity, knowledge of his business, and diligence in prosecuting it. These qualifications are the fruits of a good education in the fullest sense of the term, and are no more to be looked for without it, than good crops without good husbandry. ** But the great difficulty, at present, lies in finding appropriate occupations for such youths between their fifteenth and twentieth years. In many cases, sons of farmers are, during that period, put to farm-labour. If they are kept steadily at it, and are made proficient in every kind of work performed on the farm, it is a good professional training, as far as it goes. The more common one—at least as regards the sons of the larger class of farmers—which consists of loitering about, without any stated occupation; attending fairs and markets, and, probably, the race-course and hunting-fields, is about the most absurd and pernicious that can well be imagined. Such youths are really to be pitied, for they are neither inured to bodily labour, nor afforded the benefits of a liberal education. It need not surprise any one that such hopeless lads often prove incompetent for the struggles of life, and have to yield their plans to more vigorous men who have enjoyed the benefit of bearing the yoke in their youth. Unless young men are kept at labour, either of mind or body, until continuous exertion during stated hours, confinement to one place, and prompt obedience to their superiors, have ceased to be irksome, there is little hope of their either prospering in business, or distinguishing themselves in
their profession. Owing to the altered habits of society, there is now less likelihood than heretofore, of such young persons as we are referring to, being subjected to the arduous training to bodily labour, which was once the universal practice; and hence the necessity for an appropriate course of study to take place. * * * It is also common for such youths to be sent to Edinburgh for a winter or two, to attend a class of agriculture, and, perhaps, also of chemistry and the veterinary college. This is well enough in its way; yet there is wanting in it an adequate guarantee that there is real study—the actual performance of daily mental work. * * * After enjoying the benefits of such a course of training as we have here indicated, young men would be in circumstances to derive real advantage from a residence with some experienced practical farmer, or from a tour through the best-cultivated districts of the country."

Enough to show what the present age requires in the young farmer to rise or be successful in his profession.

THE LITTLE SMITHFIELD CLUB.

In order to come clearly down to the present, we must look a little way into the past. In 1798, the Duke of Bedford, Lord Somerville, and several others, with Arthur Young as honorary secretary, formed the "Little Smithfield Club," with the view to the exhibition of fat stock at Christmas-time. A specification of the food upon which each animal had been kept was to be given, and prizes were to be competed for. This society has wonderfully grown in strength, and has rendered incalculable service to the interests of agriculture, by making known the kinds of food most favourable to the rearing of cattle for meat, and by educating both the grazier and the butcher up to the knowledge of the best form of animal. In 1806, a toast of Mr. Coke, of Holkham, afterwards Earl of Leicester, was—"Small in size, and great in value." But notwithstanding the far-sightedness which, even at that time, in the face of great proclivities, he exhibited in his judgment of cattle, the tallest ox continued to take the prizes. Long legs have long been reckoned a serious fault, as they are the most profitless parts of the beast. In 1856, a little Devon ox, of an egg-like shape, which is the modern bean-shaped, gained the Smithfield gold medal, in competition with gigantic short-horns, and Herefords of elephantine proportions; and, in 1854, a large animal of Sir Harry Verney's was passed over without even the compliment of a commendation, because he carried on his carcase too much offal, and more threepenny than nine-penny beef. The Smithfield Club is now a great institution, bringing annually together all the best breeders and cattle-judges in the country.

TURNIP CROPS.

In order that the improvement of cattle might extend generally, as far as possible, throughout the country, and not mostly be restricted to rich grazing districts of the midland counties, it was felt that some addition to the usual supply of food was necessary. Already had the finest, most productive arable land of the kingdom been exhausted, by the years upon years of cultivation it had undergone; whilst the barren fallow, which annually absorbed one-third of the soil, was inadequate to the task of restoring its fertility. In this emergency a new source of agricultural wealth was discovered. Turnips sprang into notice, and were received with a sort of general enthusiasm in the farming districts. They were found to answer the purpose of a fallow crop, which cleaned and rested the old arable land; they were excellent food for fattening cattle in winter; and when raised on light land, and afterwards eaten down by sheep, which pressed the soil into firmness with their feet, led the way for corn crops on wastes which had before been hopelessly assigned to the rabbits. By this means the heaths and wolds of Yorkshire and Lincolnshire, with some assistance from marling and the travelling sands of Norfolk, Nottinghamshire, and Bedfordshire, were gradually recovered and peopled by the race of farmers, who have been first to adopt all the improvements in English agriculture for the last century. The new system, however, required capital in both the landlord and the tenant. From the landlord, it required barns and yards, and houses suitable to the wants, habits, and tastes of first-class men, with high means. But when
the spirit of improvement takes possession of a class or people, neither proper men nor plenty of means will be wanting to realise the objects in view. Mr. Coke, of Holkham, expended over £100,000, in twenty years, on dwellings and offices alone. This sum, however, was by no means unprofitably laid out; but whatever sums the new system required to be expended by the landlord, it also demanded a proportionate expenditure on the part of the tenant. It required him to lay out a large sum on flocks and herds, and, above all, in labour, for years, before the wild land began to return a profit. We are told, that a Mr. Rodwell, in Suffolk, sunk £5,000 in merely marling 820 acres, with a lease of only twenty-eight years. The value of his produce, during that period of his occupancy, was £30,000 greater than the twenty-eight years preceding his improvements. Speculations of this kind required no mean degree of intelligence to conduct them, and no small amount of spirit to enter upon them; yet they seem generally to have been crowned with success.

Turnips are said, by Young, to have been brought into farm cultivation by the celebrated Jethro Tull, and found an ardent advocate in Lord Townshend, who, in 1730, retired from taking part in public affairs. After this, he devoted the remaining eight years of his life to the improvement of his estate. It is said that he originated practices which increased the produce not only two but a hundred-fold, and from which the country still continues to draw the benefit. In England, the practice of marling and claying farms was far from being new. Indeed, it was very old. In the reign of Elizabeth, Harrison, in his Description of Britain, says—"Besides the compost that is carried out of the husbandmen's yards, ditches, and dove-houses, or out of great towns, we have with us a kind of white marl, which is of so great force, that if it be cast over a piece of land but once in three-score years, it shall not need of any further composting." The usage, however, died out; and seems not to have been again recovered until Lord Townshend and a Mr. Allen applied it to the sands of Norfolk, and converted immeasurable acres of rabbit-warrens and sheep-walks into rich soil. At the close of the last century, Young estimated that three or four hundred thousand waste acres had been reclaimed and turned into gardens, and rents rose from sums varying from a sixpence and two shillings an acre up to fifteen and twenty. Marling, however, would not, of itself, have reclaimed the wildernesses of Norfolk; it required the assistance of something else; and that was found in turnips. Townshend had the sagacity to perceive that this was to be the parent of all future crops. Without a supply of food through the winter, a limited stock must be kept, and this could yield but little manure, without which profitable farming was vain. "The turnips were, therefore, employed to secure a large dung-heap; and the dung-heap, in turn, was mainly appropriated to securing the largest possible store of turnips. This tillage, in a circle, was as productive as it was simple. The ground, cleaned and enriched by the root-crop, afterwards yielded abundant harvests of corn; and as has already been observed, the treading of the sheep upon the loose soil, while they fed off a portion of the turnips, gave it the necessary firmness. Thus, through the agency of the turnips, a full fold and full bullock-yard made a full granary." Essex and Suffolk soon followed the method, although they did not proceed in it so far as they did in Norfolk; and, in many parts, the turnips were never thinned or hoed, upon which their dimensions, and, consequently, the largest portion of their value, depended.

To the reader of the ancient agricultural writers, it will seem strange how it was that, for so many centuries, the value of the turnip was not perceived by the farming mind, when its qualities were, at least, tolerably known eighteen hundred years ago. Pliny tells us, that no crop is so valuable except grasses and corn. He also says (we quote from an article of Ancient Agricultural Literature), "That they are most wholesome food for man, and excellent, dressed in a variety of ways; that they keep through the year, either potted or when mixed with mustard; that they are most valuable in ornamental cookery, as capable of receiving six colours besides their own, one of the colours being purple—a quality possessed by no other kind of food; that, when boiled, they will feed fowls, and that the leaves are good for cattle; and, finally, that he has seen..."
one 10 lbs. weight." Columella says, that "in Gaul, the beds are used as winter food for cattle and sheep;" showing that the ancient fathers of our neighbours across the Channel were not ignorant of the value of the turnip, in supplying their flocks and herds with nourishing food throughout the long, dreary months of the winter. Nor is marling a discovery of the moderns, for it seems to have been, both in Gaul and Britain, a staple practice in husbandry. Pliny recommends six different kinds of marl used for pulverising the soil. Some were of a clayey description, which were used for light ground; some sandy, for heavy. Some were of a rocky sort, which preserved its form till several years of the effects of sun, rain, and frost reduced it to amalgamate with the soil. Some lasted ten, some thirty, and some fifty years. Some were got at in a day; and one kind which endured eighty years, and which no man had ever been known to apply twice to the same land, was obtained in Britain from narrow pits, dug to a depth of thirty yards.

THE ROTATION OF CROPS.

The course of Roman agriculture, with some partial exceptions, was of the simplest description—a crop of grain and a fallow. Every year one-half of the arable land was in grain, and the other half in fallow. A third of this was sown with a green crop of some kind, to be given to the cattle; and this was the only portion of the fallow that received the benefits of manure. The result of this mode was, that the arable land was manured once in six years; and, in that period, produced three crops of grain, and one of green stuff. This system, by degrees, wore out the land. It took the very heart out of it, so to speak; so that, in the time of Varro, a great falling-off had taken place in the returns for the quantity of seed sown. Fifty years later, Cicero gives an account of the rich Sicilian lands, and claims 2½ bushels to the statute acre. This, well cultivated, seems to have yielded eight or ten for one, equal to twenty or twenty-five bushels respectively. In another half century, Columella tells us, that over a large part of Italy, the instances are few in which the return is more than four to one; and the increasing lamentations over the penury with which the land returned its grain for the seed, as we deduced in the series of authors, are in entire accordance with the paucity of their crops.

In England, during the last century, the rotation of crops was viewed as the special characteristic of the husbandry of Norfolk. Until past the year 1750, no just ideas upon the subject seem to have been formed in any part of the kingdom; in proof of which, Sir John Sinclair makes the remark, that all courses were thought to be alike, and merits neither censure nor praise. The established rule upon which the farmers of Norfolk acted, and to which they doggedly adhered, was never to take off the same ground two corn crops in succession. But this formed only one rule or part in the whole of a valuable system. They had not discovered the importance of alternating grain with other products of the soil; but they had perceived and found the advantage of following turnips with barley; this with clover; and this with wheat. They had discovered that the fibrous roots of the clover were the best possible pabulum for the nourishment of the wheat, and that nothing else answered so well. By 1767, Young found this four-course system widely prevalent, the principal variation being in the duration of the clover, which some farmers permitted to remain for two or three seasons previously to its being broken up for wheat. All these changes occurred during the thirty years between 1730 and 1760; but, with slight exceptions, they were entirely confined to Norfolk; and it was not till Young made his appearance upon the scene, that they began to penetrate into other districts.

ARTHUR YOUNG.

One who did so much, in his time, to enlighten the agricultural mind of this country when it was involved in a cloud of thick darkness, merits some notice in these pages. The reclamation of barren sheep-walks; an improvement in the different breeds of live-stock; an increase in the quantity of food grown on arable land for their support; and a better rotation of crops, are the principal events which distinguish the progress of English agriculture during the last century. After some advances had been made, the next step was to demolish those obstructions which
kept the farmers of that day apart from each other, and which held them in the bonds of ignorance as to what was passing in every district beyond the immediate limits of their own, as complete as if they were so many Robinson Crusoes, doomed to cultivate a piece of solitary land, on a solitary rock, in the middle of the Pacific. The man who entered heartily into this work was Arthur Young, the son of a prebendary of Canterbury. A writer describes him as one of the most useful and sagacious, if not one of the most brilliant of men. Long before his time, however, Norfolk was celebrated for the superiority of her roads. The inhabitants quoted with pride an observation of Charles II., who said that the county ought to be cut up to make highways for the rest of the kingdom. This, however, only proved how deplorable, in this respect, were the other parts of the country. When Young made his "tours," and visited Norfolk, he did not fall in with a single mile of good road in it. In Essex, the lanes were so narrow that it was only possible for a carriage to get along them. "Ruts," says the writer already quoted, "of an incredible depth; and chalk-waggons stuck fast, till a line of them were in the same predicament, and it required twenty or thirty horses to be tacked to each, to draw them out one by one. The thoroughfares, in fact, were ditches of thick mud, cut up by secondary ditches of irregular depth. In attempting to traverse them, Young had sometimes to alight from his chaise, and get the rustics to assist him in lifting it over the hedge. Such was the state of things when, in 1767, he abandoned the farm, in which he had experimented too much to be successful, and availing himself of the frank hospitality which has, in every age, been the characteristic of our farmers and country gentlemen, made those celebrated "tours," which are absolute photographs of agricultural England, and are models of what all such reports should be—graphic, faithful, picturesque, and philosophical." Such was the man and his work, which did so much to impart an impetus to agriculture; and which, from his time to the present, has, without pause, continued to advance.

THE EARL OF LEICESTER.

Mr. Coke, of Holkham (afterwards Earl of Leicester), headed the agricultural movement towards the close of the last, and throughout the first quarter of the present century. Reclaiming the Norfolk wastes, marling the light lands, extensively cultivating the turnip, and introducing the rotation of crops, have all been ascribed to him. That he was the originator of all these improvements, however, can hardly be the case, as Young states, in his Tours (published some years before Mr. Coke held an acre in Norfolk), that every one of these practices were then in common use. But though the precise nature of what Mr. Coke did has been exaggerated or misunderstood, what he really did accomplish was very great. He is the first in the ranks of that class of whom Young wrote in 1770—"Let no one accuse me of the vanity of thinking that I shall ever, by writing, wean farmers from their prejudices. All improvements in agriculture must have their origin in landlords." Five years after this, Mr. Coke succeeded to the estates of the Leicester family; and here we find it stated, that "the fine house at Holkham, erected from the designs of Kent, about the middle of the last century, bears an inscription, which imparts that it was built in the midst of a desolate track; and its noble founder was accustomed to say, at once jocularity and sadly, that his nearest neighbour was the King of Denmark. There was still many a broad acre in its primitive sheepwalks; and Mr. Coke graphically described the condition of portions of the property surrounding this princely mansion, by the remark, "that he found two rabbits quarrelling for one blade of grass." This was an unprofitable, as well as an uninviting, condition of things; but he was not disheartened. He immediately set about applying the known methods practised, to bring into a state of fertility the wilderness with which he was encompassed; at the same time adopting such improvements as suggested themselves on the existing modes. He also endeavoured to persuade his neighbours to adopt his practice. Having, by perseverance, labour, and example, succeeded in rousing them from the lethargy into which they had sunk from the success which had attended the practice of Lord Townshend, the second revolution commenced. The great evil of the time, as we have already observed,
was the isolation in which farmers lived. They were nearly as much fixtures as their houses; and what was done upon one side of a hedge was hardly known upon the other. "The Lord of Holkham instituted his annual sheep-shearing, at which he feasted crowds of guests from all parts, and of all degrees. Under the guise of a gigantic festival, it was an agricultural school of the most effective kind; for the social benevolence engendered by such magnificent hospitality disarmed prejudice; and many who would have looked with disdain upon new breeds of stock, new-fangled implements, and new modes of tillage, regarded them with favour when they came recommended by their genial host. * * * Excluded by his political opinions from public office, and the favour of the court, Mr. Coke found abundant compensation in the feudal state of gatherings, at which, as a contemporary journal records, hundreds assembled, and were entertained. Farming, hunting, or shooting in the mornings; after dinner, discussing agricultural subjects; whether the Southdown or new Leicester was the better sheep—whether the Devon or the old Norfolk ox was the more profitable. In dealing with those who farmed under him, he showed the same wisdom as in his own village. He formed an intimacy with Young, and acted on three of his maxims, on which agricultural progress may be said to depend—'that a truly good tenant-farmer cannot be too much favoured, or a bad one have his rent raised too high;' that 'good culture is another name for much labour;' that 'great farmers are generally rich farmers.' By these methods he raised his rental to more thousands a year than it was hundreds when he inherited the estate, and had enriched a numerous tenancy into the bargain. * * * The wealth, nevertheless, which accrued to himself was the smallest part of the gain. He was a national benefactor upon a mighty scale, and was the cause, directly and indirectly, of adding a countless mass of corn and cattle, of beef and mutton, bread and beer, to the resources of the country."

**ARTIFICIAL FATTENING.**

In 1824, from a suggestion made by Mr. Blackie (the steward of Mr. Coke), Mr. John Hudson, of the farm of Castle Acre, entered upon the experiment of supplying his young wethers with oil-cake and sfhed turnips. What, in the last century, would have been thought of such an act? He would have been pronounced mad, and in a condition suitable only to become the inhabitant of a lunatic asylum. But what was the result? When Mr. Coke asked to see the produce of his turnips, he found that they had been sent to market twelve months before the usual time. Yet even the neighbours of Mr. Hudson, and even his own father, a man of intelligence and agricultural progress, prognosticated his ruin from his extravagance in purchasing food for sheep. Now, however, the buying of linseed-cake, or meal, or foreign pulse, is one of the regular means by which an increased quantity of meat is grown. Wherever turnips are raised and sheared, there the cake-trough is to be seen; and the improved material for feeding, united to the natural tendency of the best breeds to arrive at an early maturity, has increased, to an amazing extent, the quantity of mutton in the kingdom. It is affirmed, by Mr. Morgan, that, twenty years ago, the majority of sheep brought to Smithfield market were three and four years old; and to find a score under two, would have been a matter of some difficulty. And now a three-year-old sheep is scarcely to be met with; whilst fat sheep, no more than a twelve-month old, are abundant. Thus, independent of the vast increase in the numbers kept, three generations of sheep are fed and fattened for our tables, in the same space of time in which one was prepared in 1838. But purchased food would have been almost thrown away on the former species of tardy-growing animals. Applied, however, to the improved stock, reared on the principles of Bakewell, it has created a demand, not only for turnips from Sussex, steers from the Quantock hills, and oil-cake from Germany, but for new implements and machinery of almost every agricultural description.

For some time the Leicester breed of sheep was preferred by Mr. Coke; but he subsequently replaced them with the Southdowns. These he considered superior; and the bringing of them to the high state of perfection in which they are beheld by the present genera-
tion, was accomplished by Mr. Jonas Webb, and arose out of one of those trifling circumstances from which great results often emanate. His grandfather was a breeder of rams in Norfolk; and it was one of the oddities of the old gentleman, at his annual sales, to put his grandsons to ride on his rams, without saddle or bridle, but making them hold fast by the immense horns of the animals. Experiencing both the pain and the difficulty of retaining his seat on these occasions, it suggested itself to the mind of Jonas, that, if ever he arrived at manhood, and bred sheep, he would endeavour to provide them naturally with “better saddles of mutton.” A lean hurdle-backed Norfolk ram was at this time the animal; which, indeed, might have better racing qualities, but could not compare, in eating qualities, with the beautiful skirkin-bodied Southdown, for which Mr. Webb refused 500 guineas at the Paris Exhibition of 1855. Nothing but Norfolk sheep could have thriven upon the uncultivated Norfolk heaths of former times; and nothing but the roots of artificial grasses, the cake, and the corn of modern days, could have brought the Braham “Downs” to their present state of matchless perfection.

We have now arrived at the period when Norfolk is no longer foremost in the race of agricultural improvements, and when the new era commences in the foundation of the Royal Agricultural Society of England, incorporated by special charter.

CHAPTER II.

THE ROYAL AGRICULTURAL SOCIETY; DRAINAGE; THE FIRST FIELD DRAINED; THE CHEMISTS; PORTABLE MANURES; THE GEOLOGISTS; THE CAINS OF FARMING.

THE ROYAL AGRICULTURAL SOCIETY.

The source of the present mode of farming dates from the foundation of the Royal Agricultural Society, in 1837-38. The late Mr. Henry Handley, M.P., has the merit of having suggested the formation of this association, in a pamphlet which he published in 1837, and which seems, very rapidly, to have carried conviction to the minds of those who became the originators of the society. Mr. Handley was a Lincolnshire squire; an excellent judge of stock, and a good sportsman; whilst he cultivated his own estate, it is said, with a higher degree of intelligence than was usual in his time. The first meeting of the association was held at Oxford, in 1839; and the first number of its Journal appeared in the following year. It was placed under the editorship of Mr. Philip Pusey, who died in 1854, who was a good writer, an ardent farmer, and who devoted his time, his talents, and his fortune to recording the progress of his favourite science, and stimulating improvements in every direction to which his influence extended. He is said to have been an example of “that delightful combination of scholarship and practical energy which is so common in England; and he exercised the double influence of an accomplished gentleman and an enlightened agriculturist.”

It is impossible to calculate the benefits which have been conferred on English agriculture by the establishment of this society. The brightness of its own light has been diffused through the remotest corners of the land. In the able article from which we have already quoted, it is stated that, “with its council of peers, squires, tenants, and implement-makers; its professors of chemistry, botany, and veterinary art; its thousands of subscribers spread over every county of England; its journal of transactions and reports; and, above all, its annual encampments in the centres of successive districts, has done for farming what the great fairs of the middle
the commercial enterprises and classical knowledge, brought customers and builders into contact, and helped to extend the prejudices in the advancement of social services. They have carried to provincial cities the best live-stock, the best implements, and the best cultivators. The influence of example, of competition, and even of rank and tradition, has been brought to bear on local farmers. Spicers have been encouraged to improve their estates by the speeches of superior men; and young noblemen, in want of an object, have found it in agricultural employments. Implement-makers have had the advantage of the suggestions of their customers, and, thus taught and teaching at the same time, have, every year, become more dependent on tenants, and less on fancy farmers."

As with every institution which is founded with great objects in view, and which meets with success, there always remains something which has not been fully foreseen, and which, in the course of time, gradually develops itself. Thus it happened that, when this society was founded, not one of the promoters foresaw the importance of the machinery department. In the ten sections of its charter of incorporation, explaining the objects of the association, implements have only an incidental reference, as one of the objects to which scientific men were to be stimulated to direct their attention, in a miscellaneous paragraph, which includes the construction of farm buildings, the application of chemistry to the general purposes of agriculture, the destruction of insects injurious to vegetable life, and the eradication of weeds. At Oxford, a few manufacturers perceived an opening for procuring customers, and found their way to the "show-yard," notwithstanding the difficulties from the absence of that kind of cheap machinery which is now, happily, placed within the reach of the humblest member of the community at large. One gold medal for a collection of implements, three silver medals, and £5 for a paddle plough for raising potatoes, were all the rewards distributed in 1811, for what was destined to be the most extensive, as well as the most useful feature of the exhibition of the society. After the meeting at Cambridge, in 1840, the importance of the implement department was acknowledged; and the mechanical appliances displayed, beginning with some three hundred at Liverpool, in 1841, increased at the rate of about one hundred on every succeeding year; until, in 1853, at Gloucester, they reached their highest point in a total of two thousand. The rise and fall of a few hundreds chiefly depends upon the impetus given in away facilities of the town where the "show" is held; and the number of implements exhibited is not so great a test of the progress of mechanical invention as of the sales which are likely to be effected in any particular district. The annual show is only one of the numerous ways which the manufacturers adopt to advertise and exhibit their ingenuity of invention, and beauty of workmanship, in producing their mechanical contrivances. The real prize to the maker is the one which brings to his establishment plenty of custom.

At the show at Bury St. Edmund's, steam-engines and barn machinery constituted the class of implements brought to the test; but one hundred acres of heavy land, and twenty acres of light land, were provided for the performances of the steam ploughs. Several new arrangements were made in the show-yard; among which we may observe that a fence encircled the horse-ring; and the horses which gained the prizes were distinguished by a set of numbers, similar to those which gave so much satisfaction at the Yorkshire show of 1806. The poultry show was revived, and £200 worth of prizes were distributed.

**DRAINAGE.**

When the Royal Society was founded there were about 400 local societies in existence; but they were associations formed rather for the encouragement of the social qualities of life, than for the promotion of the arts by the means of which the materials for eating and drinking are increased. The speeches delivered at these convivial "gatherings" were usually of a highly complimentary character; and the members congratulated each other upon the pre-eminence which distinguished their own enlightened district. They were, in short, associations apparently formed for no other purpose than that of maintaining local ignorance, rather than of obtaining additional knowledge from practical experiment and
experience. This is a lamentable truth; but we must now give our consideration to those especial improvements which have, during the career of the society, taken place in the agricultural parts of the kingdom. Amongst these, perhaps, the very first deserving of especial attention is drainage. From the earliest times attempts have been made to drain. We believe there are in existence specimens of clever workmanship in this art, upwards of a century old; but when it ought to be done, and why it ought to be done, and how it ought to be done, was never reduced to the simplicity of an intelligent practical rule. Whatever books there were upon the subject, were entirely destitute of principles. Lord Bacon, who possessed a large collection of works upon agriculture, had them, one day, piled up in his court-yard, and set on fire; for, said he, "in all these books I find no principles; they can, therefore, be of no use to any man." This we take to be one of the truer signs of his wisdom; and this was just the deficiency in all that had been done respecting drainage until, in 1814, Josiah Parkes undertook the task of explaining its principles. Two years later, he made suggestions which led to the manufacture of the steel tools which were necessary for forming the deep cuttings, as well as the cheap pipes, which were essential to carry off the water from them after they had been formed. Ten years previous to this, however, when draining a peat-bog near Bolton, in Lancashire, he made the discovery of the great effect which deep cuttings produced in relieving the soil of a certain number of inches of the water which, during a rainy season, is stagnant, and remains in that state until removed by evaporation in a dry season. Further experience brought him to the conclusion, that the shallow drainage advocated by Mr. Smith, of Deanston, about eight miles from Stirling, Scotland, was a vital error, and that four feet, which left a sufficient layer of dry, warm, surface earth, after allowing for the rise of the moisture by capillary attraction above the water-level of the drain, should be the minimum depth.

THE FIRST FIELD DRAINED.

On a farm near Bolton, Lancashire, belonging to a celebrated bone-setter, the first field was drained on the four-foot plan. From small beginnings, however, there often spring very large results. Accordingly, this was the commencement of the subterranean network of those pipes, which have more than doubled the value of our retentive soils. There was, however, still a great deal to be done. The proper tools had not yet been made, nor had a cheap conduit yet been discovered. But, in 1814, a Birmingham maker succeeded in manufacturing the cutting implements, which have gradually been brought to perfection; and, in the preceding year, at the Derby show of the Agricultural Society, a person of the name of John Reade, a gardener by trade, and a self-taught mechanic (well known as the inventor of the stomach-pump), exhibited cylindrical clay pipes, with which he had been in the habit of draining the hot-beds of his master. His method of constructing them was, to wrap a lump of clay round a mandril, and rub it smooth with a piece of flannel. Nothing could be more simple. It was seen by Mr. Parkes, who showed one of them to Earl Spencer; remarking, at the same time, "My lord, with this pipe I will drain all England." The council, on the motion of his lordship, awarded to John Reade a silver medal for his idea; and, in the following year, offered a premium for a tile-making machine. A great deal of money was wasted in attempts, and many patents were taken out for the purpose, but with indifferent success. At length, in 1815, a person of the name of Thomas Scragg, at Shrewsbury, received a prize for a machine which triumphed over the difficulties, and pipes can now be made as fast as the kilns can take them. From that hour the work proceeded at a rapid pace. In the following year, Sir Robert Peel, from the knowledge he had obtained in the management of his own property, passed an act, by which four millions sterling were appropriated towards assisting landowners with loans for draining their land, with leave to repay the advance by instalments extending over twenty-two years. Nearly the whole of this first loan was taken up by the Scotch, before Englishmen had made up their minds to take advantage of it. The four millions of government money, however, was comparatively small, when placed in juxtaposition with the sums supplied by pri-
vate enterprise, for carrying out an improvement which, on the worst class of wet land, gave evidence of its value by the realisation of immediate profits.

Besides the government encouragement given to the drainage scheme, there was another circumstance which greatly helped to promote the work. About the period when the system of deep draining was brought to perfection, the great landowners, being solicitous of encouraging their tenants, who were depressed by the approaching free trade in corn, made thorough draining the most fashionable improvement. The Norfolk sheep-folding rotation had accomplished much for light land; had brought the cultivation of roots to a high pitch, and proportionally increased the live-stock on every light-land farm. The proprietors of strong retentive soils were naturally anxious to follow in the path of their light-land neighbours, and to grow the roots which were seen to afford such high profits in beef and mutton; and deep drainage enabled them to realise these hopes and desires.

THE CHEMISTS.

Previous to the farmers, and the agriculturists generally, having become accustomed to the value of certain foreign manures which had been imported into the country, Professor Liebig suggested that the fertilising power of bone manure, which had already been used, would be increased by the application of sulphuric acid, and the consequent production of superphosphate of lime. This suggestion was not lost on some of our keen commercial speculators. Accordingly, the experiment was tried by a carboy of sulphuric acid being poured over a few bushels of ground bones, when Suffolk drills, charged with superphosphate and guano, were despatched through the farming districts of the country, to show to agriculturists, that if they desired to grow large root-crops, there was something necessary to be added to their inmemorably-established favourite manure, which they designated by the name of "muck." We are told that one of the first to experiment upon the new manure, and then to manufacture it on an extensive scale, was Mr. Lawes, of Hertfordshire, a squire and scientific chemist.

He was followed by Mr. Purser, of London; who, in 1843, began with a solitary carboy of sulphuric acid, which cost ten shillings; and frequently afterwards he purchased ten thousand carboys at a time. A few years later, Messrs. Dixon and Cardus, at Southampton, made a profitable speculation by a contract with the government of Buenos Ayres, for the exclusive right of exporting the charred flesh and ashes of joints of meat burned, for want of other fuel, on the treeless Pampas, to boil down the tallow. This animal refuse (the accumulation of a quarter of a century), when treated with sulphuric acid, is converted into valuable superphosphate. But, although every quarter of the globe, even battle-fields, were searched for bones, the supply was insufficient to meet the demand. It consequently became necessary that some new resource should be found, in order to keep down the price of those manures, become so scarce, and deemed so valuable.

PORTABLE MANURES.

Before 1835, farmers and agriculturists, in addition to farm-yard dung, or night-soil, used for manuring their lands, gypsum, chalk, lime, soot, marl, salt, saltpetre, rape-cake, and bones. The discovery of the fertilising properties of bone was made by accident, at a fox-hound kennel in Yorkshire. Generously strewed over the heaths and wolds of Lincolnshire, it proved to be the philosopher's stone, which converted rabbit-warrens and gorse fox-coverts into fields of yellow grain. A Mr. Nelson, one of the late Lord Yarborough's tenants, was wont to say, that he did not care who knew that he had made £50,000 out of his farm, by making use of bones before other people were acquainted with the manner of using them. But what proved to be a success in one parish, or field, frequently failed in the one adjoining; and sometimes the farm which had once yielded abundantly in return for a dressing of lime or gypsum, inflexibly refused to respond to a second application. More extraordinary still, the root-crop—the foundation of the famous Norfolk rotation, the Colonda of half-a-dozen counties—began to fail, devoured in infancy by the fly. This was startling enough; for, without the turnip, whence was the provender to come for sheep,
and winter-fed cattle? The philosopher, however, happily stepped in. He came to the assistance of the farmer, and, by his knowledge, relieved him from the difficulties by which he was encompassed. Nitrate of soda and guano were imported; and, as we have just shown, superphosphate of lime from bones was invented. Agricultural chemistry soon won the place of a practical or a profitable science, and the anomalies in connection with the use of lime, chalk, gypsum, &c., were explained by the joint exertions of the farmer and his new ally, the philosophical explorer and expounder of Nature's secrets—the chemist. Nitrate of soda was imported from Peru, and sold, in small quantities, by an agricultural manure-dealer, about 1835; and, in the same year, a cargo of guano was consigned to a Mr. Myers, a Liverpool merchant. The value of this manure proved immense. At first its merits were not credited by the farmers—a tardy race, and much given to incredulity in their own vocation; but the shrewd-witted dealers in artificial manures accepted the new article, and sold it, either in a pure state, or under a special name, mixed with less active ingredients. In 1843, a store, inferior to that of Peru, having been discovered on the Ichaboe Islands, off the coast of Africa, 1,100 feet long, 400 broad, and, on an average, 35 feet deep—the whole was removed before the end of 1844, and realised upwards of a million sterling. Three years before this, an article of forty-three pages, from the German of Dr. Charles Sprengel, appeared in the first volume of the Journal of the Royal Agricultural Society; in which, though every kind of animal manure was described, guano only received a passing mention as a curiosity; and no note, to supply the deficiency, was attached by the editor—so little was it then known to the most intelligent cultivators, and so rapidly had the knowledge of its value spread in the interval.

About 1851, an important addition to the portable manures was discovered by Mr. Odams, in the blood and garbage of the London slaughter-houses. This refuse had hitherto been thrown down the sewers, or upon dung-heaps; but, in 1858, it was contracted for, to the extent of upwards of nearly 500,000 gallons a year. Mixed with ground or calcined bones, and sulphuric acid, it is turned into a vigorous corn and root fertiliser, known to agriculturists as the "nitro-phosphate manure." The mere circumstances of these products becoming articles of sale, and not of home manufacture by the farmer, had the effect of greatly extending their use. The seller of artificial manures helped, in another way, the general movement, which was stimulating the whole of the agricultural mind throughout the kingdom. He made the discovery, that his fertilising stimulants were stripped of half their value when applied to wet or ill-cultivated land. "Hence," says the reviewer already quoted, "he became the eager advocate of thorough drainage, and that thorough preparation of the soil, which can only be effected by the best class of ploughs, harrows, horse-hoes, and clod-crushers. His customers would have been customers no longer, unless he could have convinced them that the fault was in themselves, and not in the goods. He argued to ears which had, at least, been opened, and prevailed without the assistance of the hedge-stake. A man grudged growing weeds on a fertile soil, for which he had paid hard cash; nor could a manure that cost £10 or £12 a ton, be refused the economy of a machine to distribute it carefully; and thus drill husbandry spread, led by pipe-drains from Norfolk, Suffolk, and Bedfordshire, into every county of England, and with it brought all the machines and implements required for a clean, rapid, concentrated cultivation."

THE GEOLOGISTS.

The chemists having performed their work, it remained for the geologists to do theirs. Accordingly, Professor Henslow, the botanist, had, in 1842, observed some nodules at Felix Stowe, on the coast of Suffolk; and, in the following year, collected a quantity of them, and forwarded them to a Mr. Potter, for analysis. The manipulation proved them to be fossils, commonly called coprolites, on the hypothesis that they consisted of the excrement of animals, and containing from 50 to 55 per cent. of phosphate of lime. From this discovery the professor might have realised a fortune; but professors of science are not proverbially shrewd in monetary affairs. The quarry of
The details of preparing seed-beds, sowing, weeding, utilising winter and spring vetches, rape, white mustard, and other crops, classed as green food for the summer and early autumn months. Neither is it necessary for us to describe his production and treatment of the various kinds of turnips, Savoys, Kohl Rabi, cabbage, and mangold-wurzel, classed as food for winter and early spring. The simple mention of this diversified list of subjects will show the wide range of agricultural produce treated of in a well-handled paper, on one single but important branch of the business of the farmer. Mr. Fowler's opening remark, however, merits attention. Very naturally alluding to the importance of maintaining the supply of animal food, he observed that the great point for consideration was, how to raise the largest quantity of vegetable produce for feeding the live stock, not upon grass farms, but upon arable or mixed farms? He believed that more stock and meat might be produced, acre for acre, on arable than on grass land; and, in discussing the subject, one gentleman observed—"He was glad to hear that Mr. Fowler thought the growth of green crops the foundation of British farming, because many of the farmers of the midland counties were disposed to place that foundation upon the plan of consuming a vast amount of corn by their cattle. This was like beginning to build a house with the chimney-pot. If, by the purchase of four shillings' worth of superphosphate of lime, Peruvian guano, or other artificial manure, they produced one ton of roots (which he held they could), and that ton was worth nine shillings by their stock, then the raising of their green crops must ever be the foundation of agricultural progress and improvement."
DIVISION IX.

IMPLEMENTS AND MACHINERY OF ENGLISH FARMING.

CHAPTER I.

AGRICULTURAL PROGRESS.

Up to a very recent period, the history of agriculture, in this country, presented a very curious anomaly; A few facts were prominently exhibited; but the gradual progress of it as an art, a manufacture, and as a branch of commerce, was entirely unnoted and unchronicled; and an industrial occupation, the capital of which, even thirty years ago, was calculated at £217,000,000, had no history, no statistics, no representative in the law or the state—no board, no minister, no department; in fact, nothing. Yet, about a century ago, this country was doing a large trade as an exporter of corn. Between the years 1773 and 1793, there was a sort of "pivot period," when the exports and imports nearly balanced each other: a slow but steady inclosure of land, at the same time, began to mark the consumption or a gradually increasing trade and population; the price of wheat averaged 45s. per quarter; and rents were from 7s. to 10s. per acre; so that the price of a bushel of wheat was, in fact, about two-thirds of the rent of an acre of land. There was no account of the progress of inclosure during the century; but a committee of the House of Commons, in 1797, computed the total quantity at about 4,000,000 acres.

In the present century, there has been a definite record kept of inclosures, of population, of corn imported, of prices, and rent of land. From 1800 to 1810, the amount inclosed was 1,657,880 acres; the population of Great Britain having increased 150,687; while the quantity of wheat imported was 6,000,408 quarters. From 1810 to 1820, 1,410,930 acres were inclosed; the population increased to the extent of 1,978,523; but the imported wheat was reduced to 4,583,780 quarters. From 1820 to 1830, 310,380 acres were inclosed, and the population increased 2,161,495. In the next decennary period, from 1830 to 1840, 236,070 acres only were added to the cultivated soil, although the population increased by 2,249,648; while the imports gradually diminished. Thus, during the forty years, rather more than 3,500,000 of acres were added to the cultivated soil, against an increase of population to the extent of 6,000,000; while the foreign supplies did not amount, on the average, to three weeks' consumption in the year, calculated over the whole period. During this time the country had passed through some remarkable phases. While a large amount of acreage had been brought into cultivation, the circulation had been restricted to a metallic currency, and wheat had fallen from 7s. 4d., at the close of the war, to 5s. 3d. And nothing but the steady increase of population, and the still more rapid increase of trade and capital, could have sustained cultivation at the point it had extended to; nor was this done without considerable reduction of rents, though to nothing like what they had been before the war. During the agitation for the repeal of the corn-laws, it was thought that the measure, if passed, would have the effect of throwing much of the land out of cultivation; but, on the contrary, Britain was beginning to present the opposite phenomenon of a population overtaking the resource of fresh inclosure, and compelled to have recourse to some other means for increasing the produce of the soil.

Just at this period, agriculture begins to...
assume a different and most important aspect, four distinct elements at once conspiring to open up new resources. These were—the introduction of the use of guano; the publication, in this country, of the works of Liebig; the establishment of the Royal Agricultural Society of England; and the introduction of a new system of drainage. The two first of these elements may almost be taken together; for, though the manure had been discovered which has since effected a marvellous revolution, the prejudice was so great against it, that, but for the authority of Liebig's name, it might not have been admitted as a manure; or, in other words, the manure having come, a man was needed to answer the challenge; and that man was found in the distinguished Professor of Giessen, whose publications, if they did not initiate, at least drew attention to the important and new-sounding fact, that, the bulk of a plant not being derived from the soil, the bulkiness of a manure had little to do with its value. Nor must we omit to mention the important point subsequently established by Mr. Lawes; namely, that "the lasting qualities of farm-yard manure are, in a commercial sense, not an advantage; for it is getting back your money by instalments, instead of getting it back all at once. A great deal of your capital is placed in the land, where it lies dormant for a long time; but science can correct that evil, by enabling you to put the right manure in the right place."

With regard to the third element, perhaps it does not merit the same value in the category of agricultural elements; for high patronage gives no lasting prosperity: and we must not forget, that if any benefit has been derived from societies, in several parts of the country, these already existed, and still exist, to extend their influence in their particular localities. If the Royal Agricultural Society has done any special good, the seeds were sown before it had been called into life; and it has only had the effect of giving a stimulus to agricultural pursuits, by summoning up a new race of potent genii, and setting them all at work for the farmer. This may be illustrated by the fact, that at the Society's first meeting at Oxford, in 1839, for the exhibition of agricultural implements, the entries were but twenty-two; while at Gloucester, in 1852, the number amounted to no less than 2,032. But this is an argument equally applicable to older organised associations, which have gone through similar changes. Drainage, the fourth element, has unquestionably been a principal cause of agricultural progress, and does not require illustration here. It may be observed, however, that there are two great heads into which agricultural improvement naturally divides itself; viz., the Chemical and the Mechanical—the former applying especially to the light soils, and the latter to the clays. It is, however, to the latter that we must chiefly look for any increase in the production, inasmuch as, on the lighter soils, the wheat crop occurs only once in the four-course system, whilst upon the clays, whether managed upon the six-course system, or upon the older three-course shift, it is grown upon a larger scale, approaching to the ratio of a third, instead of a fourth, of the arable land, and is, therefore, looked to by the farmer as furnishing the profit which, on the light soil, is drawn from the wheat and barley crop together, besides a wider range of profit derived from the sheep flock. It seems obvious that the improvement of the clay soils to their utmost extent, is the special, nay, perhaps, the only means left to us for operating in any important degree to maintain the produce of wheat proportionately with our increasing numbers. Accordingly, it is by increased mechanical means that we diminish the amount of time required for bringing the land, after the crops, into preparation for the future crops. Much has, indeed, been done by improved implements; but the application of steam culture to the soil is the greatest agricultural feat of the day. The clays are thereby enabled to hold the race more evenly with the lighter soils; for the great inherent powers of the heavy soils then come in aid to counterbalance the easier working of the lighter soils. These remarks naturally lead us to speak of the Machinery of the Farm, under which general heading, we have introduced some articles which may not properly be called machinery, but which, nevertheless, take a part in the numerous appliances of the agriculturist, farmer, or husbandman. The whole of this division we have arranged alphabetically, as it gives greater clearness and facility of reference.
ASHALTING APPARATUS.

This is an apparatus used for asphalt flooring, being well known as the best, cheapest, and most healthy flooring for barns. It renders every description of agricultural building impervious to wet, not liable to decay, and secure from the touch of vermin. The materials are cheap, and the cauldron used for it may also be used for boiling cattle-food. The price of 100-gallon size, with working-tools, is about £17.

AXLES AND WHEELS.

The naves of these wheels are of iron, cast on chills, by which the wearing parts become so hard as to resist the file; the spokes are of oak, and the ieldes of ash. They are made by machinery, which, from the accuracy this gives, renders them superior to those made by hand. They are also durable, and run easy. Mr. Crosskill is both their inventor and maker; and upwards of 90,000 of them have been sold for various purposes, and sent to every quarter of the globe. Price, per pair, £8 5s.; if with tire, 3 by ¼ inch, £7 10s.; and 2½ by ½ inch, £7. An improved set may be purchased for £10 11s. Four pairs of patent wheels and axles, fitted with naves cast on steel pins, have also been highly spoken of. The spokes are made of the best mallenable iron, one end of which is cast into the nave, the opposite end having a box screwed firmly on to receive the felloe; the end of the spoke is let up into the felloe by an auger, thereby preventing the destructive mortice holes. The tire is shrunk on hot, in the usual way. Price, No. 1, one pair 4 feet 6 inches high, 2½ inches tire, 2½ inches axle, £6 10s. per pair; No. 2, one pair 3 feet 6 inches high, 2½ inches tire, 2½ inches axle, £5 10s.; No. 3, one pair 4 feet high, 2 inches tire, 1½ inches axle; and No. 4, 1 pair 3 feet high, 2 inches tire, 1½ inches axle, £12 12s., with boxes to carry oil.

BARLEY HUMMELER.

This implement is designed to separate the horns from the barley. It is fitted with revolving cutters and wire cylinder, so that it will take off the horns, and, at the same time, separate them from the barley, at the rate of about two bushels per minute. Its price is about £3 12s. One of these machines, invented by Mr. Holben, of Barton, Cambridge-shire, consists of an elevating apparatus, which supplies the corn direct from the dressing-machine, and a breaker, making nearly 300 strokes per minute, under which the barley passes in a thin layer, at the rate of from ten to twelve quarters per hour. Whilst this process is going on, it, at the same time, brightens and improves the samples, which are delivered perfectly free from awns. It is easily worked by a lad; whereas all other machines for the purpose require two men. The price is £5 10s.

BREAKING MACHINES

Are now very much in use. One, invented by Mr. Nicholson, of Newark, Norich, has received high commendation, and was, at Chester, awarded the prize for being the best for common cake. It is made with Nicholson’s patent method of driving the movable roller with an internal cog-wheel; thus obtaining an unusually great variation in size, broken in a simple and effective manner, and greatly diminishing the friction and power required to work it. Its strength and simplicity are further increased by a new and effective setting arrangement. The price is £3 13s. 6d. Another, manufactured by Messrs Aines and Barford, received the first prize at the North Lincolnshire shows, open to all England, both in 1860 and 1861, in competition with all the prize machines by the best makers: it is immensely strong, and adapted for either hand, horse, or steam power. This machine is fitted with two sets of rollers, both of which are adjusted by a double eccentric movement. It will reduce the hardest and largest cakes into seven sizes, varying from the largest size required for bullocks, down to dust for drilling. Price, including dust-screen and wood box, £6 10s.; pulley for power, 12s. 6d. extra.

Other oil-cake breakers have obtained considerable celebrity; and among these are those manufactured by Messrs. Ransome and Sons, of Ipswich, Suffolk. They have one both powerful and effective. It is fitted with a pair of toothed rollers, for breaking the hardest cake; and, by means of a parallel adjustment, the distance between the rollers may be varied so as to reduce coarse or fine at pleasure. It is fitted with another roller and face-plate, through which the broken cake may be made
to pass when required to be reduced to powder for manure. The price of this machine is £12 5s. 6d.—Another, by the same makers, and called a Combined Mill and Oil-cake Breaker, consists of a bean-cutter, an oat-mill, and an oil-cake breaker; all combined on a neat iron stand. This is a cheap, durable, and efficient mill, for cutting oats and beans, and breaking oil-cake for beasts and sheep. Its price is £9 9s.; pulley for steam-power, extra.

CARTS AND WAGGONS.

Carts and waggons of every description, and for every conceivable purpose to facilitate farming operations, have been invented and improved. The Newcastle prize or model one-horse cart, invented by W. Crosskill, has had awarded, by the Royal Agricultural Society of England, the Silver Medal, at Lincoln, and the first prize of £3, at Newcastle. It is plain and durable; useful for general purposes; and, we are informed, that upwards of 6,500 have been sold. It has loose side and end-boards; a simple tiper for delivering manure, &c., in heaps, and patent wheels. Its price is £14 5s.; or, with harvest shelving, £15 10s.—A light spring cart, by the same maker, has had awarded to it the prize of £2 for a cheap market cart, by the Royal Agricultural Society of England, at Leeds; also, the first prize by the Highland and Agricultural Society of Scotland. It has patent wheels, 4 ft. 6 in. high, 1½ in. convex tire, to carry 15 cwt., and is well adapted for a nag-horse to convey luggage, &c. Price, £12 15s.—A harvest cart, invented by J. Hannam, Esq., of Burcott Park, is a very good one. It possesses a light and low body (expressly adapted for carrying hay, corn, &c.), and patent wheels, 4 ft. 6 in. high, with convex tire—which does not injure grass land like the flat tire with sharp edges—¾ in. wide. Its price is £14; or, with front and hind ladders or raves, £15 10s. This, also, has had a prize awarded it. An improved one-horse cart, with harvest frame, is a capital implement for farm work; and there is a very good one, made by Woods and Cockedge, Stowmarket, Suffolk. It has been awarded a first prize by the Royal Agricultural Society of England; and is made of the best seasoned timber; fitted with an improved self-acting tipping apparatus, with side boards, scrap-iron arms, fagoted, steelcd, and turned up, boxed and capped, with the improved fall linch-pin, rendering accident impossible; 11-spoke patent boxed iron nave wheels; nave of the best seasoned English timber; tire of wheels, 1 in. wide, and ½ in. thick. Price, complete, £15 10s.; without the harvest frame, £13 10s.—Mr. Thompson, of Lewes, Sussex, sells a combined one-horse cart, water-cart, and irrigator; invented, improved, and manufactured by him. This implement obtained the first prize—a gold medal—and 250 frames in Paris, in 1856, and is a complete one-horse cart, which, by a very simple and effective contrivance, can instantly be converted into a water-cart, and with an irrigating apparatus for water or liquid manure; its slight additional cost, beyond that of an ordinary cart, has commanded an extensive sale. Price, £18.—The improved harvest cart, by Messrs. Haynes and Sons, Stamford, Lincolnshire, has a great advantage over all other carts, being low to the ground, very roomy, mounted upon wheels with 3½-inch hoop tires, and Scotch iron axle-tree, so arranged that the wheels and axle can be removed in a few minutes, when not required for harvest, and put under a manure Scotch cart body, as preceding ones. Its price is £13 16s.—A pair-horse waggons, invented by W. Crosskill, has had awarded, by the Royal Agricultural Society of England, the first prize of £10 at Norwich, £10 at Exeter, £5 at Lewes, £10 at Gloucester, and £3 at Leeds. This implement has patent wheels, 3 ft. 4 in. and 4 ft. 9 in. high, 2½ by 1 in. tire; is light, will carry 3 tons, and turn in a short space. Price, with pole or single shafts, £20 10s., and with double break, £32 10s.; harvest ladders, £1 10s. extra.—The Yorkshire waggons has had awarded the first prize of £7 by the Royal Agricultural Society of England. It is constructed with oak soles, and stout red deal or plank sides. Has patent wheels, 3 ft. 9 in. and 4 ft. 9 in. high, 3 by 2 ¾ in. tire, to carry 3 tons. Price, with pole or single shafts, £30 10s.; and with deep side and end-boards, to put on for carrying bones, soot, &c., £32 10s.; drag-chain and shoe, £1 extra.—A light waggons, improved by Crosskill, has its framework of the body constructed of oak, and lined with red deal. It has patent wheels, 3 ft. and 4 ft. high, 2½ by 1 in. tire.
CHAFF-CUTTERS.]

IMPLEMENTS AND MACHINERY [CHAFF-CUTTERS.

will carry 30 cwt., and turn in a short space. This is a neat and useful vehicle, suitable for one horse, or a pair of ponies. Price, £21 with single shafts.

A two or three-horse waggon, invented and manufactured by Messrs. Hayes, is excellent for quick delivery of corn, flour, or any other produce. It is mounted upon springs and patent axles, of the best manufacture, and will carry 60 cwt. It is fitted with pole, or two pairs of shafts, so arranged that either pair will work with a single horse. It has a seat in front, whereby the horses can be driven at a fast rate. The body is so constructed, with a circular front, made of iron, that it will turn in twenty feet of ground; the front wheels, 4 ft. 4 in. high; and body no higher from the ground than ordinary waggons without springs: a great advantage in loading and unloading, and easy draught. This waggon has obtained several first-class prizes. Price, £12 10s. — The same makers produce a light one-horse spring waggon or van, mounted upon patented axles, and fitted with four side and three cross springs, of the best manufacture. The front wheels lock under; body wide and square, up-fitted with floating raves, and strengthened with angle iron plates, for top loading. The framing of the body is made of the best English oak. In every respect, it is complete for railway carriers, merchants, and manufacturers; and very suitable for town or country. — Its price is £35. It would be almost endless to describe all the excellent carts and waggons in use. They are, as we have said before, of every kind; and almost every maker has his patented article.

CHAFF-CUTTERS.

Chaff-cutters are, like carts, very numerous, many of them exhibiting very slight differences in their construction. One is especially arranged for small occupations, fitted with toothed rollers, and having all the working parts securely protected. Its price is £2 10s. — Another is constructed entirely of iron, having the improved form of toothed rollers, rising mouth, and adjustments similar to the larger machines. Its price is £3 15s. — Another is constructed to work by a simple arrangement of wheels, instead of worm; fitted with an improved form of toothed roller, rising mouth, patent steel mouth-piece, and arranged to vary the length of cut without change wheels. This is well adapted for export, packing in a small compass. Price, £5 10s. — Another has a stop-motion, and a patent steel mouth-piece, which is never worn hollow or uneven by the friction of the passing knives. Price, £7. — Another, of greater power and capacity, is adapted for steam or horse-power; fitted with the patent steel mouth and other improvements, the rising mouth adjusting itself to all and every variation or irregularity in feeding. Price, £10. — Another is constructed on entirely new principles, having two pairs of feed-rollers acting independently of each other, with the steel mouth-piece and stop motion. The accuracy of the fitting, and the solidity of construction, recommend this implement for steam-power. — Besides these, Mr. Samuelson, of Banbury, has invented a chaff-cutter on an iron frame, and adapted for hand or machine power. The feed-rollers are self-adjusting, to suit the thickness of straw or hay, so as to keep it at a uniform pressure. It is fitted with stop motion, enabling the man feeding to throw it out of gear without stopping the driving power. It has two knives, and the size of mouth is 11 in. by 3½ in.; intended to cut ¾-inch chaff, but wheels for other lengths are supplied at 5s. per length extra. Price (carriage-paid to any principal railway station in England, Scotland, and to Dublin, Cork, or Waterford), with pulley, £10 15s.; without pulley, £10. — Messrs. Ransome, of Ipswich, produce chaff-cutters adapted for large occupations, railway carriers, job-masters, &c. These may be used by steam or water-power; cuts ⅛th, ⅓, and ⅝-inch lengths, and more, if so ordered. They are fitted with rising and falling rollers, adapting themselves to the thickness of the feed; have three knives, and will cut from 30 to 35 cwt. of ¾-inch chaff per hour. The cog-wheels are all covered over, and fitted with striking-out gear. The box can be removed when not at work. Price, £24; pulleys for steam-power, extra. — Another, by the same makers, can be worked by one or two men, horse or steam-power. It cuts different lengths of chaff; viz., ⅛ and ⅝ inch, or a greater variety, if ordered. It has rising rollers and patent striking-out gear, and is well adapted for general use. Can be fitted with two or
CHURNS.

OF ENGLISH FARMING.

[CLOD-CRUSHERS.]

three knives, as ordered. Price: for one man, £10 10s.; for two men, £11; for horse-power only, £10 10s.; steam-power only, £11 11s. — The prize chalk-cutting engine, for steam-power, was invented by the late Hugh Carson, of Warminster, and improved and manufactured by the Messrs. Ransome. It was awarded the only prize at the Canterbury meeting of the Royal Agricultural Society, and at the Cardiff meeting of the Bath and West of England Society. The mouth of this machine is 10½ inches wide, and it will rise to 5 inches deep. It has two pairs of feed-rollers, rising month, and roller, and will cut three lengths of chalk. The feed can be stopped or reversed instantly at the will of the feeder, or in case of accident. It has three convex knives; and its price is £13 13s.; pulley for power and change-wheels extra.

CHURNS.

Although these implements can hardly be said to belong to the machinery of the farm, properly speaking, still they are very necessary in the manipulations carried on in one department of it. Accordingly we will describe a few of them that have obtained some degree of celebrity. The improved barrel-churn consists of a sort of barrel, made of the best oak wood, hung on a frame, so as to revolve without much friction; the cream is put inside, and the whole turned round by means of the handles; in this manner the cream is thoroughly shaken, with the least possible expenditure of power. It is adapted for from 2 to 40 lbs. of butter. Price, £1. — The patent Sussex churn, invented by Green and Hale, of Brighton, improved by R. Green, of London, and manufactured by Perkins and Son, of London, is made of block tin, with trough for placing hot or cold water, to obtain, at any season of the year, the proper temperature: to make 7 lbs. of butter. Price £1 5s. — The patent American churn, invented by C. I. Anthony, of America, has received prizes at all the meetings of the Royal Agricultural Society since its introduction, including that given at the Great Exhibition of 1851. It is simple in construction, easily cleaned, and the operation of making butter is usually performed in ten minutes. The principle is, that by means of coils in the dasher, the air is forced through the cream, thereby causing a greater separation of particles to take place, and also a larger quantity of butter to be made. The price, to make 3 lbs. of butter, is £1 10s.

CLOD-CRUSHERS.

The clod-crusher, invented by William Crosskill, of Beverley, is an improvement upon the well-known roller to which the gold medal of the Society was awarded, in 1846; and it received the first prize at the competitive trial of clod-crushers at Warwick. The roller-discs are made of different diameters, in order that they may be cleaned by the irregular motion produced; and they are kept in an upright position by a novel arrangement of the bosses or centres. The 6 ft. size is most generally used. Its price is £16 10s.; travelling-wheels, £2 extra. — There is a cast-iron press-wheel clod-crusher or land-roller, invented, improved, and manufactured by Messrs. Amies and Benford, Peterborough, Northamptonshire, with cylinders or rings 30 inches diameter, on Cambridge's principle; but the frame is made wholly of wrought iron, and has a steering wheel and guide-rod, instead of the ordinary wood shafts. By this arrangement the undue strain upon the shaft horse is avoided, and a saving of at least one-third in power is effected; the greatest possible strength is also secured. It is provided with a seat for the driver, which enables him to dispense with the services of a boy, as, with the assistance of reins, he has perfect control over both horses and implement. The price, fitted with patent scrapers, is £19. — Messrs. Wedlake and Dundy, Hornchurch, Essex, have registered an economic clod-crusher and pulveriser. The great defect of all rollers and revolving clod-crushers is, that when the soil is partially pulverised, they have a tendency, instead of crushing the remaining clods, to press them into the loose soil beneath, so that the process of harrowing and rolling must frequently be repeated, and the land thus often rendered hard and solid, without effecting the desired pulverisation. This defect is said to be both easily and quickly remedied by the economic pulveriser, which rubs the clods into a line mould, at the same time levelling the surface of the land, and leaving it light, friable, and in a greatly improved condition. Price £5 15s.
CORN-SCREENS.

The corn-screen, or smut machine, has a diameter of 14 inches, and consists of iron conical-fluted scrubbers, interspersed with covered fans at suitable distances. Immediately the grain leaves the machine an exhaust-blast is applied, which draws chaff and light seed up from the good grain. Price, £3.—Another implement of this kind, invented, improved, and manufactured by William Ball, of Bothwell, had awarded a silver medal by the Royal Agricultural Society of England, at Chelmsford, and the first prize at the trial of corn-screens by the Royal Agricultural Society, at Chester. This machine effectually separates all the thin kernel from either wheat, barley, or sainfoin, and gives an equal and weighty sample by means of a patent screen that clears itself at every oscillation. It will screen about sixty bushels per hour. Price, £16.

A new implement of this description, invented by Mr. Baly, of Bury St. Edmund’s, has two screens, worked from one spindle. The advantage of this is, that the same had employed to turn a No. 1 screen, can work this, as it requires no more power, one screen acting as a counterbalance to the other; and, compared with a No. 1 screen, just double the work can be done. It will screen, in fact, 180 bushels per hour. Price, £7.

CHEESE-PRESSES.

A single cheese-press, with wooden stool and double lever and pulley, invented by the late Hugh Carson, of Warminster, has been, and is now, improved and manufactured by Messrs. Wedlake and Dendy. It has a compound lever, and a pulley at the end of the second lever, over which a chain passes, secured at one end to the press, and, at the other, the weights are suspended; the effective weight is thereby doubled, and great pressure obtained for large cheeses. There are four weights, which can be used as occasion requires, depending on the state of the cheeses. The price of this implement is £2 15s.—Another, by the same makers, has received prizes from the Royal Agricultural Society of England, at Chester, and a silver medal at Salisbury; from the Bath and West of England Society, at Newton Abbott; and at Cardiff. It is similar in principle to the other, but has an iron stool, eighteen inches in diameter, with a channel for carrying off the whey which runs from the cheeses. Price, £3.—A cheaper press is made by Messrs. Wightman and Dening, Chard, Somerset. It has been improved by a roller being placed on each side of the follower, to facilitate its working against the uppers, or guides, thereby preventing friction. It occupies but small space, and the pressure can be regulated from 1 to 16 cwt., by means of a weight shifting on a lever. Its price is £2 10s.

CORN-DRYING MACHINE.

A patent corn-drying apparatus, invented and improved by Don and Co., of London, and manufactured by Smith and Co., of Leeds, is, perhaps, rather expensive for most farms. It is made for drying all kinds of grain, seeds, or berries; is heated by steam, and fitted with apparatus to exhaust the steam as it is given off from the grain. It is well adapted for the drying of Egyptian and Black Sea wheat, or other grain which has been washed, for the purpose of freeing it from clods of earth or other impurities, and for mollifying the grain which has been injured by salt water, or found too dry for grinding purposes. Complete, and fixed in London, its price is £150.

CULTIVATORS.

Messrs. Robinson and Son, of Burton-upon-Humber, Lincolnshire, have invented a drag-harrow, or cultivator, suitable for working fallows. It is made almost exclusively of wrought iron; the teeth can be moved either horizontally or vertically, so as to suit the number of teeth to the state of the land. The principal improvement consists in one lever in the middle, raising and lowering the whole of the harrow, without the aid of side levers, as in other cultivators. They are made of various widths, to suit different occupations; and the price is £10 10s.

A chain harrow, invented by Cartwright, of Shrewsbury, consists in the absence of any rigid links in the body of the harrow, which, in some states of the soil, have a tendency to clog; the links are expanded by improved bars, which only touch the extremities of the harrow, leaving all the links free. The size 9 feet wide by
DIBBLING MACHINES.

7 feet 6 inches, and very strong, is charged £9 10s. Messrs. Smith and Taylor, of Ipswich, have a patent cultivator, or brood-harrow, adapted for all the purposes of a broadcast, scurrier, or drill-barrow, fitted with five wrought iron tines, arranged so that either shares or points may be used, which can be raised out of the ground backwards. It is similar to a drag-rake, and is self-relieving, when chocked with weeds, stubble, &c., or when turning at the ends of the land. Fitted with side levers, to regulate the depth of work, it is charged £9 10s.

Mr. Charles Clay's cultivator and eradicator is a very good implement, applicable to all cultivating purposes, such as broadsaring, cultivating, and grubbing. The tines are fixed to revolving bars by keys, in a very simple manner, and are raised out of the soil backwards, similar to a horse-rake. Prizes have been awarded by the Royal Society, at Warwick, and by the Council of the Paris Exhibition, as well as by numerous local societies, to this cultivator, and it is now well known as a first-class implement. It is worked by two horses, with five tines. Price, £7. — This maker has also a new implement adapted to steam-power. It runs on one pair of wheels, five feet in diameter; requires one-half the usual power, and does not require to be turned at the ends. The tines are mounted upon revolving bars or axles; and, by reversing the engine, the tines place themselves in and out of work without any attention from the man, who sits at one end of the implement, and steers by a lever attached to the large pair of wheels, which are in the middle of the frame. Its price is £10.

DIBBLING MACHINE.

A new patent grain and seed-dibbling or planting machine, with six planting wheels, invented and manufactured by Mr. Freer, of Rothley, Leicestershire, is an expensive implement, but of excellent construction. It deposits its seeds by hollow iron wheels, which, when drawn over the ploughed soil, press holes, concentrating the ploughed soil, and reuniting it with the subsoil, by which means the roots of the plants are conducted deep into the earth. Another advantage of concentrating the soil beneath the roots is, that the surrounding loose soil, as it falls by the weather, breaks from the stems, allowing them to expand, and making the crop less liable to be brought down by storms. The machine is capable of depositing from one peck to four bushels per acre; but not more than half the seed must by the drill be required to produce an average of five bushels per acre more than with the drill. It is also durable, and warranted to work efficiently. Its price is £60.

DRESSING MACHINES.

Of these machines there are several good makers, each of whom has his own improvement to recommend. Mr. Crosskill's has five riddles, and two screens for wheat, beans, &c., and can be used as a blower by removing the riddles. It is very simple and effective, and an immense number are now in use. Price, £5 10s. Messers. Hobbes and Sons have manufactured 3,000 of these machines, which are very efficient and simple. They turn easy for the man; will dress a large quantity, making a good sample; are very strong, and fitted up with great care. Price, £9 9s.; carriage wheels, 7s. 6d. extra. — The same makers have another, which is very useful for small occupations, and is much approved. It is made on the same principle as the preceding, but smaller, with riddles of 18 by 10; and the price makes it a favourite in small occupations. It is £5 10s. — A 20-in. riddle corn-dressing machine, for all kinds of grain, is made by Messrs. Stacey and Sons. With improved wind-board it is convertible, with ease, into a powerful blower or rectifier; being simple, and its performance equal to the more complicated arrangements. Fitted with six corn-sieves, its price is £10 10s. — Another, to which upwards of forty prizes have been awarded during the last twelve years, including the first prize at the Highland and Agricultural Society's shows, held at Glasgow, Edinburgh, and Dumfries; and first and second prizes at Perth. These machines effectually separate the grain from all impurities; are easily driven, and deliver the grain at the side. They are made by Richardson, of Carlisle, in Cumberland. Price, £9 10s. — Another, for hulling clover and trefoil seed, and made by the Rev. R. Hunt, of Earl's Colne, Essex, received the prize at the Bath and West of England show, and the silver medal at Carlisle.
It is for separating the husk or hull from the seed, which it does in a most expeditious manner, and without injury to it; a dressing apparatus is attached for separating chaff, seed, and hard cob, mounted on four wheels for travelling. Its price is £46.

DRILLS.

These implements are made by numerous manufacturers, but are all very similar in their construction. What is called the Improved Sulfolk Lever Corn Drill, made by Messrs. Garrett and Son, obtained the prize of £10 at Norwich. It is adapted for drilling in rows, at any distance apart, wheat, barley, beans, peas, and other grain; also turnips, mangel-wurzel, and other seeds, on every description of land, and will deposit quite evenly on steep or side hills. The price of the 13-row drill, with good levers, is £26 15s.—Messrs. Holmes and Son have a seed and manure drill, on the flat ridge. This machine received the highest prize of the Royal Society of Leeds, and has rollers working between the manure and seeds, which effectually cover the manure, and leave the ridges in their proper form. The seed is also covered up by a light roller following, when worked as a ridge drill. Price, £25. —Messrs. Tasker and Sons have invented a broad-cast corn-sowing machine, which delivers the corn by cups from the box on to a wire screen, which distributes it regularly; the quantity is regulated by different-sized cog-wheels. Three screens are sent with each machine, to be used according to the description of corn to be sown. One horse can draw it, and twenty acres a-day can be gone over. Price, £16 10s.—They have also invented a corn drill for eleven rows. This implement will drill every description of grain in rows at any distance apart, from six inches and upwards, and is seventy inches wide between the carriage-wheels. The quantities sown are regulated by different-sized cog-wheels, and the supply of corn from the box to the barrel by movable slides. The price, fitted with improved steerage, is £27 10s.; without steerage, £23.—Another machine of theirs, the nine-row corn and seed drill, is suitable for small occupations. It will drive all kinds of grain and turnip seed, the quantities being varied by different-sized cog-wheels. The distance between the rows may be increased to suit the various crops. The whole of the different parts are arranged as simply as possible. Price, £21; mangel-barrel, £1 10s. extra.—They have, besides, a drill for sowing turnips and mangel-wurzel seed with manure. The quantity of manure drilled can be regulated by a slide moved by racks and pinions, and can be adjusted, at pleasure, by the man in attendance. It is 8½ inches between the carriage-wheels. Price, £24 10s.; steerage, £4 10s. extra.

ELEVATORS.

A portable straw elevator was invented by James Hayes, of Elton, and improved and manufactured by Messrs. Clayton and Shuttleworth. It is adapted for taking the straw from the end of shakers, when worked in conjunction with a portable thrashing machine, to the height of 20 feet, or more; absorbs very little power; will deliver the straw, in any direction, from a straight line to right angles, and is calculated to save the labour of three men. The price is £59.—The same firm has another implement, invented by S. W. Campain, of Deeping St. Nicholas, and improved by them. It is adapted for conveying the straw, by means of an endless wire rope, to any distance, height, or angle. The apparatus is simple, and not liable to get out of order. Price, complete, including carriage for traveling, £15.—Another implement, of a similar description, was invented by James Hayes, of Elton. It is worked in conjunction with the portable thrashing machine, and will deliver the straw 20 feet from the machine, on to a stack at any angle, which saves, also, the labour of three men. Price, £59.

FARM RAILWAYS.

Specimens of improved portable farm railways, invented by William Crosskill, have appeared at various exhibitions. The rails are constructed to carry loads of 15 cwt., and are made of wood edged with iron where the wheels run, and framed together in lengths of 15 feet. These lengths are connected by an improved fastening-piece, easily adjusted, and not liable to get out of order. Price, 4s. per running yard. There is an additional charge for points, switches, &c. Trucks are cou-
OF ENGLISH FARMING.

Grubbers, scarifiers, scullers, &c., perform a very important function in agriculture, diminishing the amount of labour, and reducing the expense of tillage. It has been calculated that, by the use of these machines, the number of ploughings is brought down to one-half, and the work more effectually done. Messrs. Bentall have long been known for their broad-share: it has three or more points, the centre one projecting, and may be used as a broad-share with several tines, to a breadth of 6ft. 6in., or, with the centre point alone, as a subsoil plough. This implement is especially adapted for heavy soil. Messrs. Bentall have also cultivators for light land.—Messrs. Clay's implement, of this class, is strong, the tines being raised backward, as in a horse-rake, and the width of the cup can be varied during the working.—Tennant's self-cleaning grubber cleans and pulverises the soil, and is made so as to take to pieces easily, and be packed into a small compass.

HARROWS.

Amongst the makers of harrows, Messrs. Howard, of Bedford, take a high place. Their set of patent four-beam iron harrows are recommended as useful three-horse harrows, having a width of 10 feet. Price, £4. Their patent jointed iron harrows are of similar construction to these, but with six rows of teeth, and furnished with joints in the centre of each harrow, which allow them to adapt themselves to the form of the ridges, or any unevenness of the surface. By a simple arrangement these joints may be easily locked, or allowed as much play as required: this is a valuable improvement. It is found desirable, in very rough work, to fasten the joints. Width, 9½ ft. Price, £1 6s. Their patent jointed iron harrows gained the first prize, as the best light harrows, at the Gloucester, Lewes, Chelmsford, and Warwick meetings of the Royal Agricultural Society of England. The teeth are arranged so as to leave a fine surface, and they are adapted for a pair of horses. Width, 8½ ft. Price, £3 12s. Their patent two-beam
IMPLEMENTS AND MACHINERY

Iron harrows are adapted for land ploughed in small stitches of eight, ten, or twelve furrows. These harrows having but two beams, they adapt themselves to the shape of the ridge, and fall into the furrows better than wider harrows. The couplings are made with an improved joint, which preserves the relative distance of the harrows. Width, 9 ft. Price, £1 4s.—Mr. Cambridge, of Bristol, has a patent-jointed self-expanding chain harrow, invented and improved by him. This harrow is so made as to yield to the land, however uneven it may be. The links are made to work between each other, producing double effect. It is fitted with a tubular iron whippetree, which is not so heavy as wood; yet stronger, and more durable. The links are made of round iron, which work cleaner and lighter in draught, but producing more effect. It is so constructed, that two most perfect harrows are combined in one, as the front part can easily be removed, and the two other parts attached to the whippetree. It is 3 ft. 6 in. wide, and 7 ft. 6 in. long. Its price is £6. He has also a set of three four-beam patent tine harrows, invented and improved by himself. They are made with thin cutting tines, which are more effectual than any other. The beams are of double-flanged or ribbed iron, put on edge, which makes the strongest beam that can be used for harrows. The tines are fitted in the flanges of the beams, and secured by bolts and pins, and there is no possibility of their getting loose. Each tooth cuts a separate track, at equal distances. The price of the set is £1 10s. A set of light patent solid frame harrows, with adjustable teeth, have been invented and improved by Messrs. Ransome and Sons. They are of entirely novel, yet simple construction. The teeth are of equal size throughout, not being shanked as usually is the case, and therefore very strong. They can be shifted when the points are worn, so as to make the teeth as long as when new. Any tooth can be taken out in an instant, and replaced with the least trouble. The framework is quite independent of the teeth, and is not taken to pieces when packed. It covers nine feet, and the price is £5.—A set of patent double-action steam harrows are invented and manufactured by the Messrs. Howard. They are made to work either backwards or forwards, like the steam cultivator, the attendant steering them in the same manner. They are most useful implements after the land has been broken up by the steam cultivator; and fifteen to twenty acres a day may be done with them much more effectually than by horse-power. Price, £12.—The improved Norwegian harrow, by the same makers, is adapted for steam-power, and worked backwards and forwards in the same manner as the last implement. Price, £18.

HAY MACHINES.

A great saving of labour results from the use of these machines, and the work is more quickly done; the great point to be attained in the construction being, that the work shall be done without clogging. All the working parts of the machine must, therefore, be so arranged as to prevent any grass or dirt from interfering with the mechanism. The patent haymaking machine, invented and manufactured by Messrs. Howard, was first exhibited at the Leeds meeting of the Royal Agricultural Society of England, in 1861, when it gained the first prize. The fork barrels are so arranged as to render clogging almost impossible. The forks themselves are mounted on short heads, in sets of three, and placed in zigzag position, which more perfectly separates and distributes the crop. The gear-work is strong and simple; the sliding pinions used in other double-action machines for reversing the motion being dispensed with. A simple eccentric moves the pinions in and out of gear instantly. A similar movement is also used for raising and lowering the barrels. Its price is £15; if fitted with patent roller—to prevent the grass lodging on the front—15s. extra. Their patent haymaking machine is similar to the preceding, but with double shafts, for two horses abreast. Price, £17; if fitted with patent roller—to prevent the grass lodging in the front—15s. extra.—Messrs. Ashley and Co., of Stamford, have a patent haymaking machine, to which, for ten years in succession, all the prizes of the Royal Societies of England, Scotland, and Ireland, were awarded, as well as the prizes of all the principal provincial societies; also seventeen additional prizes since the expiration of the ten years; seven
prizes having been taken in 1861, including the
first prize of one hundred guilders, at the
great trial of haymakers, at Haarlem, in Holl-
and. The first prize gold medal and 200 francs
were also awarded to it at the great meeting
in Paris, 1860. It still continues to maintain
its well-earned reputation; 500 having been
sent out during the last two years without a
single failure. The price of this excellent
machine is £15 15s.; if with wire guard, to
keep the hay off the horse in windy weather,
15s. extra.—The same makers have another
similar machine; but it has attached to it
double-edged steel blades, for cutting down
young thistles.—They have also patented a
method of attaching forks to the same for
breaking and distributing manure on grass
land. Price, £15 15s.; if with eight thistle
knives, 32s. extra; forks, 40s. extra; forks and
knives, £3 3s. the set complete.—Another, in
many respects similar to the preceding, but
simplified in its construction, with external
instead of internal shifting gear, and the fork
bearers revolving on a solid main axle, is made
by them. It is remarkably easy to take apart
for cleaning or repairs, by an ordinary smith;
and the apparatus for reversing the action and
throwing out of gear is operated upon by means
of a lever at the near side, so that the man
has entire control of his machine without leav-
ing his horse. He can also raise or lower the
machine while going along by the side of his
horse. Price, extra strong, £16 16s.

HORSE-HOES.

In the manufacture of hoes, Messrs. Gar-
rett and Sons have been very successful.
Their patent lever horse-hoe has successfully
carried off fourteen prizes—£65 in specie—
and five medals. It will hoe effectually all
drilled crops of grain or roots, and on every
description of soil. A man and a boy will do
from ten to fifteen acres per day, at a cost of
6d. per acre. Fitted with the new patented
arrangement for regulating the position of the
hoe blades, its price is £19. Messrs. Carson
and Toome have a wrought iron horse-hoe, for
hill sides, with hoes, and five times; invented
by the late Hugh Carson, of Warmington. It
received a prize from the Bath and West of
England Society at Cardiff, and was highly
commended by the Royal Improvement Society
of Ireland, at Londonderry. It has a new
steering apparatus, under the immediate cen-
tral of the man attending it, which turns the
wheel, and, at the same time, alters the line of
draught in the contrary direction. It thus
secures straight work on the hill side. Price,
£14.—Messrs. Priest and Woodnough have a
patent horse-hoe for roots, invented by them-
selves. It was awarded a prize at the meeting
of the Royal Agricultural Society of England,
at Salisbury, and first prize at that society's
meeting at Leeds. It is adapted for hoeing
between the rows of all drilled crops. The
hoe is made the same width as the drills it is
to follow, and hoes at once as many rows as
drilled. Each hoe works on a separate lever, which is pressed into the ground
by weight like a drill, so that all the ground
between the plants is cut, however uneven it
may be. The exhibitor's patent improve-
ments are indispensable to the effective work-
ing of the implements. Price, £19.—They
have another machine for corn and roots, to
which was awarded a prize by the Royal
Agricultural Society of England, at Salisbury,
and first prize at Leeds. It is of similar con-
struction to the preceding, but set for hoeing
wheat. The patent improvements allow the
attendant to adapt the hoe to lands or ridges,
or side hills, as well as to regulate the depth
of the hoeing while it is in motion. Price,
£22.—Another implement for small occupa-
tions, for turnips, &c., is similar in principle
to the preceding, but reduced in size, and num-
ber of levers and hoes, to adapt it to farms of
moderate extent. It is fitted with an arrange-
ment whereby the man steering, by depressing
the steerage handles, takes the hoes out of work.
Price, £12 12s.—Another, for small occupa-
tions and general purposes, is also similar in principle
to the preceding, but fitted with sufficient
levers and hoes for two hoes to work between
the different rows of plants. These horse-
hoes are well adapted to follow small occu-
pation drills. Price, £14 11s.

A patent turnip-thinner and horse-hoe com-
bined, invented, improved, and manufactured
by John Eaton, had a prize of £5 awarded to
it at Leeds. It is especially adapted to thin
or bunch-out turnips or wuzels, on the ridge
or flat, preparatory to singling by hand;
leaving the bunches at nine, twelve, or fifteen
inches apart, and hoeing all the ground between the rows at the same operation. —
Another, of a similar description, is made by the same manufacturer. A man and cob horse, with these implements, will bunch-out and hoe from three to four acres per day, requiring only children, or inexperienced persons, to follow after the cut plants are withered, leaving the best and single plant — thus expeditiously often saving the whole crop. — Another implement enables the operator to miss the plants in thin places, by simply raising the handles, and thus avoid cutting-up one plant that ought to be left growing, the flat hoes remaining in work as before. These implements can be used as ordinary horse-hoes, by simply taking off the revolving frame. — Another implement can regulate the size of the bunches left, according to the state of the soil or superabundance of the plants growing, by putting on longer or shorter revolving hoes. Extra hoes for the purpose at 5s. per set. The price of each of these machines is £6 6s.

HORSE-RAKES.

These implements very materially diminish the labour, and, in consequence, are very extensively adopted. In most of them, the times are made to act separately, so as to yield to any inequality of surface. The leverage has been lately much improved, the action being very light. The Messrs. Howard have patented a horse-rake, which has carried all the first prizes, for some years past, awarded by the Royal Agricultural Society of England for this implement. It is used for collecting hay, corn, stubbles, twitch grass, and leaves; for dragging meadows after a flood, raking in clover and grass seeds, and as a weed extirpator on corn crops in the spring. A guide is fixed to all the rakes, to prevent the lever from being strained by careless usage; the end of the guide forms loops, through which a pair of reins can be passed. Extreme width, 7½ feet. Price, £8 5s.; if fitted with twenty-eight steel teeth, £8 12s. 6d. — Another, invented and manufactured by the same makers, gained the first, and only prize, as the best horse-rake at the Leeds meeting of the Royal Agricultural Society of England, in 1861. The teeth of the rakes are formed so as to collect no rubbish with the corn, and, by a new arrangement, are allowed greater freedom to adapt themselves to the irregularities of the surface. The raising bar is placed above the heads of the teeth; so that when the lever is put into action, the raising bar, pressing upon the heads, brings the teeth out of work. Price, £8 15s.; if fitted with thirty-two steel teeth, £9 2s. 6d.

— Another, with movable shafts and wheels, is on the same principle as the former, but made so that the shafts can readily be moved to the end of the rake, by which means the implement can be drawn endwise through any gateway, or along very narrow roads. It is well adapted for Wales, and other mountainous districts, where the roads are too narrow for the ordinary horse-rake. Price, £9 10s.—Messrs. Smith and Brothers, of Thrapston, Northamptonshire, have a steel-toothed horse-rake, which took a prize at the Royal Society's Show, at Salisbury; also a special prize at the Manchester and Liverpool Agricultural Show, at Wigan. The beams are made of tubular iron; the teeth of spring steel; which makes it light, strong, and durable. It has a lever behind to raise the teeth when the rake is full. It is mounted on wrought iron wheels, which are capped to prevent the hay from winding round the axles. Price, £7 15s.—A patent balance horse-rake, invented by C. Woods, of Ipswich, improved and manufactured by Messrs. Ransome and Sons, is made on an entirely new principle. The man rides, and, by his weight, partly counterbalances the teeth; so that the work of discharging the load, which is done by his foot, is greatly lessened. The wheels are of wrought iron, and very high, so that the draught is light. This rake is especially useful when large tracts of land must be covered in a short time, both at home and abroad. It covers 10 ft. in work. Price, £17 10s.—The same firm has also invented and improved a lever horse-drag rake. This light and effective implement rakes the land quite clean, and is unloaded without stopping the horse. The form of the teeth is so constructed as to enable them to carry a great load. By means of a sliding-rod, each alternate tooth may be raised out of work— a desirable arrangement for raking twitch, &c. It is fitted with side levers, by which the teeth can be heightened or lowered at plea-
sure; and also with steel teeth. This implement will cover, in work, 6 ft. 6 in. Price, £8 5s.

MANURE DISTRIBUTORS.

The introduction of artificial manures has necessitated the construction of implements which shall distribute them equally over the surface. These distributors are well adapted for the purpose. Many of the drills are also arranged so as to deposit these manures in an even manner.

Chambers's patent broadcast manure distributor, invented and improved by Thomas Chambers, jun., and manufactured by Messrs. Garrett and Sons, has taken prizes at Lincoln, Carlisle, Salisbury, and Leeds. It is made with screw regulator and frame shafts; is well adapted for the regular distribution of guano, blood manure, salt, nitrate of soda, &c.; and will sow from two to sixty bushels per acre on flat or ridge. Its price is £19. — Another, on the same principle as the preceding, but of more simple construction, is charged £16 10s. — The liquid manure distributor, or water-cart, invented by W. Crosskill, carried the silver medal of the Royal Agricultural Society of England, at Cambridge. The body is made of iron plates, fitted with a brass valve, which a man can open and shut as he walks by the side of the horse. The spread-board is easily adjusted, so as to hang level when on hill sides. It is fitted with patent wheels, 4 ft. 6 in. high, with convex tire, and holds 120 gallons. Price, £17; or, with apparatus for watering four rows of turnips, &c., 15s. extra. — A portable pump, for liquid manure or water, by the same inventor, was awarded the first prize by the Highland and Agricultural Society of Scotland, at Edinburgh. It has a 3½-in. working barrel of cast iron, fitted with brass valve and bucket, so that it is not liable to get out of order. Price, with seven feet of leather hose, and three feet of copper tube, £5 15s.; portable tripod stand, 15s. extra. — Another liquid manure distributor, or water-cart, was awarded the first prize of £6 by the Royal Agricultural Society of England, at Leeds, 1861. It will hold 200 gallons, and is much used for conveying water to cattle, portable steam-engines, &c. Price, £22; or, with apparatus for watering four rows of turnips, &c., 15s. extra. — The patent manure distributor of Messrs. Priest and Woolnough, is made for depositing broadcast guano, and other artificial manures, in quantities of from three to forty bushels per acre; and is fitted with a patent manure barrel and steel spring scrapers. The pressure of the spring scrapers on the barrel is so light, that considerable difference is made in the horse’s draught; and they may almost instantly be removed when not required. Improved means are adopted to insure a regular delivery of manure; and the distributor is mounted on iron wheels. Price, £19.

MILLS.

The machines which fall under this heading comprehend crushing mills, grinding, crushing and grinding combined, bean, malt and oat mills, flour mills, and bone mills. A few of them will suffice for our purpose. The universal mill, invented, improved, and manufactured by Messrs. Ransome and Sons, consists of a pair of smooth rollers of equal diameter, for crushing oats, malt, barley, linseed, &c.; with a bean mill attached for cutting beans, peas, Indian corn, &c. It will cut and crush every kind of grain or seed on the farm. It is mounted on a strong iron frame, and is constructed with a view to durability and economy of power. Price, £21 10s.; pulley, extra. — A steel grinding mill, invented by John Hardley, of Shide, and improved and manufactured by Messrs. Picklesy, Sims, and Co., as a general grinder and crusher, has been acknowledged, by competent judges, to be a high-class machine. It combines the properties of a pair of stones and the smooth-roller crushing mill, and its advantages are consequently manifold. It is suitable for grinding all kinds of grain into meal for feeding purposes, at the rate of twelve bushels per hour, or it can be adjusted merely to break the grain. Price, £12 10s. — A portable corn mill, invented, improved, and manufactured by Messrs. Ransome and Sons, is mounted on a strong, compact, wooden frame, and is fitted with three-feet best French burr-stones, with a flour-dressing apparatus, for preparing flour for household purposes, which can be thrown out of gear when grinding barley, beans, peas, &c. This machine is adapted to be driven by steam, water, or horse-power; will produce, of barley-meal, six bushels per hour, or of fine
flour, three bushels per hour, with the power of four horses. Price, £70; pulleys, 70s. per pair extra. —The same makers have also a portable corn mill. This is a useful mill, mounted on a strong, neat, and compact iron frame, and is fitted with 24-inch best French burr-stones; the lower stone, in this mill, being the runner. The adjustments are easy of access, and it is not liable to get out of order. It can be worked by steam, horse, or water-power. Price, £35. —They have also a portable horse-gear threshing machine, which is arranged so that it can be put to work without unloading the horse-gear. The power is communicated to the barn-works, through an intermediate motion, by means of a strap. The horse-gear is timed for horses, and calculated on the strength of foreign horses. It may be worked by oxen, if necessary. Price, £35.

MOWING MACHINES.

The mowing is an offshoot of the reaping machine, requiring no delivery; it is more simple in its construction, and has been brought to a great state of perfection, cutting any description of grass crop with ease and certainty. Messrs. Burgess and Key have made great improvements in this machine. Cranton's is made on Wood's principle; it is a smaller implement, and can be worked by one horse. Many of the manufacturers have also combined implements, both for reaping and mowing. This has been done with a view to economy in the purchase-money; but as the principle involved differs in each, the combination can scarcely be expected to produce an implement which can work effectually. Wood's prize grass mowing machine, invented by W. A. Wood, of Hoosick Falls, New York, awarded the highest prize by the Royal Agricultural Society of England, at Leeds, in July, 1861, was highly commended by the Highland and Agricultural Society of Scotland, at Perth; and received a gold medal and 1,000 francs, and the grand gold medal of honour, from the French government, at Vincennes, in June, 1860; also, the highest prizes by the United States' National Agricultural Society; first prizes of the Yorkshire, the Royal North Lancashire, the Royal North Lincolnshire, and the Kent County Agricultural Societies. Of this implement, 500 have been sold in one season. It is said to be unsurpassed in closeness of cut, simplicity of construction, lightness of draught, portability, &c., and will cut one acre per hour, with one man and two horses. It is built in the best workman-like manner, with steel-cutter bars and cutters, connecting-rod, crank-pin, and shafts; the metal used for the wheels and gearing is of a very superior quality, which admits of being made much lighter without reducing its strength, making them more durable, and requiring less power to work them. The cutters are so arranged as to follow the uneven surface of ground when at work, and can, by a lever, be instantly elevated to pass over cut grass and other obstructions by the driver. The knives never work when the machine is backed; they are placed in front, the more easily to be seen by the driver. Price, including two extra knives, six blades, six fingers, bevel pinion, oil cup, &c., £22. —Another machine, constructed on the same principle, is a little cheaper, on account of its not being arranged with shafts for one horse, and a shorter cutter bar, which is 3 ft. 6 in. long. When not in use it will pass through 4-ft. gates. It is light, portable, and of easy draught; simple in construction, and well adapted for the use of small farmers; and will cut from five to six acres per day. Price £20. —Wood's prize combined mowing and reaping machine, is another implement patronised by his late royal highness the Prince Consort, the Emperor of the French, the King of the Belgians, &c., &c., and has been awarded more prizes than any other in the world. Simple in construction, light draught, portable, easily managed, it can be changed from a mower to a reaper, and vice versa, in a few minutes. Of this machine, the large number of 1,200 have been sold in three years. It will cut any kind of grass or grain at the rate of ten to twelve acres per day. Its price, including extra knife, blades, fingers, pinion, and package, is £35. Notwithstanding the great merit of these machines, and the extensive patronage they have received, we have some excellent makers amongst ourselves.

PLOUGHS.

In implements like the plough, the permanent form having been determined by
experience, improvements can only be made in the manufacture of the secondary parts, and in the proper adjustment of the whole. Iron has, in a great measure, superseded wood, the metal combining strength with lightness; the mould-boards are of varying length, to suit different soils, and the coulters can be inclined to one side or the other. The Messrs. Ransome may be said to have originally taken the first steps in improving the plough; and, with Messrs. Busby, Hornsby, and Howard, still sustain the reputation they all have so long merited. The Messrs. Ransome, besides their ordinary ploughs, have introduced a double-furrow plough, for turning two furrows at the same time; by removing the mould-boards of the ridging-plough, it is adapted for a subsoiler, to work after the plough; and, by attaching a pair of open-ribbed mould-boards, it is adapted for raising potatoes.—Messrs. Howard, in addition to their other ploughs, have a small pony plough.—Messrs. Hornsby, also, besides implements adapted for heavy and light lands, have a pony plough.—Messrs. Hunt and Pickering have invented a new mode of pitching the share: by a simple contrivance, the nose can be altered so as to regulate the depth; and the patent oil-boxes for the wheels, while retaining the oil, exclude the grit.—Messrs. Page have some very excellent forms of ploughs, with an adjusting coulter. In some localities the wooden beam has been retained, and attention has, therefore, been directed to the improvement of the implement under this form of construction.—Messrs. Grey have a sub-soil pulveriser, with improved leverage; and Messrs. Hancock, a triple-trenching plough, which, on any soil, will make a seed-bed at one operation. These are gratifying tests of the ingenuity, and also of application, in reference to the agricultural department of science. It must be remembered that the steam-plough was unknown at the Exhibition of 1851. It might then be considered as in an embryo state, soon, however, to burst forth as an agricultural fact. In general terms, the principle which has now been established would appear to consist of a strong frame, containing either fixed ploughshares or tines for stirring the soil, to which wire ropes are attached; these are received on a revolving drum, worked by a portable steam-engine, the framework being drawn to and fro between anchors fixed at opposite points, until the operation is completed.—Mr. Fowler's name stands among those who have directed attention to the development of steam-ploughing. In that implement the soil is turned over either by shares or by tines fixed in a frame, and having a double set of each, so as to be worked either way. The windlass is attached to the engine itself, or there are revolving drums worked by the engine: to prevent the drag of the slack chain on the land, wire-porters are used—a very important element in saving the wear and tear and the dead weight. The Messrs. Howard make use of revolving drums, worked direct from the engine, by which much power is saved; the wire ropes pass through two revolving wheels lying horizontally, and near the ground. A great improvement has lately been made in the working by the additional central wheel, placed at a little distance from the others, which regulate the action of the wire rope; the rope-porter also is new, and very efficient.—Mr. Stevens's general-purpose implement differs from the others. It is made of wrought-iron and steel, and consists of a main framework, which carries two underframes. To these are attached eight ploughs, four at each end, which rise and fall parallel to the ground, thus avoiding the balancing or tipping motion. The centre wheels that support the whole machine are strong, and stand 5 ft. 6 in. in height, by which the draught is considerably diminished when in motion.—Mr. Hayes has invented an improved windlass for steam cultivation; the framework is very strong. The following are the peculiarities:—"The plough can be instantly stopped by anchormen at the headland, without stopping the engine, the engine continuing in motion as in thrashing or other work: no signals are required; the work may be performed in foggy weather, or by moonlight, with perfect safety to the machinery. One man can superintend engine and windlass. A double cylinder is not needed, as the engine is not stopped; and no wheels are required to be put in or out of gear."—The machine of Messrs. Samson and Jewell is called a paring and breaking cultivator, and is adapted both for horses and steam-engines. It consists of an iron frame,
upon which are placed four paring ploughs in succession; behind each ploughshare is a rotary digger; as the plough turns the soil, the digger, revolving rapidly, thoroughly pulverises it, and it is at once made into a seedbed. The machine is worked by a coggled wheel.—Mr. Halkett's is known as the guide-way system of steam-cultivation; in order to adapt it, rails must first be laid down. The machine consists of a large frame running on the rails, and drawn by a steam-engine; to this framework are attached all the implements employed in the cultivation of the soil; and there are arrangements by which labourers can work upon the frame. The system is complete in itself, and, in certain soil and localities, might be made use of to advantage.—These several implements indicate the different plans that have been invented; but they are all worked by portable steam-engines acting upon wire ropes, by means of which the frames themselves are drawn to and fro. Besides the general advantages which must arise from the establishment of steam-ploughing, there is this especial one—that lands, whether heavy or light, can be tilled in unfavourable seasons, when it would be impossible to use horse labour. This principal process of cultivation is thus rendered more certain, and less dependent on the changes and chances of the weather. To descend from generals to particulars, we may instance a two-wheeled general-purpose plough, invented and improved by William Busby, of Newton-le-Willows, and manufactured by the Busby Implement Company. It received the award of the council medal at the Great Exhibition in 1851; a first-class medal at the Paris Exhibition; also six prizes from the Royal Agricultural Society of England in eight years; £10 at the Rotherham meeting, 1856; and a prize at Warwick, 1860. Its price is £4 4s.; steel breast clasp chain and weight, 16s. extra. Price, £5 complete.—The same company have also a new implement, which is called a combined plough and presser, invented by Thomas Harrison, foreman to the Rev. W. F. Wharton, Bannningham Rectory, and J. G. Harrison, Kirby Ravensworth, Yorkshire. It completes the ploughing and pressng the seed-furrow at one operation, saving much labour at seed-time, and requiring little, if any, more horse-power than the ordinary plough. The price of the plough is £3 15s.; presser, 40s. extra. The pressing plate wheel may be readily attached to any plough. Price, £5 15s., combined.—Messrs. Page and Co. have a double-breast or moulding plough, for earthing-up or forming ridges or bouts for turnips, potatoes, mangold, &c., or for striking water-furrows. The breasts are made of steel, and can be expanded or contracted, as required. The plough is also easily convertible into a horse-hoe, by merely removing the breasts and attaching a set of hoes. The price is 75s.; with one wheel, 70s.; two wheels, 75s.; marker to regulate the width of ridges, 7s. 6d. extra; and horse-hoes, 10s. extra.—Another, similarly constructed, but adapted for the use of a small horse or pony. Price, with one wheel, £2 15s.—Another combined moulding plough, horse-hoe, and stirrer. This is, perhaps, one of the most useful, efficient, and economical combined implements ever introduced, it being adapted for three superior implements, and easily and simply arranged for transition into a one-horse hoe, a moulding or boutting plough, and a five-tined expanding scuffler or scarifier. This implement is especially adapted for small occupiers, to whom it is recommended as a valuable appendage. Price, £4 10s.; if without boutting-ploughing, £3 10s.—The combined plough, drill, and harrow, invented by Levi L. Sovereign, of Canada, manufactured by Clubb and Smith, of 118, Fenchurch-street, London, is another instance of combining several implements in one. The object of this implement is to complete three operations by once going on the land, which economises time and labour, and also prevents horses compressing the soil after the land is ploughed. It is so constructed as to deposit the seed entirely out of the reach of birds. Any width or depth can be drilled. Seed drilled by this implement in Western Canada, produced far superior crops to any wheat otherwise sown. Price, £25.

**POTATO-DIGGERS.**

A potato-digging plough and cultivator, invented and improved by L. D. Owen, and manufactured by Childs and Owen, of New Oxford-street, London, weighs only 55 lbs.; is light of draught, and simple in its construction.
One man, with a pair of small horses, will easily dig potatoes as fast as twenty persons can pick them up. The potatoes are turned out and distributed on the surface of the ground so clean, that scarcely one bushel in a hundred, whether large or small, is left uncovered. Price, £2 10s.—Another, invented by Levi L. Sovereign, and manufactured by Clubb and Smith, Fenchurch-street, London, will, when the tops of the potatoes are gathered, raise the potatoes into baskets. With two horses it will save the labour of ten men. Price, £25.

Reaping Machines.

The invention of the reaping-machine is due to the ingenuity of the Americans. It is true that, in the early part of this century, a machine, with a revolving drum, had been used to cut corn in this country; but it did not achieve success; and it was not until Messrs. M'Cormick and Hussey brought their implements over, that any practical solution of the subject took place. These, with the machine of the Rev. Mr. Bell, have been the models on which all improvements have taken place. In the report of the Exhibition of 1851, there were only two reapers mentioned as being present—M'Cormick's and Hussey's; and at a trial made, the council medal was given to M'Cormick, Hussey's on that occasion not working well. At a subsequent trial, however, this implement worked equally with the other, but it was too late to alter the decision. There are two principles on which reapers have been constructed—the one, where the implement is drawn forward by the horses; the other, where it is propelled from behind by the horses. The awards of the Royal Agricultural Society seem to have been distributed without any reference to this distinction, so that the principle is still in abeyance.—Messrs. Burgess and Key's implement is an improved M'Cormick, the cutting being done perfectly; the delivery is effected by means of Archimedean screws, by which the cut straw is thrown on one side, ready for the binder. There is a revolving fan, to bring the standing corn more readily upon the cutting-knives. It is thus made entirely self-acting, working with two horses; and, by a simple contrivance, the machine can be shut up so as to pass through any ordinary gate.—Croskill's machine is an improved Bell's. It is propelled by three horses abreast, and guided by the driver, who walks behind the horses. The delivery can be made on either side, by means of revolving endless bands. The breadth of cut is 7 feet, so that the work is done expeditiously.—Messrs. Ransome's machine is drawn by horses; the delivery is made on the side, by means of a series of rakes and arms revolving round a vertical shaft.—Messrs. Samuelson's implement is a modification of the same plan.—Messrs. Kemp, Murray, and Nicholson's reaper is on Hussey's plan, the delivery being made by a man seated on the machine; thus, with the driver, two persons are employed. The cut corn falls upon a tipping platform, which is delivered on the side by rakes.—Messrs. Dray's is on the same principle.—Messrs. Cuthbert's machine also requires two persons, the delivery being made by a rake over a receiving platform.—Bamlett's is a combined implement, worked with one horse only; the delivery is made by a man on the machine.—Messrs. Pickles and Simms' is made on Bamlett's patent, but with improvements. There is a simple contrivance by means of a lever, by which the cutting-knives can be raised or lowered 6 in. This gives to it the power of a combined machine, and, at the same time, there is the power of accommodating the cutters to any inequality of surface; these two last can be worked by one horse. In 1851, M'Cormick's machine, at the Exhibition, created a greater sensation, in its way, than either Power's statue or Hobbs' locks. Its fame at once, of course, raised up for it a host of antagonists and imitators; and it was not till the golden fruits of many autumns in the fields of England, France, Belgium, and Germany had been saved by this machine, that its superiority was tacitly acknowledged; and even competing agricultural implement-makers were compelled to own that, if not the best, it was certainly the most popular, and the most generally used. The manufacture of the machine, for this country, was, after 1851, entrusted to the agency of Messrs. Burgess and Key; and, since that time, as many as 3,000 have been made, and supplied to the farmers of the United Kingdom, and probably as many more exported to the continent. Since 1851, however, Mr. M'Cormick's patent
for these machines has expired in America, and, of course, the attempt to renew it was violently opposed by all who had, or fancied they had, a better reaper themselves. In the course of the investigation, it came out in evidence that Mr. M'Cormick had sold no less than 40,000 of his reapers in the United States alone; when the patent authorities at Washington, thinking that, out of such a large transaction, the inventor of the machine must himself have reaped a golden harvest of no common weight, declined to renew the patent. Hence Mr. M'Cormick was driven to invent another and a better machine, which has been approved in this country. The old machine, as we may term it now, was one which cut the corn, and, as it dropped back upon the platform behind the cutters, turned it off in "swath"—i.e., left it in a continuous roll alongside of the track of the machine. In very moist countries, this swath delivery is rather an evil; and during wet seasons, the machine has been often left unused altogether. In addition to this drawback, a great amount of manual labour is, of course, necessitated to collect the swath into sheaves, and this, too, must in some cases be done before the return of the machine over the same track. The object, therefore, has always been to invent a machine which will deliver, on the ground, the cut corn in sheaves ready for binding; and such a machine Mr. M'Cormick has now invented. It is founded entirely on his old machine, as made by Burgess and Key; the new patent consisting simply in the introduction of an automaton rake, which, at regular intervals, by one rapid sweep, draws the corn on the platform together, and, with a quick turn, throws it aside in a loose sheaf out of the way of the machine. The mechanism by which this is effected is very simple, though, from its very simplicity, it is difficult to give a clear idea of it to the reader. Putting it in its briefest form, we may say that the wheels on which the old machine was drawn along, set in motion a mechanism by which the corn was cut close off at the ground, and, at the same time, revolving a light four-armed wooden fan or gleaner, which, as fast as the corn fell, pushed it on to the platform. This, in substance, is the old machine. The new one consists in an addition of the automaton rake, which has two actions. During one part of the revolution of the gathering fans, it acts with and as one of them, till its wooden teeth are level with the platform where the cut corn lies. It then ceases to revolve, and, by a most ingenious piece of mechanism, makes a sudden horizontal movement, throwing aside, on to the ground, the entire sheaf, and instantly after resuming its motion as one of the revolving fans. This machine was publicly tried in the presence of a number of gentlemen farmers, about three miles beyond Hemel-Hempstead. This trial was made under the most unfavourable circumstances; in fact, under circumstances which, the farmers present contended, should have prevented the machine from being tried at all. The night and morning had been very wet, and the rain was still falling, when the machine, drawn by two horses, and wielding its fans and rake in the most aggressive manner, was brought to a field of twenty-one acres, covered with a heavy crop of red lamas wheat, completely saturated and bent down by the wet. Along the edge of this field, where the ground was very rough, and the corn struggling and beaten down, the machine was turned. Much misgiving was expressed, before starting, as to the power of the rake to act on such ground against wind and rain, and to remove the soddened crop from the platform into regular sheaves. A very few moments, however, sufficed to put these fears at rest. The reaper went to its work about three miles an hour, making a clear cut broad track of 5 ft. 6 in. wide, and turning out neat and remarkably large loose sheaves, at intervals of about 15 ft. apart. The movements of the reaper were exact and perfectly noiseless, and it was easily turned in any direction. An ordinary agricultural labourer at first drove it. Afterwards Mr. Dixon took the place of driver; but the results were the same. The bunches were well laid; the cut was clean and close to the earth; and the spacing between the sheaves as clear and accurate as if every foot had been measured. At one part the corn was tangled, and badly flattened—badly enough to have presented difficulties to the ordinary reaper; but the machine went through it with the same ease and regularity as through all the rest. The horses were then turned direct and across the thickest part of the crop, from corner to corner of the field; and though, as a
matter of course, the passage of the animals
drawing the machine trampled down a large
portion of the stalks before its track, the reaper
still worked as clearly and efficiently as ever.
First came one of the fans, pushing its quan-
tum, when cut, on to the platform; then a
second, third, and fourth, when the rake swept
round in a semi-curve, and turned the whole
mass out in a thick sheet on to the ground.
The horses appeared to draw it easily—more
easily, in fact, than the old machine; while,
from the strength and simplicity of the im-
proved mechanism, it was evident that, even
in the most inexperienced hands, nothing but
willful damage could derange its slight but
strong machinery. It is estimated that this
reaper can reap and stack, in sheaves, from
sixteen to eighteen acres of wheat per day, at
a cost, including wear and tear of plant, food
of horses, &c., of 1s. 6d. per acre. Manual
labour costs from 7s. 6d. to 10s. per acre; and
a good reaper averages only from half to a
little over half an acre a-day. The new machine
effects a saving of, at least, one-third of the
manual labour that was still necessary with
the old reaper; and the price at which Messrs.
Burgess and Key will be able to sell it, will
be lower than that which has hitherto been
charged—probably about £34.

ROLLERS.

A universal-jointed land-roller, invented,
improved, and manufactured by Mr. Nicholson,
is a three-part plain roller, constructed on an
entirely new plan, to adapt itself to the ground,
however rugged or uneven the surface, or
high or irregular the ridges, thereby overcom-
ing the great defect of all ordinary land
rollers. By an ingenious arrangement of
universal joints, each part will move up or
down, or at any angle, independently of the
others. Price, 18 in. diameter, to cover 7 ft. of
ground, £11; driving seat, £1 extra.—Messrs.
Woods and Cockededge have constructed a
double barley roll, to which has been awarded
a prize of ten guineas by the Royal Agricul-
tural Society of England. It is designed for
rolling spring corn, and is so constructed as to
obviate the evil complained of with those in
common use, which, in turning, are apt forci-
bly to displace the soil, and disturb the newly-
sown seeds. This implement has become one

of general utility to the farmer, from its ap-
lication to so many purposes as a roll.
Price, £8 8s.—Amies and Barford have a new
implement, called a Water Ballasting Roller.
It is made with two separate water-tight cylin-
ders of best wrought iron, which can be
filled at pleasure. A removable plug is let into
the solid plate, so that a tube or hose-pipe can
be inserted, and the cylinders filled in two or
three minutes. When full weighted this roll
reaches 25 cwt.; when empty it is about 12
cwt., so that a two or three-horse roll is secured
in one implement. The size of the cylinders
is 27 in. by 6 ft. 6 in. Price, £17 10s.—Mr.
Cambridge has a patent double-action press-
wheel roller and clod-crusher, to which was
awarded the Royal Agricultural Society’s
prize at the Warwick meeting. It is com-
posed of a number of patent plain wheels;
and a serrated or notched wheel, of peculiar
construction, is placed between each plain
wheel, by which arrangement the effective
action of the best clod-crusher and wheel-
roller are combined. It is 6 ft. wide, with

ROOT-WASHER.

Mr. Croskill has an improved Archimedean
root-washer, consisting of an open cylinder
partly immersed in water, containing an Archi-
medean screw. The potatoes, roots, &c., are
put into a hopper; and as long as the cylinder
is turned round in one direction, they remain
in it, and are well cleaned; but when the
handle is reversed, the Archimedean screw
brings them out of the cylinder without the
necessity of lifting it out of the water, as in
all other root-washers. Price, £5 10s.

SACK-BARROWS.

A combined sack-barrow and elevator, in-
vented, improved, and made by Amies and
Barford, is a convenient implement. By its
aid one man can fill, tie, and remove a sack of
corn with ease, thereby doing the work of three
men at a great saving of time and money.
For corn-factors, maltsters, merchants, wharf-
ingers, coal-wharves, and farmers’ use in
general, this machine is found invaluable, as
also for facilitating the removal of corn from
a steam thrashing-machine. To prevent the
possibility of breakage, the best malleable iron
racks are now substituted for cast iron ones. Price, £3 5s.

SOWING MACHINES.

A grass and seed broadcast sowing machine, invented, improved, and manufactured by Barrett and Exall, consists of a box 12 feet long, with a spindle running through the centre of it, on which are fixed brushes working against copper regulators, and a barrow, on which the box is placed transversely when fixed for work. The barrow-wheel drives all the machinery, and the quantity of seed is regulated at pleasure. Price, £3 3s.—A broadcast corn-distributor, invented and manufactured by Gower and Son, is quite a new implement, and has been brought out to supply a want in wet seasons—of a machine to sow when the use of a drill is impracticable. Two men, or a man and a lad, can sow with it more expeditiously, and with much greater regularity, than by hand. Price, £5.

STEAMING APPARATUS.

A fixed steaming apparatus for large farms, gaols, unions, asylums, &c., was invented by the late W. P. Stanley, of Peterborough, and improved and manufactured by Messrs. Amies and Barford. It consists of a strong 2-horse power boiler or steam-generator; two 100-gallon boiling or compound pans, made of strong galvanised iron, for boiling water, cooking, washing, brewing, and other domestic purposes; also for preparing linseed meal, and other compounds for cattle, horses, and pigs; two 12-bushel galvanised chaff or root pans; strong brass feed-pump for boiler, with all pipes, cocks, and fittings as fixed. A similar apparatus is in constant use at the Northampton, Cambridge, and Arley asylums; the Strand and Poplar unions, London; and nearly 200 other public and private establishments. Price, £50; wood and felt lagging to the boiler, £5 10s. extra.—Another, called the farmer’s portable steaming apparatus—invented by the same gentleman, and sold by the same maker—received the prize of 300 francs and a gold medal at the Paris Exposition; and more recently distinguished at the public trials open to all England at the North Lincolnshire shows, and at every other local show where it has been subjected to competition. It consists of a strong wrought iron portable boiler or steam-generator, with an improved oval flue of Lowmoor iron, one 6-bushel root pan, and 40-gallon compound pan, as fixed. Price, £27 10s.; water-gauge, 20s. extra.—Mr. Thompson, also, has a paragon portable steaming apparatus, which combines every improvement for steam-cooking for agricultural purposes, or for asylums, or other large establishments: the boiler is constructed to produce the necessary steam with a minimum quantity of fuel; it is fitted with a steaming-pan to contain six bushels of roots, and a 40-gallon copper boiler, in wood tub, for boiling linseed compounds, soups, &c., by steam; but the apparatus may be arranged, in various other forms, to suit any particular requirement. Price, complete, £21 10s.

STEAM CULTIVATORS.

The patent steam plough and cultivator, with windlass and rope-porter, manufactured by Messrs. Fisken, Newcastle-upon-Tyne, takes its place among other agricultural mechanical improvements. It is a three or four-furrow plough, on the balance principle, capable of being used as a cultivator. The peculiarity of the apparatus is, that the power is transmitted from the engine by an endless rope, acting on self-moving anchor-windlasses, so that the plough is dragged directly from one windlass to another. Price, £150.—A new implement, called a regulating windlass, invented, improved, and manufactured by Messrs. Hancock and Co., has also a claim upon the notice of the agricultural world. The hauling-drum are tied to, and mounted on, independent shafts; and each drum is acted on by "clutches" of two speeds, by which the speed of the implement is adapted to the power of the engine without stopping. It is a common 8-horse power engine; is enabled to master all the difficulties of steam tillage; and by which the land can be tilled to a greater depth by a light engine than heretofore. In hauling implements up hill, or through heavy or wet patches of ground, the speed can be two miles an hour of the implement up hill, the engine working equal to 16-horse power; and four miles an hour down hill, the engine going at 8-horse power, or any speed that may be required. Price, £100.
STEAM-ENGINES.

There are, no doubt, some who look upon the introduction of a steam-engine into rural matters, with the same kind of horror that the poet Wordsworth did the invasion of a railway into his own lake scenery. A steam-engine may not be, perhaps, an object for poesy; although we do not see, if treated in the right way, why it should not be considered worthy of poetical illustration quite as much as the many rural objects which have so long been sung in the poet's song. There is nothing in a spade, per se, poetical, or in a plough. They have been merely rendered so. The labourer himself is only poetical afar off; and few will care for a closer connection, especially after a day's toil. When the eye has become used to the steam-engine in the field, and the ear to its puffing and snorting, some poet may arise to clothe it "in liquid lines mellifluously bland," and thus give to it a poetical name and habitation. Our business, however, is to deal with it practically. A steam-engine, as compared with the human or equine machine, is more useful, economical, time-saving, and money-making. There is a limit to the labour of man, and the drudgery of the horse. Each requires rest to recruit exhausted nature; but the steam-engine knows not fatigue. Feed it with the "black diamond" drawn from the bowels of the earth, and, so long as the supply lasts, the engine plies its ceaseless toil. It cares not for sunshine or rain. The storm passes over unheeded; and it knows no distinction between night and day.

Fixed engines have been in use some time in the north. It is only within the last fifteen years that movable engines have been brought into use through the instrumentality of the Royal Agricultural Society, as being more convenient; for, with a fixed engine, the produce has to be taken to the barn; while, with a movable one, the corn may be at once threshed out in the field. A saving is thus effected in time, in labour for the tenant, and in buildings for the landlord, fewer being required for storing, &c. One of the principal points to be taken into consideration as to the efficacy of an engine, is the amount of the consumption of fuel; and even, in 1851, great progress had been made: for, as stated in the report of the Exhibition, "our best engine now consumes less than 8 lbs. of coal per hour per horse-power; whereas an engine made by the winning manufacturer of four years ago, consumed 2s. 8d.; that is, four times as much fuel for the same work."

Now, however, there are portable steam-engines in the field. Messrs. Aveling and Porter; Barrett, Exall, and Andrews; Burrell, Brown and May, Clayton and Shuttleworth, Garrett, Gray, Hornsby, Humphries, Ransome and Sims, Robey, Ruston, Turner, and Tufnold, are all makers of portable engines. There are also fixed engines, which, under the requirements of modern farming, may, in some circumstances, be of more avail even than portable engines for carrying out the necessary operations. It is unnecessary to particularise the merits of all these makers' machines. They are well known. We may, however, notice a 10-horse-power patent portable steam-engine, invented by Messrs. Biddell and Balk, of Ipswich, and improved and manufactured by Messrs. Ransome. This engine is fitted with Biddell and Balk's patent boiler, which is so constructed, that the fire-box, tubes, and tube plates can be taken out all in one piece, and put in again, with facility; the advantages of this boiler being facility of cleaning, inspection, and repairs. The boiler is proved to 100 lbs. pressure on the square inch. The crank shaft is of wrought iron; the bulk of the plates are Lowmoor, the others being best Staffordshire. Price, £280; steam-gauge, 60s.; pulley, extra.

THRASHING MACHINES.

This is the most complicated agricultural machine in general use. Before 1829, so great was the imperfection of farm machinery, that, technically speaking, the duty performed was 25 per cent. only. But the application of steam has induced improvement in all kinds of machinery, and in none more than in thrashing machines. So great, indeed, have been the improvements, that they may be considered as equal to new creations. The corn now is commonly delivered from the stack upon the machine, and then from the machine into sacks ready for market—a great saving of time and money. These improvements received due notice at the Exhibition.
of 1851, and prizes were awarded to Messrs. Garrett, Hensman, and Holmes; and though not now possessing actual novelty, there have been so many improvements effected, that the present machine is almost a new invention. The Messrs. Garrett, instead of three blasts, have now contrived one blast, by which the currents of air are conducted through separate channels to dress the grain. The machine is, in consequence, much simplified in its construction, and requires less power to drive it. Messrs. Barrett, Exall, and Andrews manufacture a finishing-machine, with their perforated beater drum, and the patent corn-elevator, which dispenses with the ordinary tin cups; there is less wear and tear, and the working gear is more simple.—Messrs. Clayton and Shuttleworth’s improved machines are fitted with a centrifugal-force corn-elevator, which dispenses with six driving-pulleys and three driving-bands.—Messrs. Hornaby’s has only one belt for working, giving three dressings with two blasts.—There are also only two running spindles and four pulleys; the machine is fitted with a centrifugal-force elevator, and a new differential shaker.—Messrs. Ransome and Sims have introduced a new rotary shaker, which separates the straw, carries back the grain to the dressing part of the machine, and carries away the straw. There is also an adjustable rotary screen, which separates the good from the light corn.—Messrs. Turner have a small machine which may be worked by a 4-horse-power engine.—There are also machines made by Messrs. Barrell, Gibbons, Gray, Holmes, Humphries, Robey, Ruston, Tasker, and Underhill. In connection with the threshing machine, a new implement has been brought forward within the last few years. It consists of a frame, on which is a straw-elevator: the straw thrown from the threshing machine is received upon the elevator, and is carried by an endless revolving band, with projecting spikes, to a height of 20 feet, and upwards, doing the work of several men in stacking the straw. The old winnowing machine has not been altogether superseded by the threshing machine; but, in an improved condition, still keeps its place, being better adapted for small holdings than an implement which can only be worked by steam-power. Nor has the steam-power machine thrust out the horse threshing machines. They are useful on small occupations, and continue in great demand on the continent, where the system of farming has not reached the standard that is required in this country. Many of these useful machines are still manufactured by some of the largest implement-makers.

TURNIP-CUTTERS AND PULPERS.

A root-cutter, invented and improved by G. A. Biddell, of Ipswich, and manufactured by Messrs. Ransome, is an excellent machine. The knives remain stationary, while the hopper revolves on a vertical axis. By this arrangement great freedom of cut is attained, and it is impossible for the last piece to escape without being cut. It works easily, and cuts roots at a rapid rate. They are made to cut slices, finger-pieces of different sizes, and very thin strips. Price, £5 10s.; wheels and handles, 12s. extra; pulley for steam-power, extra.—A patent root-pulper, invented by the late F. Phillips, of Brandon, improved and manufactured by Woods and Cocksedge, has been awarded several prizes by the Royal Agricultural and other societies. This machine has been perfected, and is now offered as the most simple and effective implement for pulping of roots. All complicated parts are done away with; there is no worm or cutter-block, and no oscillating motion is required to assist the cutting-barrel in reducing the largest roots to a fine regular mince. This is a small-sized machine for limited occupations, for stables, or where one or two cows are kept. Easily worked by a lad. Price, £3 10s.—Another, of larger size, by the same makers, has the cutting-barrel or cylinder 12 inches in diameter, 14 inches in width, and is constructed entirely of iron; each tooth being fixed in separately, and secured by a wooden wedge, so that any common labourer may replace the teeth at a cost of a penny each, without taking the barrel out of its bearings. It will cost considerably less to keep in repair than any other turnip-cutter yet made. Price, £4 15s.—Another, fitted with brass bearings, and made stronger for increased power, will cut a very large quantity with greater ease than any other machine of the kind, as has been proved at the trials of the Royal Agricultural and other societies. This size is especially adapted for
OF ENGLISH FARMING.

Agricultural stock-feeders. It produces a perfect pulp, without any way bruising or smashing the roots, or destroying or losing the juice—a most important feature. Price, £5 10s.—Another, with a 20-inch barrel, will perform a very large quantity of work when attached to steam-power, and is especially adapted to large stock-feeders. Since the first introduction of Phillips' root-pulpers, several thousands have been sold to the first agriculturists of every country in Europe. One of their best qualities is, that they never clog, and seldom get out of repair; and in case of accident to the teeth, these can easily be replaced at the cost of one penny each. Price, £7 10s.—Messrs. Perksly and Sons have a root-pulper, which is a new implement. It is constructed with a double cone cylinder formed of perforated steel plates, with gauge or diamond-shaped cutting-points: the ends of this cylinder, being larger than the centre, discharge the pulped matter as rapidly as it falls into the interior, without the assistance of an iron weight, worm, or other contrivance, hitherto ineffectually employed for such purpose. The cutting-plates are fixed upon the cylinder in sections, and are cheaply and easily replaced by duplicates in cases of accidental breakage. It will perform a greater amount of work, more efficiently, and with less power, than any other machine of the kind, and is less liable to breakage, and more readily and cheaply repaired. The frame and other parts of this machine are of iron. Price, £5 10s.

WEED EXTRIPATORS.

A poppy and weed-extriripator and fertilising lever harrow, invented by the late Fred. Phillips, Esq., of Brandon, and improved and manufactured by Woods and Cockedge, has been awarded a silver medal by the Royal Agricultural Society of England. It loosens, by its gentle action, hidebound lands, making them tender and friable; opening countless millions of pores to the influence of the atmosphere, promoting vegetation, and bringing fresh nourishment to the plant. No farm should be without it, as the extra produce on a few acres will more than repay the cost in the first year. Iron frame and levers. Price, £5 10s.—Another, called a Weeding-Paddle, or Thistle-Destroyer, by Reeves, has been awarded a silver medal at the Royal Agricultural Show at Leeds. It is simple, and used the same as a common weeding-paddle, which, at the same time as it is pushed into the ground to cut off the weed, discharges a portion of salt on the bleeding root. The salt thus penetrating the roots, effectually destroys them. It is portable, and is easily used as a common paddle. Price, 10s. each.

WEIGHING MACHINES.

A three-ton cart-weighing machine, improved and manufactured by Mr. Mason, is fixed level with the ground, so that a cart can be easily weighed, or any ponderous article. It is also fitted with a pen for weighing cattle; will weigh from 1 lb. to 3 tons; and is taken out of gear by a lever, so that it cannot be injured when out of work. Price, £21; with pen for cattle, £2 10s. extra.—Another portable machine for weighing cattle alive, is set on wheels, with large platform and guard, to weigh 15 cwt. with mall weights. Price, £9.

—Another, for weighing pigs and sheep alive, is adapted for all general purposes by removing the guard and balance-weight, which is done in an instant: having a large platform or scale, it can be used either for corn, wood, or any bulky article. Price, £4 10s.—Another, adapted for the same purpose, but on the lever principle, only requiring small weights, is made by the same manufacturer, to weigh 4 cwt. Price, £4.—A combined sack-holder and weighing machine, invented by John Spencer, and improved and manufactured by Mr. Mason, will enable sacks of corn or other products to be filled and raised, by a rack and pinion attached to the machine, to the weight required for carrying off on the back. Price, £5 5s.

WINNOWING MACHINES.

The manufacturers of implements of this description are Messrs. Hornsby, Gooch, Garrett, Dray, Coleman, Sawney, Caborn, Campain, and Hunt. On these machines generally, the report of the Exhibition of 1851 contained the following remarks:—"Even winnowing is becoming a refined process; for, instead of trusting the corn to the wind, it is now placed in a machine so discriminating, that the best of these—Messrs. Hornsby's—required, on the part of the judges at the York meeting,
specific terms for describing its work, more than are easy to understand." It then goes on to say—"Messrs. Hornsby and Son are, above all others, the most successful in these machines, dressing more than double as much corn as any other in a rough state; it is also excellent for finishing the corn for market; we, therefore, awarded it a medal." Price, £13 10s. This machine received a prize at Carlisle. The report then adds—"Mr. Gooch exhibited a machine which did its work well."—Messrs. Garrett have several corn-dressing machines, which were highly commended at Carlisle, the price varying from £7 10s. to £12. Extra sieves may also be obtained for beans, peas, &c.—Messrs. Dray have a patent grain and seed-separator, invented by G. Salmon, of Illinois. "The judges at Carlisle said of this—"We consider it likely to throw a new light on dressing machines. Its performance in the hands of its inventors was wonderful; but it must be seen to be appreciated. We awarded it a medal."—Messrs. Coleman have corn-dressing machines; prices varying from £7 10s. to £8 10s.; and Messrs. Caborn have also a machine—the price being £14.—Mr. Sawney's winnowing machine is priced at £8 10s.—Mr. Campain has a very complete machine, price £25. This includes a patent elevator, which raises the dressed corn by a revolving hand, to which are attached tin troughs. These receive the corn as it is dressed, and, raising it, deliver it into a sack placed to receive it. A very considerable saving of time is thus effected.—Mr. Hunt's engine for drawing clover and trefoil seed was considered worthy of especial mention at Carlisle, and had a silver medal awarded to it. This machine separates the husk from the seed, at the rate of from two to three bushels of clover per hour, and from four to six of trefoil seed. It is mounted on a pair of wood or iron travelling wheels, and a pair of draughts are attached, so as to render it portable. The net price for steam-power is £25; for horse-power, £27; and the travelling wheels, with draughts of iron or wood, from four to five guineas extra. Numerous testimonials of merit have been given for its efficiency and superiority.

In closing the account of these valuable implements, we cannot do better than give the sentiments of the Jurors of the Exhibition of 1851, which are just as applicable now, as they were then:—"Adopting the standard of economy as the test of their merit, we find that if a ploughing be valued at 8s., they can save 7s. an acre yearly over the whole of an arable farm; and we may adopt this calculation in their favour more confidently, because, by other means, an equal saving of horse-work can be made at other seasons in other descriptions of work. Some exceptions to this general use of cultivators will occur, of course, to every farmer; but the substitution of them for the plough has long been known to many good farmers, though probably it has not, as yet, been carried out upon system by any one of them to its fullest extent."

CONCLUSION.

Whatever strides have lately been made in the science of chemistry and the improvement of mechanics, as applied to agricultural operations, there is yet another subject which, under the name of Meteorology, ought to claim the serious attention of those who are occupied in the cultivation of the soil. As in other matters connected with agriculture, the first step in improvement, or the first advance in the acquisition of any views of practical importance, has been made in Scotland; so, on this point, the men of the north have, for some time, busily interested themselves in establishing a system of observations of what may be generally termed meteorological occurrences, which cannot fail to be of great value in guiding the agriculturist in his course. It must be evident, that to be of any practical use, such observations cannot be confined to one spot, but must be carried out over a large extent of country. Every one in his own neighbourhood, with but little trouble, can add to the general stock of knowledge, and thus the book of nature will be gradually unfolded. A great fact will then be made apparent to the comprehension of the farmer; namely, that he must not look to the result of a favourable or an unfavourable season—to the chances of war or famine—to the supplies that may come from other countries, to bid him down as it were in his own;—but that he must extend and enlarge his views; and he will then find that, if he grounds his calculations upon reasonable expectations, the laws
OF ENGLISH FARMING.

[CONCLUSION.

of nature will be found sufficiently firm and invariable to afford him every hope that his labour will not be lost, if, at the same time, he takes advantage of the science and skill which have already opened their resources for his use. The variableness of climate, in these islands, arises from causes of easy explanation. There are disturbing forces, on the one hand, from the vast tract of land comprising the continent of Europe; and, on the other, from the extensive influence of the Atlantic Ocean. The changes that we thus experience are dependent on elements existing afar off. From the cold and inhospitable steppes and tracts of Russia on the one hand, and from the tropical warmth conveyed through the waters of the Mexican Gulf on the other, may be traced the influences that affect our climate. And thus it is found that the temperature is more equable than is felt in similar latitudes, either in America or on the European continent. But these elementary influences produce a marked effect on the characters of climate in those parts of our island that receive their impulse from one or other of these causes. Thus, on the west coast there is a larger quantity of rain-fall than on the east. Here, then, a rule for agricultural operations is at once arrived at. Cereal grains flourish better in the east; while grasses and green crops find a more genial climate in the humid atmosphere of the west. There are, besides, local causes affecting climate, but still dependent on these great outlines. It is from these peculiarities of local situations that information may be derived, which, by being classified, can be made generally useful in guiding the inhabitants as to the course to be pursued, so as to regulate their system of husbandry under the most advantageous circumstances. And we urge, therefore, upon the agricultural body, not to keep their attention confined to the chemistry and mechanics of agriculture—although, separately, each is of inestimable importance; and, combined, they have, within a few years, completed a total revolution in all the routine of the farm—but to study Nature and her laws; and there will be found such rules as cannot fail to point to the farmer how to act, so as to make the governing influences of the world in a manner subservient to himself.

325
DIVISION X.

THE PRACTICE OF HORTICULTURE.

CHAPTER I.

THE GARDEN OF EDEN; THE GARDENS OF HESPERIDES; THE GARDEN OF CYRUS; GARDENS OF THE EAST GENERALLY; GREEK GARDENS; ROMAN GARDENS; VEGETABLE GARDENS.

THE GARDEN OF EDEN.

The cultivation of a garden, as it is one of the most innocent, so must it have been one of the first of the employments of man. According to the sacred writings, our Adam and Eve were placed in Paradise, or the Garden of Eden; and profane historians and poets of the remotest antiquity, have bequeathed to us descriptions of gardens, redolent of the most enchanting beauty, and breathing fragrances capable of inspiring the utmost delight. Respecting the locality of some of these gardens, however, learned topographers are very widely divided. For example, the garden of Eden is supposed, by some, to have been situated in Armenia; by others, in Persia; by others, in Chaldea; and James Silk Buckingham informs us, that the people of Damascus implicitly believe that it was placed in the neighbourhood of their city. Happy belief! as it must impart to the reflective and dreamy mind of the Turk, the most agreeable visions of the long, long past. But the inhabitants of Ceylon declare that the garden of Eden was in their country, in which we know there is an Adam's Peak, rising to a height of 7,420 feet above the level of the sea; an Adam's Bridge, which consists of a chain of shoals extending across the gulf of Mannar, between the island and the peninsula; and a tomb of Abel. They have also a tree, the Divi Ladner, which, they say, bore the forbidden fruit, which still grows in great beauty, amidst an abundance of the most deliciously scented flowers, most inviting and tempting to all who behold them. The form of the fruit is such as to suggest the idea of a piece having been bitten out of the side by the sweet and innocent mouth of our first mother; and, to confirm this fact, the Ceylonese affirm, that the fruit was exquisite before this event took place, though it is now poisonous. Other countries have been chosen for the localisation of this celebrated garden; and a Swedish professor of the seventeenth century, composed a book to prove that Sweden was the happy land in which Eden had been placed. If so, it must have been very cold in winter.

THE GARDENS OF HESPERIDES.

Eastern nations, in general, must have taken great delight in gardens, from the manner in which their enjoyments are usually described. The gardens of Hesperides were placed in Africa, near to Mount Atlas, or, rather, somewhere among the valleys of the chain which goes by that name. They are described as situated in a spot upwards of 100 feet deep, and enclosed by very steep and almost inaccessible heights. In them grew apples of gold (oranges), pomegranates, mulberries, olives, almonds, walnuts, and grapes. The ornamental trees comprised the arbutus, myrtle, bay, ivy, and wild olive. They were inhabited by three celebrated nymphs, daughters of Hesperus, and guarded by a terrible dragon, which never slept. Here were—

"Groves whose rich trees wept odorous gums and balm; Others whose fruit, burnish'd with golden rind, Hung enviable, Hesperian fables true, If true, here only, and of delicious taste."

Some writers have supposed these gardens to have been nothing more than the oases in
the desert; but whatever they were, or are in imagination, the vast exuberance of their odoriferous flowers, and the "thousand and one" enchanting charms with which the Greek mind, as seen in its poetical mythology, has invested them, have been thoroughly demolished by the ruthless hand of Lieutenant Beechy. It is a sad, but, we believe, an undeniable truth, as shown by this writer, that these famous gardens were nothing more than old stone quarries, out of which the material necessary to build the town of Be-renice, now Bengazi, had been taken.

THE GARDENS OF ALCINOUS AND LAERTES.

The garden of the Phœnician king, Alci- nous, is said to have been situated in an island of that name, supposed to have been Corin, in the Ionian sea; but, wherever it was situated—whether in Corin, or in some one of the Asiatic islands, as some suppose—its description, by the Homeric muse, is exceedingly beautiful. It lay close to the gates of the palace of the king; and was carefully defended from the inclemency of the weather by such means as may be supposed, at that time, to have been at the command of a powerful sovereign. It consisted of four acres, and was fenced all round with a green enclosure. It was planted, here and there, with fruit trees; and contained beds of culinary vegetables, and some borders of flowers. The poet, however, describes it in much warmer terms than we are attempting to do; here the reddening apple ripened into gold; and—

"Here the blue fig with luscious juice o'erflows,
With deeper red the full pomegranate glows;
The branch here bends beneath the weighty pear,
And verdant olives flourish round the year.
The balsmy spirit of the western gale
Eternal breaths on fruits, untaught to fail;
Each dropping pear a following pear supplies,
On apples, apples, figs on figs arise;
The same mild season gives the blooms to blow,
The buds to harden, and the fruits to grow."

Besides its fruits and flowers, it contained a couple of fountains, or wells; the one for the use of the palace, and the other for watering the garden.—The garden of Laertes was similar to that of Alcinous; and they are both described in the Odyssey.

THE GARDENS OF CYRUS.

The Babylonian or Assyrian kings seem to have possessed a remarkable predilection for magnificent gardens. Those of Cyrus, the founder of the Persian empire, have frequently been described. According to Mr. London, who condenses from Dr. Falconer, the form of these gardens was square, each side having a length of about one hundred feet, and the whole giving an area at the base of closely upon four acres. "They were made to rise with terraces, constructed in a curious manner above one another, in the form of steps; and were supported by stone pillars to the height of more than three hundred feet, gradually diminishing upwards till the area of the superior surface, which was flat, was reduced considerably below that of the base. This building was constructed by vast stone beams, placed on pillars of stone (arches not having then been invented), which were again covered with reeds cemented with bitu- men, over which was placed a double row of bricks united by cement. The bricks were covered with plates of lead, which effectually prevented the moisture from penetrating downwards. Above all, was laid a coat of earth, of depth sufficient for plants to grow in it; and the trees planted there were of various kinds, and were ranged in rows on the side of the ascent, as well as on the top; so that, at a distance, it appeared as an immense pyramid covered with wood. The situation of this extraordinary effort of human skill, aided by wealth, was nearly adjoining to, or upon, the river Euphrates, from which water was supplied by machinery, for the fountains and reservoirs employed for cooling the air, and watering the gardens." Yet the monarch whose power and wealth enabled him to construct these wonderful monuments, was as deeply impressed as the most reflective philosopher could be, with the fast-fleeting glories of all earthly materialities. Saadi, in his Gulistan, copies the inscription which Cyrus ordered to be put upon his crown. "What avails a long life spent in the enjoyment of worldly grandeur, since others, mortal like ourselves, will, one day, trample our pride under foot! This crown, handed down to me from my predecessors, must soon
pass in succession to the heads of many others." Remarkable as this may be, it is not nearly so striking as his epitaph:—"O man! whoever thou art, and wherever thou comest (for come I know thou wilt), I am Cyrus, the founder of the Persian empire. Envy me not the little earth that covers my body." Peace to his manes!

GARDENS OF THE EAST GENERALLY.

From the foregoing descriptions, it will readily be inferred, that gardens, among the Asiatics generally, were objects from which great pleasure was received; and hence the reason that they are so frequently spoken of by the inspired writers in such a way as to illustrate subjects of a spiritual or heavenly nature. One of the first essentials of an Eastern garden seems to have been elevation of situation. "When Semiramis came to Chanon, a city of Media," observes Diodorus Siculus, "she discovered, on an elevated plain, a rock of stupendous height and considerable extent. Here she formed another paradise, exceedingly large, enclosing a rock in the midst of it; on which she erected sumptuous buildings for pleasure, commanding a view of both the plantations and the encampment." The existence of these gardens, however, has been questioned; and so has even that of Queen Semiramis.

Looking back to a period 1500 B.C., Solomon's gardens necessarily come into view. The form of this plot was quadrangular; and it was encompassed by a high wall. It was adorned with plants of various descriptions—curious as objects of natural history, such as the hyssop: but it was also fragrant with the rose, the lily of the valley, cinnamon, spike-nard, camphire, saffron, and other plants. Its timber trees were the cedar, the pine, and the fir. Its fruits were the pomegranate, the fig, the grape, the apple, and the date. No doubt, like Milton's Eden, it was supplied with grots and caves of cool recess, over which the mantiing vine—

"Lays forth her purple grape, and gently creeps Luxuriant; meanwhile murmuring waters fall Down the slope hills, dispersed, or in a lake, That to the fringed bank with myrtle crown'd Her crystal mirror holds, unite their streams."

In the hotter parts of Eastern countries, a constant supply of water is so necessary, that were the application of this precious beverage to be denied to a garden but for a few days, everything in it would be literally burnt and destroyed. There is, therefore, in these parts, no garden whatever without a certain supply of water, obtained either from some neighbouring river, or from some reservoir, either collected from springs or filled during the rainy season, to an extent sufficient to yield an ample quantity for the rest of the year. As a general description of the manner in which an Eastern garden is laid out, that of the Emir of Berytus may be taken. Referring to this piece of art, Mr. Maundrell, in his Travels, says—"The best sight that the palace affords, and that which is most desiring of recollection, is the orange garden. It contains a large quadrangular plot of ground, divided into sixteen lesser squares, four in a row, with walks between them. The walks are shaded with orange trees of a large spreading size. Every one of these sixteen lesser squares in the garden was bordered with stone; and in the stone-work were troughs, very artificially contrived for conveying the water all over the garden, there being little outlets cut at every tree, for the stream, as it passed by, to flow out and water it." Kempfer describes the royal gardens at Isphahan as being watered in a precisely similar manner.

GRECIAN GARDENS.

The Greeks, original, elegant, and refined in most things, yet copied the Persians in gardening. We are informed by Diogenes Laertius, that the philosopher Epicurus took great delight in a garden, and chose such a scene for teaching his principles. This plot was in the city of Athens; and he is stated to have been the first who introduced the charms and enjoyments of trees and flowers into the heart of a city. Thus the pleasures of country life could be experienced without the necessity of going out of town, and those of town life might be participated in without having to go into the country. This was in accordance with the philosophy which teaches that happiness consists in pleasure, not certainly altogether of the pleasures of sense, but of that species of pleasure which would
deny an energetic activity to the faculties of the mind. The Athenians, however, enjoyed both the philosophy and the flowers, among which were the narcissus, the violet, and the rose. "The rich and polished Athenians," observes Gilbert Laing Meason, "preferred a residence in the country, that they might withdraw themselves from the jealously of curious citizens. In villa gardening they borrowed from Asia Minor. They had myrtles and roses; the box and the lime tree were planted for topiary works; and Theophrastus tells us that flowers and fruits were cultivated in the winter; and that the violet was in profusion in the market of Athens while snow was on the ground." The cemeteries of the Greeks may be included in their public gardens; and groves, and even the waysides, were sometimes chosen for the burial-places of public men.

ROMAN GARDENS.

The gardens of the Romans were similar to those of the Greeks, the one being a copy of the other. Those of the Emperor Nero partook of the appearance of one of our modern parks. Tacitus says—"Moreover, Nero turned the ruins of his country to his private advantage, and built a house, the ornaments of which were not miracles of gems and gold, now usual in vulgar luxuries; but lawns and lakes, and after the manner of a desert; here groves, and there open spaces and prospects; the masters and centurions being Severus and Celer, whose genius and boldness could attempt by art, what nature had denied, and deceive with princely force."
The city gardens of the Romans seem to have been nothing more than small square plots in the fronts of their houses, enclosed with trellis-work, planted with espaliers, and ornamented with fountains, urns, and other sculptural works of art. Plants in boxes and pots appear, sometimes on the walks and window-sills; and over the doors there appear climbers, resembling honeysuckles. The size of the plots would seem to have varied, as they do with us, from a few square yards up to, perhaps, a quarter of an acre.

VEGETABLE GARDENS.

In the laws of the Decemviri, among the Romans the word hortus originally meant both a garden and a country-house; but, in the course of time, the word pinguis was added to it, when the conjunction of the two words signified a kitchen garden. We are informed by Cato, that the principal citizens had their horti, or garden-farms, in which they reared their vegetables, close to the city. In the earlier ages these farms were cultivated by the hands of their proprietors, as was the case with Cincinnatus; and the success of some of these dignified growers, in the culture of certain plants, suggested family names, not only for themselves, but for future generations. Thus we have Pisum, from the pea, Cicero, from the vetch; Fabius, from the bean; Lentulus from the lentil; and others. If the owner had reared too large a crop of vegetables for his own use, the remainder was taken to the Fora Olitarum, and there exposed to sale. The principal culinary products cultivated by the Romans were cabbages, which were esteemed alike by the sovereign and the slave; turnips, carrots, beet, parsnip, radish, skirret, asparagus, sorrel, onions, and several kinds of garlic. Of leguminous plants, the pea, and the common, as well as the kidney bean, were cultivated. Of salads, endive, mustard, lettuce, succory, and others. Of pot and sweet herbs, dittander, alisanders, orache, parley, fennel, elecampane, chervil, and a variety of others. Mushrooms were in repute; and although not vegetables, we may here observe, that bees, snails, and dormice had appropriate places assigned them, as necessary additions to the kitchen garden.
CHAPTER II.

PRELIMINARY OBSERVATIONS; NONESUCH; PROGRESS OF GARDENING IN ENGLAND; THE ROYAL GARDENS AT WINDSOR.

PRELIMINARY OBSERVATIONS.

By the time that the Roman commonwealth had ceased to exist, the catalogue of fruits then cultivated had risen to a considerable number. According to Hirschfeld, the Romans had received the almond from Syria, the citron from Media, the peach from Persia, the apricot from Epirus, the pomegranate from Africa; pears, apples, and plums from Armenia, and cherries from Pontus. The list was greatly extended by the numerous different species of some of these, and the principles of grafting and pruning were both understood and practised. Even the mode of generating heat, and applying it to the purposes of horticulture, seems to have been known; but, with the decline of the empire, garden cultivation also declined, or, at least, became stationary. Subsequently it seems to have sunk into the torpid state into which the whole of Europe had passed; but, with the revival of learning, it awoke from the long slumber of the dark ages, and, once more, began to unfold its innumerable charms to the eyes and imaginations of men. For some time it continued to be repressed by the dreams of alchemical empiricism, the restrictions of unlucky days, and the supposed effects of lunar influences; but it gradually shook itself free from these chains of ignorance and superstition, and joined in the race of general improvement, which was fast taking place in society. Throughout Europe its advancement has been general; but in no state has it made greater progress towards its present condition, than it has done in Great Britain, where it has been cultivated with great steadiness, assiduity, and ardour, by men not only possessed of the means and position, but of the talents capable of developing the science in all its departments. It is to Britain, therefore, that we will chiefly confine ourselves in treating of this subject; and, also, more especially to the middle por-

tions of the island, taking mostly, for our guides and authorities, such men as Dr. Lindley, the first of physiologists, and Mr. C. Mackintosh, the first of gardeners. Before entering upon this portion, however, we will notice a few of the royal gardens of England, briefly tracing the progress of the art down to the present time.

NONESUCH.

After the revival of gardening in England, it made great progress in the time of Henry VIII., who encouraged and patronised the art, to an extent commensurate with his means. It was in his reign that the royal gardens of Nonesuch were laid out and planted. In a survey taken in 1550, above a century after the death of Henry, these gardens are said to have been divided into several compartments, alleys, and rounds, intended, no doubt, as an exemplification of improving taste, and surrounded with thorn hedges. On the north side was the kitchen garden, and, on the west, a wilderness separated from a little park by a hedge; the whole containing ten acres. In the private gardens were fountains, and basins of marble, pyramids and statuary, representing various subjects. Indeed, it seems altogether to have been an extraordinary place for the age. Hentzner tells us, that “Nonesuch was built by Henry VIII., with an excess of elegance and magnificence even to ostentation; as one would imagine everything that architecture can perform to have been employed in this one work. There are everywhere so many statues, that seem to breathe; so many miracles of consummate art; so many casts that rival even the perfection of Roman antiquity, that it may well claim and justify its name of Nonesuch, being without an equal; or, as the poet sung—

This which no equal has in art or fame,
Britons deserve to Nonesuch name.

“The palace itself is so encompassed with
PRACTICE OF HORTICULTURE.

In England.

The art was improved. It was in this reign that Chatsworth, the splendid seat of the Duke of Devonshire, was laid out; and Daines Barrington thinks that garden buildings were first erected in England during this reign, at Beckett, near Farrington; and the celebrated Inigo Jones was the architect. Evelyn flourished in this reign; and, by his writings and his taste in gardening, did much to improve the art.

During the reign of William and Mary, Switzer says that gardening had attained to the highest point of perfection; and we dare say that it is the opinion of many that such is the case at the present day. But any sudden revolution in the taste of the nation would change the whole of its features, now deemed beautiful and perfect, within the compass of a very few years. Daines Barrington informs us that King William greatly extended what is called topiary-work, which consists of giving fanciful forms to arbours and thickets, trees and hedges. This grotesque style was patronised by William, who loved to see clipped yews, accompanied with magnificent gates and rails of iron. The largest iron sercens of this kind in England, after those of Hampton Court, were formed by Switzer, at Leasowd, Flintshire, the grounds of which were laid out by that artist in a mixed style. Mr. Loudon informs us, that Hampton Court being, at this time, the actual residence of the royal family, the gardens underwent considerable improvement. "An elegant alcove and arched trellis were added at the end of one of the alleys, and four urns placed before the principal part of the house—supposed, by Daines Barrington, to have been the first that were thus used in England. Towards the end of this century, vegetable sculptures and embroidered parterres were probably in their highest vogue—a conjecture confirmed by the works of Le Blond, James, Switzer, &c., published during this and the following reign." Longleat, the magnificent seat of the Marquis of Bath, was laid out in this reign.

In the reign of Queen Anne, the principal alteration which appears to have been made, took place in the royal gardens at Windsor, when the parterre before the great terrace was covered with turf. It was this queen who...
caused the old gardens at Kensington, commenced by William, to be finished. Wise (of London and Wise, noted gardeners) was engaged for this purpose. He converted the gravel-pits into a shrubbery, laid out in meandering walks; the effect of which upon the mind of Addison was so great, that he elevated Wise to a comparison with an epic poet, considering the improved pits as episodes to the garden, which of course was, in the eye of the Spectator, the epic itself. Both London and Wise were nurserymen and designers, who enjoyed great popularity in their time. To them succeeded Bridgeman, who banished vegetable sculpture, substituting in its place wild scenes and cultivated fields. This was a better taste. He still, however, continued to clip his алleys, though he left to their natural growth the central parts of the masses through which they were pierced. "Blenheim, Castle Howard, Cranbourne, Bushy Park, Edger, Althorp, New Park, Bowden, Hackwood, Wrest, and, indeed, almost all the principal noblemen's seats in the ancient style, were laid out during this, the preceding, and part of the latter reigns, or between the years 1660 and 1713. Blenheim was laid out by Wise in three years. Wanstead in Essex, and Edger in Hertfordshire, were the last of London's designs.

Under the first of the Georges, gardening languished rather than improved; but under the second George, his queen enlarged and planted Kensington gardens. She also formed what is now called the Serpentine River, by uniting a string of detached ponds. This bold step was the precursor of subsequent changes in taste. It would appear from Daines Barrington, that Lord Bathurst informed him, that he (his lordship) was the first who deviated from the straight line in pieces of made water, by following the natural lines of a valley, in widening a brook at Ryskins, near Colnbrook; and that Lord Strafford, conceiving that it had been done from poverty, asked him to confess fairly how much more it would have cost him to have made it straight. In Mr. Loudon's Encyclopaedia, it is stated that Christopher Wren (chaplain to Charles I., Dean of Windsor, and father of Sir Christopher Wren, the architect) claimed, as his, the invention of making serpentine rivers. In a marginal note, affixed to Sir II. Wotton's Elements of Architecture, published in 1621, he says—"For disposing the current of a river to a mightier length in a little space, I invented the serpentine, a form admirably conveying the current in circular, and yet contrary, motions upon one and the same level, with walks and retirements between, to the advantage of all purposes, either of gardenings, plantings, or banquetings, or very delights; and the multiplying of infinite fish in a little compass of ground, without any sense of their being restrained. In brief, it is to reduce the current of a mile's length into the compass of an orchard."

The extent of Kensington gardens, originally, was twenty-six acres, to which Queen Anne added thirty, and Queen Caroline nearly three hundred more, taken out of Hyde Park, and laid out by Bridgeman. Beckham, who wrote in 1742, says—"The gardens of Kensington Palace, which are three miles and a-half in circumference, are very fine; they have been much improved and enlarged since his present majesty came to the throne, under the care and management of the late ingenious Mr. Bridgeman. They are kept in the greatest order; and in the summer-time, when the court is not there, are resorted to by a vast concourse of the most polite company." Canons, the magnificent seat of the Duke of Chandos, is one of the principal places laid out in the ancient style during this reign.

Having thus traced the rise, progress, and decline of the ancient style of gardening in England, we will now, without entering into the disputed point as to the originators of the modern style, give, principally from Mr. Loudon, a brief description of the royal gardens at Windsor, as being, perhaps, the finest in this country.

THE ROYAL GARDENS AT WINDSOR.

Notwithstanding that Windsor Castle has been a royal residence since the time of William the Conqueror, we hear nothing of the garden till the time of Henry V., when James I., of Scotland, celebrated it in a poem whilst a prisoner within the walls of the fortress. In the reign of Elizabeth, the principal terrace was formed on the north side of the castle; and in that of Charles II., this same terrace was extended round the east,
and a part of the south, front. During the reign of William and Mary, the Little Park was enclosed by a brick wall, and avenues of elms and clumps of forest trees planted. This was continued to be done by Queen Anne; but not one of these august personages seems to have thought anything about a garden. Although plans seem to have been suggested for furnishing the castle with gardens and pleasure-grounds, they do not appear to have borne fruit. Whately, the author of Observations on Modern Gardening, wrote, in 1772, a paper upon the subject, which he left in manuscript, and which, many years afterwards, came to light in the Gardener's Magazine. In this paper he says—"A more magnificent and delightful royal residence can hardly be imagined than that of Windsor Castle. The eminence on which the castle stands is detached from every other, and advanced into the plain which it commands; it falls in a bold slope on one side, while it is easy of access on the other; and, as the palace occupies almost all the brow, the whole hill seems but a base to the building. It rises in the midst of an enchanting country, and it is there the most distinguished spot; but though the situation is singular, it is not extravagant; it is great, but not wild. It is in itself noble, and all around it is beautiful. The view from the terrace is not the most: picturesque, but it is the gayest that can be conceived. The Thames diffuses a cheerfulness through all the counties where it flows; and this is, in itself, peculiarly cheerful. It is luxuriously fertile; it is highly cultivated; it is full of villas and villages, and they are scattered all over it—not crowded together. No hurry of business appears, and no dreary waste is in sight. Country churches and gentlemen's seats are everywhere intermixed with the fields and the trees. Every spot seems improved, but improved for the purposes of pleasure. All are rural, none are solitary: and the scenery of the plain is, at the same time, contrasted with the rich woods in the Great Park—their height, their shade, and their verdure."

This enthusiasm of Whately is by no means undeserving his theme; for, in reality, the whole domain which encircles the castle of Windsor, is, perhaps, not only the most beautiful, but the most magnificent in Great Britain. The Great Park has a circumference of eighteen miles; and both it and the Little Park are studded with large trees, mostly arranged in avenues. It is observed by Whately, that the space which these avenues enclose might be divided into three parts. "The declivities of the hill towards Frogmore and Datchet are comprehended within one of these divisions; the level from the foot of the hill towards Datchet, constitutes the second; and all the plain which borders on the Thames, from Datchet to Eton bridge, is included in the third." Mr. Loudon observes, that, in the first of these divisions, the ground varies considerably. Ancient oaks and lofty elms are scattered about, sometimes crowning the brow of the descent, and at others giving richness to the valleys. Among these trees appear different views of the towers of the castle; and, from some points, two fronts may at once be seen in perspective. The beauties in the second division are of a tamer character. The castle is entirely hid; and the principal point of importance is a little water-course, which might easily be converted into a rivulet. The plain between the castle and the Thames is remarkably rich; and it is on this side that the slopes are situated, which, in the latter part of the reign of George III., were turned into a garden. On the other side of the Great Park stretches Windsor Forest—a vast tract, which exhibits almost every possible variety of scenery. The slopes, which form the declivity of the hill, making the north terrace, were first enclosed in the reign of George III.; but about eighteen acres of pleasure-grounds adjoining them were subsequently laid out.

In the reign of George IV., a grant was obtained for making improvements in Windsor Castle; and a suite of apartments was built, under the direction of Sir Jeffery Wyatville, a new terrace being formed in front of them, which was carried round a small flower-garden. This garden comprises between three and four acres; and is twelve or fifteen feet below the level of the new terrace, which is on the same level as the old terraces. The descent to the garden is by two flights of stone steps. The orangery is formed under part of the terrace, and has an opaque roof. It is lighted by upright windows, after the manner of the old
orangeries at Kensington and Versailles, facing the south and south-west. It follows, from this arrangement, that those walking on the terrace round the flower-garden, look down on its arena of grass, and beds of trees and shrubs on the one hand; and outwards towards the splendid park scenery on the other. The effect thus produced is dignified and grand, and well suited both to the castle and the situation. The slope is grass; and the greater part of the level surface of the garden is in grass also, with beds of shrubs and flowers parallel to the walks. There is also a slope of turf from the inner edge of the terrace to the level arena of the garden. Several years after the foundation of this garden, it received the addition of a number of marble vases and some statues, nine of which were in marble, and seven in bronze. Some of these are from the antique; but the others resemble those seen in the French gardens, laid out in the time of Louis XIV. A fountain was also erected in the centre of the garden; and additional improvements are still being made to this royal domain, which is the finest in England.

CHAPTER III

POINTS IN A GARDEN; PLAN; SIZE; FORM; WATER-SUPPLY; SITUATION; SOIL; WALLS; SLIPS AND RING-FENCE; SHELTER; HOT-HOUSES; THE MELON-GROUND; DISTRIBUTION OF THE GARDEN AREA.

POINTS IN A GARDEN.

Previous to the planting of a garden, there are various points to which attention should be given, and which will indeed, to a large extent, absolutely determine the manner in which it must be arranged and laid out, in order that its space may be thoroughly utilised, both as regards beauty, and the fruits, vegetables, and flowers with which it is intended to be stored and adorned. The principal of these points comprise Plan, Size, Form, Water-supply, Situation, Soil, Walls, Slips, and Ring-fence; Shelter, Hot-houses, the Melon-ground, and the Distribution of the Area.

PLAN.

Whatever is to be carried out with taste, skill, or enterprise, no matter of what character it may be, the mind should previously form a clear conception upon, at least, its principal features, if for no other purpose than to impart greater vigour to action, and ensure greater certainty of success. It is thus that every general conducts his campaigns. It was thus that Napoleon I. acted previous to his setting out to make his Italian conquests, when he swept the legions of the Austrians before him. He planned and calculated; foresaw, conquered, and entered the capitals of his foes, and even predicted where battles should be fought between the contending forces, and which actually did take place on the very spots, as indicated by black and red-headed pins on the maps of the countries through which he was to lead his armies. Although the designing of a garden is a much more humble effort than the planning of a campaign, still it ought to be considered of sufficient importance to those who are to enjoy its fruits, to induce them to make a draft of its general features in their own minds before they commence to form it. Indeed, everything connected with this part of it should be clearly set down upon paper. “A well-arranged plan,” says Mr. G. Mackintosh, “is as necessary in commencing a garden, as in beginning to build a mansion, if unity and system are things worth caring for. The whole of the projected arrangements of a garden should be laid down on paper, and submitted to competent examination. The execution of the different parts
may be carried into effect at once, or progressively, according to the wants and wishes of the owner. Thus the walls may be built; artificial shelter planted, if required; the ground drained, levelled, and trenched, so that the fruit trees may be early planted, as it requires some years to bring the majority of them to a fruit-bearing state."

SIZE.

As a matter of course, the size of a garden must be determined by the amount of products desired to be obtained from it, the place in which it is situated, the family it is to supply, and, in some degree, their social position. It should, however, be proportioned to the dwelling to which it is attached, and to the number of inhabitants it does or may contain. This is a judicious rule; yet it is always better to have the garden too large than too small; and it is not considered anomalous for a large garden to be annexed to a small house. It is well known that there are some families who care very little about vegetables; whilst there are others who prefer them to almost every other kind of food. Some will go for weeks together without them, whilst others will not go a day. Accordingly, it may be as well to state, that the quantity of ground to be laid out for a family of four persons, exclusive of servants, should be a rood, provided it be good working, open ground; and the same proportion preserved in calculating for higher numbers. If it be possible, however, to allow more, it should be done, as the over-ground may be allotted for the cultivation of the strawberry in all its varieties; or, if not for this, it may be stocked in such a manner as to secure the family from, at any time, running short of vegetables. It should also be considered that artichokes, asparagus, and a long succession of peas and beans, require a quantity of ground; whilst, if cucumbers, melons, &c., are to be raised in any considerable quantity, the hot-beds necessary for them will occupy a good deal of room.

FORM.

Either a square or an oblong is the form most approved of by practical men for a garden. Abercrombie, however, proposed the long octagon form; or, in other words, an oblong with the angles cut off, reasoning, as a reason, that it equalised the advantages of aspect between the inner and outer sides of the wall. Hill recommended a geometrical square, "set out in such a manner that each wall may have as much benefit of the sun as possible." Besides these, circular, oval, and irregular figures have been recommended and adopted; but the general opinion is, that the square or oblong form is the most convenient; but every form appears to be admissible. "The oval, polygonal, and trapezium forms have been adopted for the walls of a garden," says Mr. Loudon, "in order to procure a more equal distribution of sun and shade; but the inconveniences attending the culture and management of the compartments of such gardens are considerable. Nor does it appear that an equal distribution of sun is so suitable as that of having some walls as advantageously exposed as possible for the more delicate fruits, and others less so for harder sorts, and for retarding fruits."

WATER-SUPPLY.

Water is one of the most essential elements in all garden operations. To a kitchen garden it is indispensable; and from whatever source it is supplied, it should be kept either in open cisterns, reservoirs, or in pipes properly protected, in different parts of the garden. It should, also, be handy to the hot-houses. Many kitchen crops are lost, or produced of very inferior quality, from being denied a sufficiency of water. It is from this circumstance that lettuces and cabbages are often hard and stringy; that turnips and radishes do not swell; that onions decay; and that cauliflowers die off. Generally, in dry seasons all the Crucifera (turnips, cabbages, radishes, &c.) become stunted, or covered with insects, even in rich deep soils. Even the foliage of fruit, as well as other trees, requires watering in dry seasons. By dispensing it freely, it destroys and prevents the accumulation of insects, and the fruit of the strawberry-bush, and other fruits, are enlarged by it. "If there be no natural stream that can be conducted through a garden," observes Nicol, "water should be conveyed from the nearest river, lake, or pond; soft water being most desirable for the use of a garden."
SITUATION.

As convenience of situation is one of the first considerations that concerns us in the taking of a house, so ought it to be in making choice of the ground intended for a garden. In making this choice, the bottoms of valleys and all low situations should be avoided. "The greater warmth of low situations," observes Dr. Darwin, "and their being generally better sheltered from the cold north-east winds, and the boisterous south-west winds, are agreeable circumstances; as the north-east winds, in this climate, are the freezing winds; and the south-west winds being more violent, are liable to do much injury to standard fruit trees in summer, by dashing their branches against each other, and thereby bruising or beating off the fruit; but in low situations, the fogs in vernal evenings, by moistening the young shoots of trees, and their early flowers, render them much more liable to the injuries of the frosty nights that succeed them, which they escape in higher situations." Thus, of two evils, choose the least; and Professor Bradley adduces a fact decisive of Dr. Darwin’s opinion. A friend of his had two gardens, one not many feet below the other; but so different that the low garden often appeared covered with the evening mists, when none appeared in the upper one; and, in a letter to Bradley, he mentions, that his lower garden is much injured by the vernal frost, though his upper one has escaped. A similar fact is mentioned by Lawrence, who observes that he has often seen the leaves and tender shoots of tall ash trees after thick mists, to be frozen, and, as it were, singed in all the lower parts and middle of the tree; while the upper part, which was above the mist, remained uninjured.

As the selection of ground for a garden is a most important point, we will dwell upon it a little longer, and adduce several other opinions as to situation. Abercrombie says that this should not be so elevated as to be exposed to boisterous and cutting winds; nor should a very low situation be chosen, if circumstances afford any choice: but it should be situated conveniently for access from the house. Nicol and Forsyth agree in preferring a gentle declivity towards the south, a little inclining to the east, to receive the rays of the morning sun. "If it be situated in a bottom, the wind will have the less effect upon it; but then damps and fogs will be very prejudicial to the fruit and other crops. If situated too high, although it will, in a great measure, be free from damps and fogs, it will be exposed to the fury of the winds, to the great hurt of the trees, by breaking their branches, and blowing down their blossoms and fruit." Respecting the situation of the kitchen garden Nicol speaks very strongly. In relation to the house, he considers the most awkward situation for the kitchen garden is to be in its front; especially if placed near, so that it cannot be concealed by some sort of plantation. "Generally speaking," he remarks, "it should be placed in the rear or flank of the house, by which means the lawn may not be broken and rendered unshapely where it is required to be meet complete. The necessary traffic with this garden, if placed in front, is always offensive. Descending to the consideration of more humble gardens, circumstances are often so arbitrary, with respect to their situations, as that they cannot be placed so as to please or give satisfaction by their products. There are cases where the kitchen garden is necessarily thrust into a corner, and, perhaps, is shaded by buildings, or by tall trees, from the sun and air; where they are placed on steep slopes, in a northern aspect, the subsoil is a clayey or cankering gravel, and the site cold and bleak. Such situations as these are to be avoided, and may be considered among the worst possible. The next worst are open, unsheltered plains; but even there, if the soil is tolerably good, and the subsoil not particularly bad, shelter may be formed, so that, in a few years, the garden may produce a return for the expense laid out in its improvements."

SOIL.

As a good man may often enhance the respect of a humble office, so may a good soil make a fair garden, even in an indifferent situation. A bad man, however, degrades the best of positions; and a bad soil, let the situation be what it may, will never make a good garden. But it is within the power of
man to change the soil, although he cannot, except to a very limited extent, change the situation. He may cover what is bad with what is good; and, by degrees, so completely metamorphose the surface of the earth, that he will have no difficulty whatever in rearing the best crops upon it. Many of our best gardeners, in days gone by, were sometimes in the habit of sacrificing soil to situation; but this is not now so much the case. Nicol thought that several kinds of soil were necessary in the same garden; and Dr. Neill was of the same opinion. "It is a happy circumstance," says Nicol, "that, in many instances, we meet with different soils in the same acre. In the same garden they should never be wanting; and where nature or natural causes have been deficient, recourse must be had to art, inasmuch as the variety of fruits and vegetables to be cultivated, require different soils to produce them in perfection." Forsyth, in his Treatise on Fruit Trees, recommends a deep soil, "of a mellow pliable nature, and of a moderately dry quality; and if the ground should have an uneven surface, by no means attempt to level it; for, by that uncereness, and any little difference there may be in the quality, you will have a greater variety of soil adapted to different crops. The best soil for a garden is a rich mellow loam; and the worst a stiff heavy clay. A light sand is, also, a very unfit soil for a garden."

The soil of a new garden should be from two to three or four feet deep; and, according to Loudon, its varieties should comprise—strong clayey loam, light sandy loam (which are the two grand objects), a composition of one-fourth strong, with three-fourths light, loam; half strong and half light, and one-fourth light, and three-fourths strong. These, he says, by a proper treatment, and with the proper application of manures, may be rendered productive of any of the known and commonly cultivated vegetables in the highest degree of perfection. In selecting a piece of ground for a garden, it is not a bad plan to take for our guide the natural herbage with which it may be covered. Neill recommends this. He observes—"The plants growing naturally on the surface should be noted; as, from these, a pretty correct opinion may be formed of the qualities of the soil. The subsoil should also be examined. If this be radically bad, such as an iron lith with gravel, no drawing, trenching, or manuring will ever prove an effectual remedy; if, on the contrary, the subsoil be tolerably good, the surface may be greatly meliorated by these means. In every garden, two varieties of soil are wanted—a strong and a light one; or, in other words, a clayey loam and a sandy loam; different plants requiring these respective kinds. For the general soil, a loam of middling quality, but partaking rather of the sandy than the clayey, is accounted the best." Loudon recommends these qualities of soil:—a strong loam, a light loam, and a loam of medium quality; the latter occupying the borders, and about half of the compartments.

WALLS.

Walls with a south aspect have always been considered the best for growing fruits; and the approved height is from ten to twelve feet; but this is a circumstance usually decided by the form and size of the garden. With respect to the height of fruit-walls, considered merely as such, Nicol gives the preference to twelve feet; that height being very convenient for pruning, watering, and gathering the fruit. It also admits of a sufficient expansion for the branches of most trees. A small garden encompassed by high walls, has a bad effect, and presents a gloomy appearance; but if they be of different heights they give relief to the view. In a garden of an acre, for example, forming a parallelogram of the best proportion, and gently elevated, the north wall may be raised to the height of fourteen feet; the east and west walls to twelve feet; and the south wall to ten feet above the ground-level. Although walls are erected round a garden chiefly for the purpose of rearing fruit against them, still they have another advantage.—A kitchen garden may be as perfectly fenced and sheltered by hedges as by walls, which was the case in former times. But in order to obtain the finer fruits, it becomes necessary to build walls, or to erect pales as substitutes. The influence which walls have in increasing the temperature of the air immediately in contact with them, is estimated at 7° of south latitude. The mean temperature of a south wall, or within a few inches
of one, is equal to the mean temperature in the open plain of 7° further south. Hence it is that grapes, which ripen in the open air at Bordeaux, require a south wall in the vicinity of London, which is 7° further north.

The best materials for building the walls of a garden are pronounced to be bricks; and where these cannot be got, it is better, Forsyth says, to dispense with walls altogether, or to adopt wooden ones. Nicol is of the same opinion, although he considers stone best for the foundation and basement. Bricks are warmer and better for training trees upon than stone. It is, therefore, recommended that the south, east, and west aspects, should either be entirely composed of bricks, or faced with them. If the wall be entirely constructed of, or backed with stone, though faced with bricks, and trees are to be trained against such backings, the stones should be laid in regular courses of from four to seven or eight inches thick, and be each fifteen or twenty inches long, in order that there may be a frequency of joints, and that the trees may be properly trained against the wall. Dark-coloured whinstone (greenstone or basalt) is, after bricks, the next best material; and the nearer it approaches to black, the higher does it rise in value. Walls having south, south-west, or south-east aspects, against which apricots, figs, nectarines, peaches, and the finer kinds of pears and plums are grown, should be built with this stone, provided bricks cannot be obtained. The basement of the wall, however, should always be built of durable stone.

SLIPS AND RING-FENCE.

There are few who have walked into the country, and still fewer, we presume, whose usual abode is in the country, who have not observed that there is generally round the walls of large gardens a fence consisting of a hedge of some sort—a paling or a low wall, or sunk fence, placed at some distance from what may be called the inner or principal wall, by which the garden is surrounded. This is technically designated the Ring-fence, and the intervening space between it and the principal wall, is denominated the Slip. One of the objects of this arrangement is to enable both sides of the main wall to be brought into use if necessary; another is, to obtain an additional portion of garden-ground; and another is, to serve, in some degree, as a protection to the principal garden. The slip, according to McPhail, and most authors, should not be narrower than thirty feet; neither should it be so wide as to throw the plantation for shelter too far off. According to Nicol, the breadth should be, at least, twenty feet; in order to afford a sufficient border for the trees and a walk. It may, however, be increased in breadth to such an extent as to allow ground without the space, enclosed by the principal walls, for the supply of the family; and it may be enlarged on all sides, or any particular side, for that purpose. In addition to these opinions, Forsyth states, that the garden should be surrounded with a slip from forty to sixty feet wide, or more; and this, again, enclosed with an oak paling from six to eight feet high, with a chesal-de-frize at top, for the sake of additional protection, as well as of giving more strength to the paling. By making slips on the outside of the garden wall, ground, upon which gooseberries, strawberries, and currants may be grown, is obtained; and that part of the slip lying nearest to the stables (if well sheltered, and, at the same time, exposed to the sun), may be laid out in melon and cucumber beds; whilst, as has already been stated, both sides of the principal garden wall may be occupied by fruit trees.

SHELTER.

Shelter from the inclemency of the seasons is as necessary to the infancy or blossoming of the vegetable, as it is to that of the animal world; and horticulturists concur in the opinion that a garden should be especially sheltered from the east, north, and west winds. McPhail says that this should be done by hills, rising grounds, high buildings, or plantations of trees, and at such distances, on the east and west sides, as not to intercept the rays of the sun. Nicol is of opinion, that the kitchen garden should be sheltered by plantations; but should by no means be shaded or crowded by them. If walled round, it should be open and free on all sides; or, at least, to the south-east and west, that the walls may be clothed with fruit trees on both
Westerly winds seem to prevail most in the months of July and August; north-east during those of January, March, April, May, and June; north-west from November till March. The north-east wind is less frequent during February, July, September, and December; and the north-west less frequent during September and October, than in any other months.

As similar calculations have been made in the neighbourhood of Glasgow, the following table may serve for the west of Scotland:

<table>
<thead>
<tr>
<th>Wind Direction</th>
<th>Number of Days</th>

<td><strong>Total</strong></td>
<td><strong>365</strong></td>
</tr>
</tbody>
</table>

In Ireland, the prevailing winds are the west and south-west.

Whilst these tables may assist in enabling us to determine the quarters in which the garden requires the greatest shelter or protection, we may observe that this may not unfrequently be derived even from the natural shape and situation of the ground. It is observed by Néill, that gentle declivities at the bases of the south or south-west sides of hills, or the sloping banks of winding rivers with a similar exposure, are very desirable. If plantations exist in the neighbourhood of the house, or of the site intended for the house, the designer of a garden naturally turns his eye upon them as the means of his principal shelter. He takes care, however, that his ground shall be chosen at such a distance from them as will prevent his fruits from being shaded by them. If the plantations be young, and contain beech, elm, oak, and other tall-growing trees, allowance, as a matter of course, is made for this in the measurement of the distance. It is a rule, however, that there should be no tall trees on the south of a garden, except at a considerable distance. This has been suggested from the fact, that during winter and early spring, they fling their long shadows into the garden at a time when every sunbeam is a welcome visitor. On the east, also, they must be sufficiently removed to admit the orient beams of the early morn; but on the west, and more particularly on the north, trees may be suffered to be nearer—say, perhaps, within about a hundred feet—and they may be more clustered.

**HOT-HOUSES.**

It is frequently a matter of choice as to where the hot-houses shall be placed in a kitchen garden; but in extensive establishments, a whole garden, or walled enclosure, is sometimes entirely devoted to the cultivation of the products belonging to this department of horticulture. This is the case both at Kew and at Frogmore; but in places of more moderate dimensions, the hot-houses either find a position against the north wall of the garden, or against some of the cross-walls, which, here and there, partially intersect its area. Occasionally they are placed in the slip, which has greater width accorded to it for that purpose, either on the east or west sides of the garden, or on the north, where there may chance to be a favourable declination of the ground. It is the opinion of Mr. London, however, that their effect is always best when they are situated within the boundaries of the garden proper, either attached to, or on, the north of the cross-walls. In this way they are sources of greater interest to the proprietor, and come more naturally into the general course of promenade than by any other arrangement; for it must not be forgotten that the pleasure or satisfaction derived from even culinary hot-houses, does
not wholly consist in being put in possession of certain fruits of excellent quality (for, if so, recourse need only be had to public markets), but in marking the progress of the trees or plants on which these fruits are grown in all their different stages; and, as Nicol observes, in being able to say—These are the products of my own garden."

It is advisable not to mix culinary hot-houses with such as are erected for the rearing of ornamental plants. This is the case in some old-fashioned places which, like the customs of the East, have been handed down from father to son, as if they had been stereotyped from time immemorial. This, however, should not now be the case, if there be space enough for a different arrangement. In the old plans alluded to, the green-house, the plant-stove, or botanical hot-houses, were attached to those in which the culinary products were reared, without any considerations of taste, or suitableness whatever, entering into the minds of their owners. In some instances it was a work of necessity, and may still be in moderately-sized gardens; but where variety and effect are taken into the calculation, "the ornamental or curious productions of gardening will be kept separate from those whose beauty consists entirely or chiefly in their utility. In this way two distinct and strongly marked characters are produced, instead of scenery of a mixed and, as it were, neutralised character."

THE MELON-GROUND.

It is a practice pretty well established to place the melon-ground in the slip. Where the range of the hot-houses occupies the north wall, with such a degree of slope, or declivity, as will shorten the shadow of this wall in winter, when the sun is low, the melon-ground may then most appropriately be placed in what may be designated a bay of the slip behind the north wall. Mr. Forsyth, as he usually does, gives reasons for assigning a portion of the outside slip next the stable to hot-beds for raising melons and cucumbers. These are, first, because there will be no litter to carry within the walls to dirty the walks; secondly, the beds will not be seen from the garden; and, thirdly, there will be a convenience in carrying the dung, by which a great deal of time will be saved in carting and wheeling. It will be necessary, especially in exposed situations, he says, to enclose the melon-ground with either a wall or paling, from six to eight feet high. It was formerly a practice to enclose melon-grounds with reed-fences; but although these are tolerably warm, and are easily removed from one place to another, being made in separate panels, they are very apt to harbour vermin. It will certainly be found the most convenient plan to have the mould and compost-ground as near to the melon-ground as possible; and if placed between the pits and the hot-beds, it will be all the better. This is Loudon's opinion; so that when the melon-ground is placed in the bay behind the north wall, the compost-ground will occupy a space which would otherwise be too much shaded for hot-beds or pits.

DISTRIBUTION OF THE GARDEN AREA.

The most propitious seasons for forming or laying out a garden are those of the spring and summer; but at whatever period the operations are commenced, they should be disposed in such a manner as to enable them to be finished early in autumn, in order to admit of the planting of fruit trees, and the laying nicely the edges of the walks. When we have resolved to make a garden, the distribution of its several compartments is necessarily one of the primary considerations. In this we must, in a great measure, be guided by the form and size which we have determined to make it. "The best figure," says Forsyth, "is a square, or oblong, where the garden itself is of either of these forms; but if not, they may be laid out in any other figure that is thought to be most convenient." In some of our best gardens, the compartments are laid out in beds four feet wide, with narrow alleys. These alleys, however, occupy a large space, and are, therefore, not to be recommended for a small garden. Mr. Neil thinks that their "advantages of convenience and neatness, in enabling the workmen to clean and gather the crops without trampling the ground, seem to compensate for the sacrifice of space." For currant, gooseberry, or raspberry bushes, the compartments remain undivided; whilst for large perennial plants,
such as rhubarb and artichokes, narrow beds are not requisite.

In reference to the laying out of borders, it is recommended by Abercrombie, that those next the walls should be composed of prepared soil of from eight to twelve feet wide, and the same description of soil extended under the walls, in order to allow a liberal width for the roots to spread without impediment. Next to the borders a space should be left for a walk entirely round the garden, of from four to six feet wide. Some persons fancy a border on the inward side of the walk, for the cultivation of espaliers and esculents of small growth; whilst others divide the central parts, at once, into main compartments or divisions. In regulating the walks or alleys, convenience of access is the principal object to be attended to; and when the ground is large, its centre should be traversed by a walk, with parallel borders, from which cross-walks may be made to ramify, if necessary. It must be remembered that it is not enough to provide good surface soil for fruit-tree borders. In addition to this, the ground must be thoroughly drained, and the roots must not be permitted to penetrate the subsoil, but be kept within a few inches of the surface of the ground, that they may draw their nourishment from the upper soil. Respecting the most congenial soil for the nurture of fruit trees, we find an intelligent writer in the Gardner's Chronicle, observing, that the soil, in the most productive part of Kent, is locally called hossack or stone-shatter. The surface of this is a mixture of sandy loam, largely intermixed with small pieces of light-coloured Kentish rag-stone, and is from six inches to two feet deep on solid stone rock. In this soil, "fruit trees of all sorts flourish and produce abundantly; even peach and pear trees, of the most delicate kinds, grow with the greatest luxuriance, and are free from disease. To what are we to attribute this result? Fruit trees growing in the kind of soil just described produce short-jointed wood; when the roots are stimulated by rich manures, rampant luxuriant branches are produced; when they descend to a distance beyond the genial influences of the atmosphere, they absorb a large quantity of water, which the leaves are unable to get rid of by perspiration, and the inevitable result is green canker, and a whole host of diseases. Such trees continue to grow to a late period of the autumn, when the excess of the temperature, and the absence of sunlight, render it impossible for them to give off their supernumerary water by perspiration, the only means by which all trees and plants are enabled to part with it." On the other side of the question we find it stated, that trees in the stone-shatter soil, "grow slowly; their tissues become perfectly organised as they proceed, and are not liable to be acted upon by accumulated moisture. As the days become short, and the power of the sun declines, the motion of the fluids and the action of the cells gradually cease, when the whole system is in unison with the course of nature; in winter the roots are almost dormant, the branches are short-jointed, and well-ripened, and all are prepared to withstand the severity of the weather, and to awaken in spring, full of life and blossom."

In laying out the area of the garden, the principal points demanding attention are clearly enumerated by Mr. Loudon, in the following passage, with which we will conclude this part of our subject. "The area, or space enclosed by the garden walls, is usually formed into compartments, very commonly called quarters and borders, or narrow slips, running parallel to the walls and walks. The magnitude and number, both of compartments and borders, as well as of the walks, depend on the size of the garden, and partly, also, on the taste of the designer. Rectangular figures are almost universally preferred to both. The breadth of wall-borders ought, generally, to be the same as the height of the accompanying wall; the borders may be broader, but do not produce a good effect when narrower. In a garden of an acre within the walls, the walks are never less than six feet broad, the surrounding or wall-border from ten to fifteen feet, and the marginal borders from seven to eight feet wide. In the latter an espalier rail is frequently fixed about five feet from the edging of the wall; in other cases the trees are planted along the middle of the border, and trained as dwarfs; an alley, or a path, commonly two feet wide, separates the borders from the compartments. In the slip may be formed irregular compartments, or borders,
CHAPTER IV.

VEGETABLE STRUCTURES; PROPAGATING BY SEEDS; BY BULBS, SUCKERS, AND RUNNERS; BY SLIPS AND OFFSETS; BY LAYERS; BY BUDDING AND GRAFTING; BY IN-ARCHING AND CUTTINGS; BY SINGLE LEAVES.

VEGETABLE STRUCTURES.

In considering the microscopic portion of the vegetable structure, we find that its elementary tissues are few and simple. They consist of organs, to which the designation of cells and vessels has been given; the former taking the shape of minute bladders or vesicles, varying in size and form; and, united together, constituting what is called a cellular tissue. The latter are closed tubes of an elongated form, often tapering to each end, and, when combined, constituting vascular tissue. The distinction between cells and vessels is based on their comparative length; but occasionally, cells become lengthened so as not to differ from vessels in that respect. This is the case with some veins, and also with the filamentous or thread-like tissue of fungi. Where such long cells exist, they are briefly characterised by the thin and delicate nature of their texture. The first form of the elementary organs of plants is a closed spherical or elongated vesicle, its walls being composed of a membrane, in which a fluid is contained. If, after its development, it still continue closed, it then receives the name of cell; but if a row of vesicles, arranged in lines, become united in the course of development, so as to form a tube with an uninterrupted cavity, by absorption of the cross walls, then what has received the name of a vessel is produced. "On making a transverse section of a succulent stalk," says a modern scientific writer on Botany, "such as that of rhubarb, or of a cucumber or melon, we perceive, by the aid of a glass, circumscribed angular meshes and rounded openings; and, in a longitudinal section of the same stalk, similar meshes are also seen, with long tubes of various kinds. The membrane, forming the walls of both cells and vessels, is composed of a substance called cellulose, in many respects resembling starch, but differing in giving a yellow in place of a blue colour with iodine. The membrane has, in general, no visible pores or perforations, but fluid matters pass through it easily. Some plants—such as sea-weeds, mushrooms, and lichens—consist of cellular tissue alone, and hence are called Cellular plants; while others—such as ordinary flowering plants—consist of cells and vessels combined, and receive the name of Vascular plants."

PROPAGATING BY SEEDS.

Among the most curious, as well as difficult,
operations of gardening, is the propagation of plants. This is universally done by seed; but also, to some extent, by germs or bulbs, suckers, runners, slips, and offsets. Artificially, it is done by layers, budding, grafting, marching cuttings, and single leaves. It is a general rule that imported seeds should be sown as soon as possible after their reception, except in the case of such as speedily vegetate, which, however, should not be put into the ground either late in the autumn, or early in the winter. The reason for this advice is, that if they vegetated during the dark months of the year, the probability is that the young plants would be cut off. Hard seeds, and such as have no tendency to rapid vegetation, may be sown at those seasons when it is calculated that their growth will commence. A primary object, however, as regards all seeds, is to be sure that they have the principles of life in them; for some are deprived of their vitality very early after they are gathered, while others retain it only for one, or perhaps a couple of seasons. Another consideration of some importance, is the size of the seeds, as on this depends the depth to which they require to be covered with the soil. For the same reason, the texture of their own covering must be attended to. Mr. Loudon tells us, that on the form and surface of the outer coating of seeds, sometimes depends the mode of sowing, as in the carrot; and on their qualities in general, depends their liability to be attacked by insects. The germination of the seed, likewise, greatly depends on the presence of moisture, and a due amount of heat and air in the soil. No seed will sprout or germinate at 32° Fahr., nor if enclosed in hermetically sealed vessels, nor even if too deeply buried in the earth. Such are the points to be kept in remembrance in propagating by seed; whilst the nature of the climate, the soil, and the season, must assist in determining how, where, when, and by what quantity, the seed should be sown.

PROPAGATING BY BULBS, SUCKERS, AND RUNNERS

Whether the bulb be cauline—that is, growing immediately on the herbaceous stem or stalk—or radical, it generally requires to be planted very soon after it has been removed from the parent plant. It should, also, be put into light earth, and buried no deeper than about the depth of its own diameter from the surface. Bulbs which have attained to maturity, may be preserved for several months out of the soil, without their powers of vitality suffering in any degree; but infant bulbs cannot bear treatment of this kind. If withheld from the soil, they soon dry up, and become seriously injured, if, indeed, they do not entirely lose their vitality. *Suckers have been described as mere runners underground; and propagation by them is seldom adopted, unless it be in the case of some hardy shrubs, and the pine-apple. Plants raised by these means, among the former, however, are usually held to be of inferior quality; but in the case of the pine-apple it is otherwise. Where a system of good culture is pursued, an abundant stock is easily maintained to meet the necessities of a private supply, by making choice of the strongest suckers produced on the stem. The redundancy of these, of course, depends, more or less, on the amount of check which the plant may have sustained by the formation of the fruit. Rare sorts may be vastly increased by retaining the stump instead of throwing it away, which is usually done after the fruit has ripened, and placing it in a damp pit, with a bottom temperature of 90°. Every latent eye should then sprout, and a large quantity of young plants be the result. Loudon, in speaking of propagating by suckers, says, all that is necessary to be done is to dig them up, and to cut off each plantlet with a portion of root; after which its top may be reduced, by cutting off from one-fourth to one-half of the shoot, in order to fit it to the curtailed root; and it may then be planted either in the nursing department, or, if a strong plant, where it is finally to remain. Propagating by runners is, with a certain species, both convenient and certain. All that is necessary to be done, is to allow the plantlet on the shoot, or runner, to be well rooted before being separated from the parent. It may then be planted in the spot where it has been determined it shall remain.

PROPAGATING BY SLIPS AND OFFSETS.

A slip is a shoot which springs from the
PROPAGATION.] PRACTICE OF HORTICULTURE. [LAYERS, ETC.

upper part of the roots of herbaceous plants, and may be readily seen in the auricula, or in under-shrubs, as the thyme. When the lower part, from which the roots proceed, has acquired a comparatively firm texture, or begun to ripen, the shoot sought is to be slipped or drawn from the parent plant, so far as to take with it a claw of the old wood stem, or root. As this claw is usually ragged in its edges, it is to be made smooth by means of a sharp knife, and the slip then planted in a congenial soil. It should be kept in shade until it strikes root afresh, or appears to have recovered from the effects of its separation from the parent plant. Propagating by offsets is, strictly speaking, applicable only to young radical bulbs, which, when taken from the parent roots, are only termed offsets.

PROPAGATING BY LAYERS.

A layer is a branch bent into the earth, and half cut through at the bend, the free portion of the wound being called a "tongue." It is, in fact, a cutting only partially separated from its parent. Dr. Lindley, in his celebrated work on the Theory and Practice of Horticulture, informs us, that the object of the gardener is to induce the layer to send forth roots into the earth at the tongue. "With this view he twists the shoot half round, so as to injure the wood vessels; he heads it back so that only a bud or two appears above ground; and, when much nicety is requisite, he places a handful of silver sand round the tongue part; then, pressing the earth down, so as to secure the layer, he leaves it without further care. The intention of both tonguing and twisting is, to prevent the return of sap from the layer into the main stem, while a small quantity is allowed to rise out of the latter into the former; the effect of this being to compel the returning sap to organise itself externally as roots, instead of passing downwards below the bark as wood. The bending back is to assist in this object, by preventing the expenditure of sap in the formation, or rather completion, of leaves; and the silver sand is to secure the drainage so necessary to cuttings." Layering is practised in the case of roses and other shrubs, which do not strike so readily by cuttings. It is a matter of no importance as to how the layering is effected. It may, therefore, be varied according to circumstances.

PROPAGATING BY BUDDING AND GRAFTING.

These operations, says Dr. Lindley, consist in causing an eye or a cutting of one plant to grow upon some other plant, so that the two, by forming an organic union, become a new and compound individual. The eye, in these cases, takes the name of bud; the cutting is called a scion; and the plant, upon which they are made to grow, is named a stock. Propagation by eyes and cuttings is, therefore, the same as budding and grafting, with this important difference—that, in the one case, the fragments of a plant are made to strike root into the organic soil, and to grow on their own bottom, as the saying is; while, in the other, they adhere permanently to living organic matter. In like manner, the operation of inarching, or causing the branch of one plant to remain attached to its parent, and, at the same time, to grow upon the branch of another tree, is analogous to layering.

The object of these operations is to effect many purposes. Plants, such as the apple and the pear, will bud or graft easily; but they are both difficult to strike from cuttings. There are many other plants of a similar constitution. It would appear, that the species which are naturally delicate, become strong when grafted on robust stocks. The result of this is a greater abundance of fruits and flowers. "Thus, the more delicate kinds of vines produce larger and finer grapes when worked upon such vigorous sorts as the Syrian and Nice. The double yellow rose, which so seldom opens its flowers, and which will not grow at all in many situations, is said to blossom abundantly, and grow freely, when worked upon the common China rose. One plant may be made to bear a different variety upon every branch, as has been seen with pelargoniums, fuchsias, and cacti. The peculiar qualities of some plants can only be preserved by working. This is especially the case with certain kinds of variegated roses, which retain their gay markings when budded, but become plain if left to their own modes.
of growing. Fruit may be obtained from seedling plants by these processes much earlier than by any others; the quality of seedling fruit trees may be ascertained in two or three years, instead of twenty or thirty; and thus long and objectless expectation may be avoided." It has been ascertained, by Mr. Knight, that it is within the reach of possibility to transfer the blossom-buds of one plant to another, so as to obtain flowers or fruit from them immediately. He thus fixed on the wild rose the flower-buds of garden roses; and these buds being plentifully supplied with nourishment, produced much finer roses than they would have done had they been permitted to retain their natural situation. He repeated many similar experiments upon the pear and peach tree, with equal success; but in the case of the pear, he discovered, that if the buds were inserted earlier than the end of August, or the beginning of September, they became branches and flowers.

The modes in which these manipulations were performed, were both numerous and various; and the whole theory was fully explained by De Candolle, in his Vegetable Physiology; by D'Albret; also by Knight, and others. The most valuable information on the subject, however, is to be obtained in Dr. Lindley's Theory of Horticulture, from which we have already quoted, and which is one of the best works on this subject in the language. As the parent possesses considerable influence over the scion, great care should be taken in making the selection. If nothing more than the increase of individuals was to be expected from the operations of budding and grafting, then the stocks most readily obtained, if of a relationship near enough to the scion or bud, would be the most suitable. But this is only of secondary importance. What is of far higher moment, is the fact that the operation ennobles the tree, by metamorphosing its character to an improved condition, whether as regards its flowers or fruits. To a certain extent, it hardens a tender sort when worked on a stock more capable of enduring cold, or one which is better adapted to the low-soil temperature of northern latitudes, than such as may be natural to the tree from which the bud or scion is taken. This fact is denied by Mr. Knight; but it is maintained by Dr. Lindley. In his Theory of Horticulture he says—" Probably in Persia, the native country of the peach, that species, or its wild type the almond, is the best stock for the former fruit; because the temperature of the earth is that in which it was created to grow. But in a climate like that of England, the summer temperature of whose soil is so much lower than that of Persia, the plum, on which the peach takes freely, is a hardy native, and suited to such soil; and its roots are aroused from their winter sleep by an amount of warmth insufficient for the peach. Experience, in this case, completely confirms what theory teaches; for although there may be a few healthy trees in this country, growing upon the almond stock, it is certain that the greater part of those which have been planted have failed; while, in the warm soil of France and Italy, it is the stock upon which the old trees have, in almost all cases, budded."

That budding and grafting may be practised with greater certainty of success, a soil suitable to the nature of the stock should be carefully chosen. Thus experiment has proved that, in loamy soils, the apple succeeds best on the Doncin stock; and in chalky soils, the crab. The pear thrives best in a loamy soil, or in light soils enriched with decayed vegetable matter, when grafted on the quince; but on light chalky soils the wild pear is preferable. The plum succeeds best on loamy soils; when worked on the plum stock; but it does better on the almond, if on chalky or light soils. The cherry thrives best in loamy, or in light rich soils, when worked on the wild cherry; and in chalk when on the mahaleb stock. In horticulture, as in every other science, one condition influences another. Thus, the stock considerably affects the fruit as well as the strength of the scion. This has been proved in the case of the Stanwick nectarine, which has a great tendency to crack rather than ripen in the ordinary way. We are informed that this tendency can be cured by being first budded on a very strong magnum bonum plum, about a foot high from the ground. The quality of the fruit is, in general, also improved by growing the plant in this manner.

Budding has been defined as consisting in
introducing a bud of one tree with a portion of bark adhering to it, below the bark of another tree. In order to accomplish this, a longitudinal incision is made through the bark of the stock down to the wood; and is then, at the upper end, crossed by a similar cut, so that the marks made bear a resemblance to the letter T. The bud, with a portion of the bark, is then pared off from the scion, and the back portion pushed below the bark of the stock, until the bud is actually resting on the naked wood of the stock. The upper lips of the incision in the stock, as well as in the bud, are made to fit each other, when the whole is fastened down by a ligature of bast applied wet, narrow tape, adhesive straps, or white or green worsted, which completes the operation. The bud should be inserted either when the vegetation of a plant is languid, or the growth above the place of insertion should be arrested by pinching the terminal bud. If this be not done, the sap, which should be impelled into the bud, in order to aid in the process of adhesion, passes on to other parts, and the bud is literally starved to death. For similar reasons, when a bud has firmly fixed itself upon a stock, and began to grow, the stock should be headed back nearly as far as the bud, with the view of forcing all the ascending current of sap to flow towards it. It is necessary that this should be done; for, if not, the buds of the stock itself will receive the nourishment which ought, more properly, to be given to the stranger.

In the operations of grafting, there are also some very essential points to be attended to. Dr. Lindley says, it is always found that a union between the scion and the stock occurs most readily when the latter is headed down; but as he is here thoroughly practical, we will take the liberty of quoting his own words. "The scion," he says, "should always be so prepared that a bud is near the point of union between itself and the stock; because, such a bud, as soon as it begins to grow, assists in the formation of wood, and, also, in binding the two together. The scion should be more backward in its vegetation than the stock, because it will then be less excitable; otherwise its buds may begin to grow before a fitting communication is established between the stock and scion, and the latter will be en-

hausted by its own vigour. If, on the contrary, the stock is in a state of incipient growth, and the scion torpid, cellular granulations will have time to form and unite the wound; and the scion will become distended with sap forced into it from the stock, and thus be able to keep its buds alive when they begin to shoot into branches. In order to assist in this part of the operation, a 'heel' is sometimes, in difficult cases, left on a scion, and inserted into a vessel of water, until the union has taken place; or, for the same purpose, the scion is bound round with loose string, or linen, with one end steeped in water, so as to secure a supply of water to the scion by the capillary attraction of such a bandage. Indeed, the ordinary practice of surrounding the scion and stock at the point of contact with a mass of grafting clay, is intended for the same purpose; that is to say, to prevent evaporation from the surface of the scion, and to afford a small supply of moisture; and hence, among other things, the superiority of clay over the plasters, mastics, and cements occasionally employed, which simply arrest perspiration, and can never assist in communicating aqueous food to the scion."

In concluding our remarks upon this portion of our subject, we give the following recipes, from Dr. Lindley's work, for making grafting-wax:—1. Bees' wax and tallow, equal parts, laid on warm with a painter's brush. 2. Four proportions by weight of pitch, four of resin, two of bees' wax, one of hog's lard, and one of turpentine, melted and well mixed. When this, or some similar composition, is spread on brown paper, it forms grafting-paper, as it is sometimes termed, which, being cut into slips, can easily be applied.—Another substitute for grafting-clay is sheet india-rubber, cut into narrow strips or bandages, from one-half to three-quarters of an inch broad. The india-rubber is said to possess all the requisites sought for in clay. It is air-tight and water-tight, and will not fall away; it is, also, elastic, which admits of the swelling of the scion in its growth; and it is applied with great ease and rapidity. After wrapping the bandage round the graft and stock, as a linen bandage is applied to a cut finger, the last turn only requires securing, by tying with a piece of thread or thin bast.
PROPAGATING BY IN-ARCHING AND CUTTINGS.

In-arching is supposed to have been the most ancient kind of grafting, as it naturally and by accident takes place in forests. The point in which it stands distinct from grafting, is found in the scion not being cut or separated from the parent, but remains attached to it, until it becomes part and parcel of the stock to which it is tied and adapted in a variety of ways. The scion and stock are, accordingly, mutually independent of each other, the former subsisting on its own resources until a complete union takes place between them. Professor Thowine enumerates no less than thirty-seven varieties of this mode of propagation. Practical gardeners, however, reduce these to two, which are thus defined by Mr. Mackintosh:—Crown in-arching, which consists of cutting off the head at the time of operating; side in-arching, which retains the head for a certain time. For performing these operations, generally, the spring is the proper season; but any season when the sap is in suitable condition, as it may be in hot-houses, will serve for the purpose. The effect of in-arching is the same as that of grafting, by inducing an earlier disposition to the bearing of fruit. It may, likewise, be applied to plants which may be difficult to propagate by other means. In order that in-arching may be the more certainly accomplished, Mr. Mackintosh says, that "it is necessary that the plants, both the stock and scion, should be either growing near to each other, or, if in a portable state, placed so that their branches may meet. A portion of the bark is then removed from each at the intended point of union—say from one inch to three inches in length, according to the size and strength of the subjects. These parts are fitted together so that the inner barks of both coincide; and the process of tying and claying, or mixing, follows, as in common grafting. Some, however, tongue the scion and stock in the same manner as is done in tongue-grafting. In either way, the cambium shortly becomes developed; the alburnum of the scion and stock becomes united; and when this is accomplished the scion may be cut off; a little below where it is united to the stock, either at one operation, or only partially cut through first, and, in a few days, completely severed. A week or two after the union has taken place, the remaining portion of the scion, if any is left on, when separated from the parent plant, should be cut off close to the stock, that the wound may heal over, and leave the stem as perfect as possible. Side in-arching without tonguing is well adapted for young shoots of camellias, oranges, &c.; and when the wood of both scion and stock is soft and full of sap, a union speedily takes place. Tongue in-arching is useful when both or either stock or scion are more fully matured, and are somewhat hard and dry."

Propagation by cuttings is, with the exception of grafting, by far the most common of all the modes of artificial plant culture, and depends upon its success from the circumstance of the cuttings themselves bearing leaf-buds or eyes upon their surface. In so far as physiological science can explain the operation of propagation by cuttings, Dr. Lindley states, that "it appears that roots are formed by the action of leaves; that branches are developed from the buds; and that the buds are maintained by the suitable aliment stored up in the stem. Everything beyond this seems to be connected with specific constitutional powers, of which science can give no explanation." The earth in which cuttings strike most readily is thus practically described by Dr. Neuman:—"Different sorts of trees do not root equally well in all soils. There are some cuttings which can scarcely be made to succeed in saline earth, while others succeed in it very well. The soils considered the best for striking cuttings in the open air, are those which are free, sandy, and soft to the touch. Tamarix elegens, and T. Germanica, prosper in a soil rich in saltpetre; but the Gingko and Poplars cannot strike in it. Cuttings made in glass-houses generally require to be planted in earth mixed with peat in preference to any other, but varied according to the nature of the plant. Whatever composition is used, we must take care not to employ it too dry, or too moist; in the first case, the earth not being able to sustain itself in a convenient manner around the cutting, the latter falls or is displaced when we wish to water it; in the second case, the earth being too compact, it
hinders the formation of roots. Nature makes vain efforts, and the cutting suffers, decays, and dies, in spite of its disposition to vegetate."

It is a rule with all practical gardeners, that the root end of a cutting should be close between a leaf-bud. Every one, however, seems to have a mode of his own in managing cuttings; and as the whole are too numerous to describe, we give the following by Professor Delacroix. "My cutting," he says, "is placed entirely under-ground, so as to form a subterranean curve, of which the convexity is uppermost, the very middle of the curve being on a level with the surface of the soil. At this middle point there must be a good eye, or a small shoot. In this way the whole length of the cutting is protected by earth, and the smaller end, instead of becoming the seat of dryness, which is always more or less injurious, becomes a passage for absorption. The bud, which, under these circumstances, is the only part exposed to the air, bears, without injury, or rather, with advantage, all the causes of excitement."—"Although I did not commence my experiments before the end of June," says a writer on this subject, "I have seen quite enough to satisfy me that the method may be of serious advantage. Two drills, about three inches apart, were drawn parallel with each other, in a kitchen garden of indifferent quality, situated on a calcareous plain near Besançon. A hundred cuttings of apples, pears, plums, apricots, tulip-trees, roses, &c., almost all of one year's wood, were bent and buried in the manner described, with their ends in the two drills. They were watered a few times; and, at this moment, every cutting in the open air, and exposed to the full sunshine, is just as fresh as it was when planted. In most of them, the part exposed to the air (the bud) is the seat of active vegetation, especially in the pear and tulip trees, the buds of which have already made some progress."

When the means at command of the propagator are limited, there is a method of striking cuttings in vials of water. A writer in the Gardener's Chronicle, thus describes his practice:—"I tie vial-bottles together by the necks, and hang them in the windows of our small greenhouse, having filled them with clean soft water. I then put in slips of salvia, calceolaria, mimulus, myrtle, or anything I wish to propagate of the same description of plants. In about two or three weeks, or a month, the little silver-like roots appear; and in a week or ten days I plant them in small pots well watered. They never seem to flag or mind the change, and I rarely lose a slip. Myrtles are longer in forming roots; cuttings from the same plant have varied from six weeks to twelve months. They were planted in November. A string of bottles I also hang against the back of the greenhouse, where they have plenty of light; and they do equally well, although not quite so quickly." This practice is old, and well adapted to soft-wooded plants; but even some of the hard-wooded kinds, such as azalias, will strike freely with this treatment.

Light has a great effect on the colouring matter of some plants. Ducaisne found that, in the madder plant, when the lower parts of it were enclosed in cases, glazed at the side with transparent green, red, or yellow glass, the leaves and stem of the part surrounded by red glass became pallid, and exhibited signs of suffering in a greater degree than under the other colours; but all were more or less affected.

PROPAGATING BY SINGLE LEAVES.

Some plants possess the peculiarity of producing adventitious buds upon their upper surfaces and edges; and some leaves, like those of the echeverias, strike root soon after they fall to the soil. Some genera, as the gloxinia, gesnera, clianthus, and others, require to have only the footstalk of their leaves planted in sandy soil, in which, with a proper temperature, they will produce young plants. These leaf-cuttings form, at first, a callosity at their base; then roots; and, lastly, a bud, from which the future plant is organised. Some plants produce this bud more freely than others; while a few exhibit great backwardness in producing it at all.
CHAPTER V.

TREATMENT OF THE SUBJECT: PLANTING FRUIT TREES; THE SORTS AND AGES OF PLANTS; DISTANCES IN PLANTING; PLANTING; TRAINING; PROTECTION OF THE BLOOM; ESPALIERS.

TREATMENT OF THE SUBJECT.

What has, in the preceding chapter, been stated in a general way, may, in some particular instances, in this be repeated, when speaking of those trees which more especially belong to the fruit garden. We will, however, avoid this as far as possible, only allowing ourselves to do so when we think greater perspicuity will be given to the special subject of which we may be treating. It has been customary to treat the fruit and culinary gardens as one, seeing that they are in reality often both united. But it is far better to keep them distinct; although this cannot, in many cases, be done because of the want of space. In large establishments, however, where system and order are held to be leading features in the arrangement of the grounds, the fruit and the kitchen gardens should be separately disposed, and each complete in itself. This would be a vast improvement on the promiscuous mode now generally practised; but, as we have said, in places of circumscribed dimensions this cannot be accomplished; so, we fear, that the medley system of huddling fruits and vegetables together within the same enclosing walls, must still be practised; and that it must be a long time before we can expect to see many examples of an entire separation between the culinary and fruit gardens.

PLANTING FRUIT TREES.

In the formation of a garden, the selection and distribution of the different kinds of fruit trees, is one of the most important and interesting points. Those which are adapted for walls, may be considered in respect to their sort, their fruit, the mode of planting them, and the distance at which they should be planted from each other. These are points which ought never to be lost sight of; nor should the advice of Mr. Nicol be forgotten.

"I have long made it my business," says this practical gardener, "to persuade my employers, in the planting of new gardens and orchards, to limit the varieties of fruit, in the firm conviction that I was acting for their interest; for, certainly, the rage for multiplying them, and of having a numerous collection, has too much prevailed of late. It were better to be contented with a few kinds which produce well in most seasons, than to plant many sorts for the sake of variety, of which a crop is obtained, perhaps, once in three or in seven years. It is, no doubt, of very great importance to select and adapt the kinds to the climate, soil, and aspect; and, in some situations, a greater variety may be planted with propriety than in others. This matter must be determined by existing circumstances, by the fancy of the proprietor, and by the discretion of the gardener."

In selecting the various sorts of fruit trees, and distributing them along the different aspects of the wall, principles should be adopted, and, if correct, as far as possible rigidly adhered to, and acted upon. In selecting fruits to be grown against walls, the general principle is, that the more delicate species of trees, such as the peach, fig, and grape, should be planted in the warmest parts. This is the most congenial situation for them; whilst the next warmest part should be assigned to the more delicate varieties of the hardier fruits, such as the cherry and pear; as well as to such descriptions of the hardy fruits as it may be desirable to bring to a state of ripeness at a very early period. Abercrombie lays it down as a rule, that the best border and wall should be given to the peach, the vine, apricot, fig, and nectarine. These are all delicate fruits; and the vine should, in this country, have the first place in respect to aspect, as it does not readily ripen out of doors north of London. Where a south aspect is not to be obtained for these
delicate fruits, a south-east and south-west are
the next best; although some of the earlier
kinds of the apricot will attain to maturity on
an east or west wall. In so far as regards the
cherry, it may be placed in any situation,
except that which is directly exposed to the
north; but the finest cherries will not arrive at
the height of perfection unless they have a south
border. The morello cherry, the plum, pear,
apple, and mulberry, will succeed on any wall:
"but all late fruit is universally improved in
proportion to the goodness of the aspect
from the west to the east, through all the inter-
mediate points to the south; and some of the
high-flavoured French pears require a high wall,
and a good aspect, to bring them to perfection."
For a free-growing pear tree, the end of a
building is a good situation; for if the wall of
the garden be not higher than usual, it will
not have sufficient room. A long and high
wall is also required for fig trees.

THE SORTS AND AGES OF PLANTS.

Standards planted against a wall are in the
form of dwarfs and riders, which may be one
year old from the graft, or they may be
several years trained. The permanent trees
are understood to be the dwarfs, the riders
being merely temporary plants, introduced to
give fullness to the upper portion of the wall.
In selecting from both kinds, it is the practice
to choose those trees which have passed
through the training of two or more years;
or should they, every second year, have been
moved in the nursery, they may take five or
six years to train; and in such case they will
bear immediately. Young plants, however,
are preferred by some gardeners. Regarding
the age of the plants, it is observed by Nicol,
that the "maiden, or one-year-trained trees,
are to be preferred, especially if apples and
pears. Even of the stone fruits such will
succeed best; though two or three years' trained are often planted. I here allude to
the dwarfs. Riders of greater age than
dwarfs may be planted, in any case, with pro-
priety, they being considered temporary, and
it being desirable to obtain fruit from them as
soon as possible." It is recommended as a
safe plan, to plant partly maiden and partly
trained plants; by which mode, those which
fructify early, should they turn out of inferior
quality, may be replaced by others, or re-
grafted with improved species. Meanwhile,
the kinds to which approval has been given,
will afford a return sufficiently early to com-
penate for any additional labour or expense
they may have cost.

DISTANCES IN PLANTING.

The distances at which the permanent trees
are planted, are regulated by the known
growth of the different sorts selected to be
trained against the wall, as well as by the
height of that enclosure. It may be remarked,
too, that the distance of the stem of the tree
from the wall, on the surface of the ground,
should be about nine inches. In rearing nec-
tarines, peaches, and vines, this distance may
be somewhat diminished. In respect to the
height of the walls, there are some slight dif-
fferences of measurement given. Marshall
says, that for one nine or ten feet high, the
distances at which nectarines, peaches, and
apricots are planted from each other, should
be twenty feet. For a wall twelve feet
high, Nicol gives the following distances:—
apples, eighteen or twenty feet; apricots,
from twenty to twenty-four feet; figs, from
teen to eighteen feet; nectarines and
peaches, twelve or fifteen feet; pears, from
twenty-four to thirty feet; and plums, eighteen
or twenty feet. For low walls, of no more
than five or six feet high, apple trees should
be planted at thirty feet apart, and plums from
twenty to twenty-four feet. "The distances
at which wall trees ought to be planted, ac-
cording to Abercrombie," says Mr. Loudon,
"depend on the general growth of the species,
connected with these other things—whether
the individual plant has been dwarfed by the
mode of propagation, or is a free grower;
whether the species will bear to be kept
within bounds by the knife; and, lastly, on
the height of the wall. Thus, a higher wall
is a compensation for a reduced distance, and
a lower will make it necessary to increase the
intervals. Supposing the wall to be twelve
feet high, the following are good average dis-
fences for planting the kinds named:—Vines,
from ten to fifteen feet apart, or in vacant
spaces between other walls, where the distance
is less, because the vine bears pruning well,
and can always be reduced to the prescribed
PLANTING.]  PRACTICE OF HORTICULTURE. [TRAINING.

limits. Peach trees and nectarines, from fifteen to twenty feet. Fig trees, from eighteen to twenty feet or more, as the bearers are not to be shortened. Apricot trees, fifteen feet, for the dwarf early sorts; eighteen to twenty-four feet for the free-growers, as this plant does not bear the knife well. Cherry trees, from fifteen to twenty feet; the strong-growing, large-leaved sorts requiring the wider distance. Pear trees, twenty feet, if on dwarf stocks; twenty-four to thirty feet, if on free stocks. Plum trees, from fifteen to twenty-four feet. Apple trees, if on dwarf stocks, fifteen feet; if on free stocks, from twenty-five to thirty feet. Mulberry trees, fifteen or twenty feet. Along the line of the walls only nine feet high, increase the intervals to one-fifth as much again; and of walls six feet high, to one-fourth."

PLANTING.

It is generally agreed that November is the best month to plant in, as at that time the leaves have mostly fallen to the ground. It is also agreed, that about the middle of December is the period when the tree should be headed back. Before planting, the root of each plant should be trimmed, cutting off the points of those which have been bruised in the taking up, and moderately thinning them out, if too thick, or too much crowded. Maiden trees do not often require this operation; but plants which have, for several years, stood in the nursery, or which have been trained against walls or pales, and have strong roots, frequently require thinning out. The roots should, in some degree, be rendered proportionate to the tops; and as the shoots and branches are to be headed down, or to be considerably shortened or thinned out, as a consequence, the roots should also be moderately thinned and pruned. In performing this operation, however, great care must be taken that the most promising plants, and those furnished with the most fibres, be retained. The spot for planting being determined, a pit, no deeper than that from which the plant has been removed, should be prepared, and the future tree placed just as deep, and no deeper, in the ground than it was before. The roots and fibres should be spread out, and carefully bedded in suitable compost. Then the common earth should be filled in, gently trod upon round the stem, preserving it a few inches clear of the foundation, and securing the plant from the injurious effects of high winds, by nailing it to the wall. Thus, should tree after tree be planted; and they will require no further attention till the following March, when they should be headed down.

TRAINING.

In training, the knife is the grand instrument; and he who has had sufficient experience and practice to be able to apply it with skill, may be said to have a perfect command over his trees. The points which most essentially belong to the operation of training are, that they should be as simple as possible, and the work of amputation or lopping be not too frequently carried on; that it should accord with the growth of the tree; and that it should be such as to render it more easy for the fruit to come to perfection. That these points may the more certainly be secured, it has been laid down as a maxim, that the knife should be used with some degree of reserve, as nothing is more injurious to the health and fructification of fruit trees of every description, than frequent and injudicious cutting.

In placing a fruit tree against a wall, it is evident that it is put into a constrained and unnatural situation, from which it would endeavour to make its escape by every means in its power. Much care is, therefore, necessary to check this tendency, as the more it is permitted to exert itself, the more unsightly must become the form of the tree. He, therefore, to whom the charge of a garden is assigned, should be well acquainted with the theory of vegetation; should make the manner in which different sorts of trees grow a study; and, above all, should never forget the real end or object of all training—the production of bearing wood. Perhaps one of the greatest difficulties is to preserve equality in the growth of the several points of the same tree. It should therefore be known that a shoot will push itself forth more vigorously when enjoying a free situation in the open air, than when it is nailed against a wall. Considering this fact, it naturally suggests that, in
training, a weak shoot should be left free, whilst a strong one should be restrained. A shoot slightly turning off from the perpendicular will, *ceteris paribus*, be more plentifully supplied with sap than one which is laid out in a horizontal direction, or deflected from its parent stem. The growth of a luxuriant shoot may, for some time, be impeded by having its tender extremity pinched off, when one of a much weaker description may even surpass it in the capacity of fruit-bearing. By giving attention to these hints and expedients, and making a judicious employment of the pruning-knife, it will be easy for any practical gardener to execute the general forms which trees are made to assume, and which are mostly detailed in horticultural works. The most simple of these, and the most practised for their general excellence, are distinguished as the *horizontal*, the *fan*, and the *half-fan* forms. But the choice of particular modes of training is too often determined by mere fashionable prejudice, which leads to the application of the same form in all sorts of trees. "Thus," says a writer on this subject, "the French are apt to reduce everything to the *fan* system, while some English horticulturists are inclined to force trees of the most rambling growth into the *pillory* of a horizontal arrangement. Such a uniformity cannot possibly be in accordance with nature. The enlightened cultivator will employ various forms, and will determine for himself which is the most appropriate, not only for every species, but even for each particular variety of fruit trees. By attentive observation and rational experiment, more knowledge in this department may be obtained in a few years, than by a whole life spent in routine practice."

PROTECTION OF THE BLOSSOM.

In a climate so variable as that of England, more especially in the northern and eastern parts of the island, it is necessary that the gardener should be furnished with such appliances as will enable him to protect the blossoms of his fruit trees from the late frosts in the season of spring. Frames covered with osnaburg, bunting, and similar light fabrics, have been recommended for this purpose, with the observation that they should be set in a slanting position in front of the trees. It is said that the best protection for wall trees are portable wooden copings about nine inches in breadth, attached to permanent iron brackets, fixed in the wall immediately below the stone coping. These wooden defences should be applied during spring, previous to the commencement of the blossoming and expanding of the buds; and there should be connected with them a material called scrim-cloth—a sort of thin canvas, admitting light very freely, yet, of itself, sufficiently capable to ward off frosts of ordinary severity. This cloth should be let down on the approach of evening, and drawn up again on the return of the morning; but any invention which serves to interrupt radiation, though it may fail to preserve the temperature much above the freezing-point, will act beneficially. Standard fruit trees must be left to themselves; and, indeed, from the lateness of the season at which they flower, they are generally more deteriorated by drenching rains and blight, than by the immediate influences of cold.

ESPALIERS.

In making choice of the trees most suitable for an espalier rail, it may be taken as a general rule, that those which are of a finer quality than can be cultivated with advantage as standards, are the best; and, at the same time, not to take such as require the greater heat and the protection of a wall. "It should be a maxim for all climates," says the Rev. Nathaniel Paterson, who has devoted much of his attention to horticulture, "that fruit, good of its kind, though the kind be inferior, is preferable to that of a better nature, but imperfectly produced. A good crop of codlings is better than a bad crop of golden pippins. . . . Having your walls already furnished with the best sorts that may suit your climate, you have only to go a degree lower in the scale to make up your espaliers. But should your wall be so limited as not to afford room for so many of the better sorts as might otherwise be admissible, it will be proper to cultivate as espaliers certain trees which ought, in other circumstances, to have a place on the wall. That part of your rails which is opposite to the south wall, and has some benefit from its reflection, is the most favourable for such an experiment. At the
medium elevation the Ribston pippin will do
well in this situation; for though it will not
come to such perfect maturity, it will yet be
better than most other fruits, and the tree will
prove more healthy than it usually does on the
best wall. A jargonello pear, in the like cir-
cumstances, may be not unsuccessfully tried;
and in lower situations, failing the extent of
wall, a variety of the finer sorts of apples and
pears may be raised in this way. The less
favourable aspects of the espalier rows must,
of course, be fitted up with such as are
coaoser and more hardy. . . . It
may be remarked that none of the stone
fruits do well for training in the es-
palier mode, save cherries, which bear for
a number of years on the old wood; but
though they admit of the protection of a
net as well as on the wall, yet this method
is in other respects less eligible, as the young
wood cannot be laid in to the same ad-

varied.

CHAPTER VI.

PRELIMINARY; THE GRAPE-VINE; THE FIG; PEACH; APRICOT; PLUM; CHERRY; PEAR; APPLE;
STORING Pears AND apples; QUINCE; MEDLAR; SERVICE-TREE; Mulberry; CURRANT; THE
GOOSEBERRY; RASPBERRY; STRAWBERRY; CRANBERRY; ALMOND TREE; HAZEL-NUT; WALNUT;
CHESTNUT.

PRELIMINARY.

In passing to particulars from the generalities
into which our treatment of the fruit garden
has, to some extent, necessarily led us, we
will commence with the more delicate or
tender sorts of fruits, and restrict the lists which
we shall give to selections from the very best
descriptions in present cultivation. It is in
the forcing garden alone, however, that many
of the finer sorts of fruits can be brought to a
state of perfection. To that department we
must, therefore, refer the reader for whatever
details we give of these, as it is there that, in
this country, the artificial processes of vege-
tation are pursued upon the principles of ex-
perimental science, and with a view to attain
to the highest results.

THE GRAPE-VINE.

This plant is generally considered to be a
native of Peru; thence passing into Egypt,
Greece, and Sicily. From this island it was
carried into Italy, Spain, and France; and,
ultimately, by the Romans into Britain, but at
what period is uncertain. That there were vine-
yards in England in a.d. 250, is certain, if the
authority of the venerable Bede is to be be-
lieved. But, however this may be, wherever
it is now cultivated in England, it is absolutely
necessary that it should have a good aspect;
and to the north of York, a dessert of grapes
cannot be produced without the assistance of
a hot wall. It is said that, in the extreme
south-west districts of England, grapes, suit-
able for the manufacture of wine, perhaps
equal in quality to those grown in the north
of France, might be produced on dwarf stand-
ards. Of this we entertain no doubt, unless
the climate has greatly changed for the worse,
as there is abundant historical testimony,
showing that productive vineyards once existed
in that part of the island. In the catalogue
of the London Horticultural Society, 197
kinds of grapes are enumerated. Some of
these, however, are of indifferent quality, and
some are utterly worthless. We will, there-
fore, select the names of a few of those which
are considered to be most deserving of the
attention of the cultivator.

Black Damascus, Black Hamburg, Black
Lombardy, Chasselas Musqué, Frontignan,
Muscat of Alexandria, Royal Muscadine, Nice
or White Nice, Barbarossa, Black Prince, Es-
perion, or Turner’s Early Black, the Syrian
Grape, Stillward’s Sweetwater, or Chasselas
Precoce, Troubiana, the Verdelho, and White
Sweetwater.

The Black Damascus is a late variety, and
does not set well; but its bunches are large,
and the berries round and sweet. The Black Hamburg is highly valued, and more generally cultivated in this country for the dessert than any other grape. There are several seed varieties of it in existence. The Black Lombardy is a late and excellent fruit. There are five varieties of the Frontignan, distinguished as the black, blue, grizzly, red, and white. They are all of great excellence. The Muscat of Alexandria has a most delicious flavour, but it requires a high temperature, and ought to have a vineyard set apart for itself. The other varieties require no especial remark, with, perhaps, the exception of the Esperione," which ripens on the open wall in the vicinity of London.

For a vineyard of ordinary description, the Black Hamburg, Chasselas Musqué, Stillward's Sweetwater, White Frontignan, Black Lombardy, and Royal Muscadine are recommended. For a slow or late vineyard, the Muscat of Alexandria, the Barbarossa (Black and White), the Grizzly Frontignan, the Black Tripoli, and the Canon-hall Muscat. For training against the rafters of a greenhouse, the Verdelho, the Black Prince, Black Cluster, and Esperione, are the most suitable. The grapes usually grown in England against the open wall are— the Esperione, White Muscadine, Miller Burgundy, Grove-end, Early Black, Pitmaston, White Cluster, and the White Sweetwater. Both in the north of England and the south of Scotland, hot walls are always required for the cultivation of the grape; but, even with this artificial help, vine-culture can never be calculated on with certainty in this country, if pursued in the open air.

THE FIG.

The fig tree is a native of Asia and Barbary, and was imported to England by Cardinal Pole, about 1525; but it is not a favourite in this country. Gardens of first-rate character, however, should not be without some trees; and the following are in greatest esteem:—

Angelique, Brunswick, Black, White, and Brown Ischias, Large White Genoa, Malta, Marseilles, Nerii, Brown Turkey, Péregusta, and Lee's Perpetual.

The Marseilles, the Brown Turkey, Lee's Perpetual, and the Black Ischia, are the best for forcing; whilst the others are better adapted for walls.

THE PEACH.

Persia is considered the original country of the peach; but this fruit, from time immemorial, has been cultivated in most parts of Asia. The characteristics of a good peach, or nectarine, are firmness of flesh, thinness of skin, depth and brightness of the red colour next the sun, and a yellowish-green next the wall. Its pulp should, also, be of a yellowish colour; and it should be full of high-flavoured juice, with the fleshy part thick, and the stone small. The two principal varieties of the peach, properly so called, is the one (the peach) with a downy skin; and the nectarine with a smooth skin. Each of these varieties is again divided by gardeners into freestones, or pêches, and clingstones, or poivre, according as the stone adheres to the pulp, or parts freely from it. In the horticultural catalogue, there are given 183 peaches, and sixty-five nectarines. One would think that invention would fail in finding names sufficient to distinguish such a family: we, however, will indicate a few of those most congenial to our climate.

Peaches.—The Acton Scot, Bellegarde (the Galande of the nurseries), Late Admiral, or La Royale, Madaline de Courson, Noblesse, Grosso Mignon, Red Nutmeg or Avant Rouge, Royal George, and Spring Grove.

The Red Nutmeg is one of the earliest, and produces abundantly. All the others are excellent varieties; and one of the very best late ones is the Late Admiral, which ought to be in every collection.

Nectarines.—Of these the best are the Early Newington, the Elrudge, Fairchild's Early, Hunt's Tawny, and the Red Roman. We may enumerate a few more first-class nectarines, suitable equally for open-air culture or for forcing. These are, of freestones—the Brinion, Downton, Murray, Pitmaston, Orange, Violette Grosse, Due de Tello, New White, and the Hardwick Seedling. Of clingstones—there are the Imperatrice and the Newington Tawny; but these last are not deemed so suitable either for open-air culture or for forcing.

THE APRICOT.

Armenia is the country in which it is sup-
posed the apricot originated; although Pallas states that it is found along the whole range of the Caucasus, the mountains of which, even to their summits, are covered with it. It is described as being, in Japan, a large, spreading tree, full of branches; and in China, as covering the mountains to the west of Pekin. It appears to have been first cultivated in England about 1562. It is used in a raw state for the dessert, and is esteemed next to the peach in the quality of deliciousness. It is also made into jellies, marmalades, and preserves. The following are the principal varieties:—

The Blenheim, Breda, Hemskirk, Moor-park, Musch-Musch, Kaisha, New Early, Roman, Turkey. Large Early, Orange, and Royal.

The Blenheim is of English origin, and a good bearer. The Breda is of the highest excellence, and in the south of England does well as a standard; but the best apricot in this country is the Moor-park, of which there are several sub-varieties, known by different names; and among them Shipley's is the best. The Turkey is an excellent late variety; and the Kaisha has quite superseded the red and white Musclines, which, in former days, were our earliest kinds.

The apricot, being a tree of much stronger growth than the peach, requires more room and pruning, both in summer and winter. The most common error in pruning apricots is the laying-in of the bearing-shoots too thickly. Referring to this tree, Dr. Lindley says that the principal branches "must be trained wider apart than those of peach and nectarine trees; but, in other respects, they should be regulated by the same principles. The main branches of the apricot may be fifteen inches apart."

THE PLUM.

The plum tree, although a native of, or, perhaps, only naturalised in, Great Britain, is supposed to have been originally taken from Asia Minor; for Pliny says that it was brought from Syria into Greece, and thence into Italy. It is frequently found growing spontaneously in our hedges; and in its cultivated state is highly esteemed as a dessert-fruit. "Plums," says Professor Martyn, "when sufficiently ripe, and taken in moderate quantity, are not unwholesome; but in an immature state, they are more liable to produce pains in the stomach, diarrhea, or cholera, than any other fruit of this class." There are many varieties, ranging from ten to nearly a hundred, as given by different authors; but the catalogue of the Horticultural Society gives 274 sorts. We notice a few of the best for the dessert, and then select some others, most esteemed for culinary purposes.

The Green-gage (or Reine Claude of the French), Coe's Golden Drop, the Drap D'Or, Angelina Burdett, the Blue Imperatrice, the Jefferson, the Reine Claude Violette, the Washington, Reine Claude de Bayav, Cowper's Large Red, Coe's Late Red, D'Agen, Blue Perdrigon, Downton Imperatrice, Lawson's Golden-gage, and the White Perdrigon.

It is supposed that the green-gage was introduced into England by the Gage family; and the foreign name having been lost, or forgotten, the present was given to it, as being the next most appropriate. It is, in every respect, a fruit of the highest excellence. When grown against a wall with an east or a west aspect, the fruit attains to a large size; but, as a wall tree, it rarely bears well till it is old. Coe's Golden Drop requires a wall of the most favourable aspect, and is excellent, both as a table and preserving plum. It does not succeed in a bleak climate. We are informed that the Angelina Burdett, the standard of England, and the Woolston black-gage, were, some years ago, raised from seed by Mr. Dowling, of Woolston, near Southampton. They are all plums of the highest excellence. Speaking of their qualities, Mr. Thompson says—"These plums are first-rate, and I should recommend their extensive cultivation. As regards the last, it throws the green-gage into the shade, for it contains all the properties of that fine plum, with more sugary sweetness. The Jefferson is the best of all the American plums. The Washington is also a good plum, and succeeds as a standard. Cowper's large red is a fruit of great productiveness, and on that account deserves a place in the garden. Gisborne's early plum is one of the best that can be recommended, especially for the northern parts of the island."

Of second-rate plums we may enumerate
the Cheston, Sharpe’s Emperor, the Fotheringham, Goliath, La Royale, Wilmot’s New Orleans, the Orleans, and the Morocco. There are also some Damasks, which should find a place in the garden. The Early Violet is a capital bearer, and highly recommended by Lindley for cottage gardens.

For preserving, and the use of the kitchen, the following are recommended:—The Caledonia or Nectarine Plum, Isabella, Shropshire Damson, Imperial Diadem, White Magnum Bonum, Red Magnum Bonum or Imperiale, the St. Catharine, the Mirabelle, Bullan, and Wine Sour, Deen’s Jedburgh Seedling, Denniston’s Superb, Tay-Bank, Topaz, Gisborne’s Plum, Guthrie’s New Apricot Plum, Pond’s Seedling, and Guthrie’s Minette.

In training plum trees they require plenty of room, and are chiefly propagated by budding upon Musell or St. Julian stocks. They are sometimes grafted; but when this is the case, gum is apt to exude from the tree at the place of junction. On common walls they should be allowed from twenty to twenty-five feet of breadth, over which to extend themselves; and for this purpose a preference should be given to such as have been trained in the nursery for a couple of years.

THE CHERRY.

In 73 a.c., the cultivated cherry was brought to Italy by Lucullus, the Roman general, who found it growing in Cerasus, the name of a town in Pontus in Asia, and from which the designation given to the fruit is derived. It is supposed to have been introduced by the Romans into Britain; but if such was the case, it would seem that it was suffered to die out. It is stated to have been re-introduced by Richard Harris, the fruiter of Henry VIII.; but Wharton shows, by a quotation from Lidgate, a poet who flourished about 1415, that the London hawkers exposed cherries for sale in a manner similar to that which is now done in the early part of the fruit season. The tree is very generally cultivated, not only as a wall, but as a standard fruit, and has been introduced to the forcing garden for upwards of a couple of centuries. The fruit is used as a dessert, and for making pies, tarts, and other elegant preparations, in both confectionery and cookery. The Horticultural Society’s catalogue, with geans included, gives no fewer than 219 varieties, of which the following may be considered as among the most excellent:—

The Bigarreau or Grasillon, Belle de Choissy, Black Tartarian, Amber or Yellow Spanish, Buttener’s October Morello, Early Purple Griotte, Elton, Harrison’s Heart, the May Duke, Late Duke, Morello, Kentish Cherry, and the Waterloo. Besides these, may be specified the Black Heart, Black Eagle, Early Heart, Bowyer’s Downton, Carniation, White Heart, Knight’s Early Black, and the Florence.

The Early Purple Griotte is the earliest of all cherries, generally ripening at the end of May. The May Duke is one of the most common, and, at the same time, one of the most valuable of cherries; but the Kentish cherry is one of the oldest and most prevalent of English cherries, much cultivated in the orchards of Kent. It ripens at the end of July, and is commonly grown as a standard. The Morello is a late cherry, much in request for confectionery; and of the same species are the Froimore, New Morello, and Rumsey’s Late Morello. The Bigarreau is an excellent fruit, largely cultivated in England for the London market.

Guignes, or Geans, are cherries, but in a state not so highly cultivated, or so far removed from their natural state. When old they are very prolific, and are usually grown as standards. The Amber Gean, and the Lunclo Gean, are the principal kinds; the former a sweet tender fruit, and an abundant bearer; the latter a small black cherry, of high flavour.

THE PEAR.

The pear tree bears its fruit on wood upwards of one year old, but principally on spurs, and very rarely on two-year branches. In the Theory of Horticulture, Dr. Lindley has the following remarks relative to the rearing of this tree:—“Plant a maiden tree in autumn; allow it to establish itself for one year, and then head it back to a good eye, a few buds from its base. Let one shoot grow as strong and upright as possible during the summer, and head it back to within thirteen inches of the
ground in autumn, cutting very close to a bud, in order that the shoot springing from it may form little or no bending. Train it upright; whilst three or four shoots, from buds immediately below it, should be more or less inclined to a horizontal direction, according to their strength; the strongest should be most depressed. These three or four constitute the commencement of the first or lower tier. For the next tier, head back the upright leader to within eighteen inches of its base, if the soil is rich; if not to fifteen inches; and from the shoots produced in the following season from buds, just under the cut, train a shoot for a leader, and three or four somewhat horizontally, as before, for a second tier. Precisely, in this manner, tier after tier must be started, till the tree attains its assigned height. All this can be effected in accordance with the natural disposition of the tree, to form an upright stem, and with the tendency of the sap to develop the uppermost buds of a shortened shoot. But it is not to be done without serious difficulties."

The list given of cultivated pears amounts to upwards of 600. We will, therefore, confine ourselves to specifying a few of the best dessert sorts, both early and late.

**EARLY.**—Autumn Bergamot or English Bergamot, Early Bergamot, Elton, Bourré d'Amalis, Citron de Carmes (this is the Madeleine of Lindley, and the Premature in Scotland), the Dunmore, Doyenné Blanc, Flemish Beauty, Fondanto d'Autoanne, Man- suette, the Summer Rose, the Jargonelle, Summer Francéral, Duhamel, Seckle, Red Doyenné, the Van Mons Leon Leclere. The summer and early autumn pears may be added. The Summer Francéral, Summer Bon-chretien, William's Bonchretien, and the Musk Robine. These generally require the protection of a wall.

The Jargonelle is the most esteemed, as it is the most common of our early autumn pears. It grows to a large size against the wall; but the fruit does not keep well. The Citron de Carmes is our earliest pear, ripening in July. It is a sweet pear without much flavour. The Summer Rose is an excellent variety, and the Summer Francéral a large bearer. The Early Bergamot is one of our best early pears; and the Autumn Bergamot one of our most richly flavoured. It ripens towards the end of October, but it does not keep.

**LATE.**—Of late pears the assortment is large; but the following may be viewed as some of the choicest:—Bergamot de Hollande, Bourré Dieu, Easter Beurré, Beurré Rance, Beurré Langelier, Brown Beurré, Beurré de Capiamont, Belle de Bourne, Moorfield Egg, Gansel's Bergamot, Bezi de la Motte, Marie Louise, Crasanne, Colmar, Passe Colmar, Poire Néel, and the Urbaniste. To these may be added, as late autumnal and winter pears, the Autumn Colmar, Aston Town, Beurré Spence, Eccassery, Bezi Vaet, Bezi de la Motte, Sylvange, Chammontelle, Glout Moreau, Downtown, Bacon's Incomparable, Duchesse d'Angoulême, Swan Egg, Winter Nelis, Flemish Beauty, Napoleon, Brougham, Calibasse, Chapter, Comp de Laney, Althorp Crasanne, Winter Crasanne, Dundas, Elton, Emeral, De Louvain, Eyewood, Fulton, Groom's Princess Royal, Jean de Witte, Louis Boune of Jersey, Mocass, No Plus Menus, and Knight's Monarch.

Of stewing pears, or the kitchen sorts, we may name—Uvedale's St. Germain, Catillar, Bellisimo d'Hiver, the Black Worcester or Ward, and the Gologil. These are either kept as dwarf standards, or placed on espalier rails, or inferior walls.

Of the early pears, the autumn or English bergamot has long enjoyed an established reputation for the high flavour it possesses. It comes to perfection about the end of October; but it does not keep. The jargonelle is the most esteemed of our early autumn pears; and when grown against a wall, it attains to a very large size. The fruit, however, does not keep well. The others call for no special remark. Of late pears, the Bourré Beurré is a plentiful bearer; and so is the Beurré de Capiamont. The Moor-fowl Egg is of Scottish origin, and presents us with two varieties, of which the Galston is the best. The tree is hardy, and the fruit of excellent quality. The plant should be grown as a standard. The Marie Louise is a large and an excellent pear, raised by Duquesne. Thompson says it is one of the finest, even as a standard, on which it bears abundantly. The Easter Beurré is hardy, and an abundant bearer. Thompson observes that it is one of the most valuable.
of the spring sorts, "compared with which, the early pears of short duration deserve not a wall." The Bourrè Race is the best very late sort yet known.

"Summer and autumn pears," says a writer on this subject, "should be gathered before they are fully ripe, otherwise they will not, in general, keep more than a few days. The Jargonelle, as Forsyth rightly advises, should be allowed to remain on the tree, and be pulled daily, as wanted; the standard fruit thus succeeding the produce of the wall trees. In reference to the Crasanne, Mr. George Lindley recommends gathering the crop at three different times: the first, a fortnight or more before it is ripe; the second, a week or ten days after; and the third, when fully ripe. The first gathering will come into eating latest; and thus the season of the fruit may be considerably prolonged. It is evident that the same method may be followed with the Brown Bourrè, and Gansel's Bergamot, or with any others which continue only a short time in a mature state."

THE APPLE.

In a wild state, the apple is a native of most European countries; but when the cultivated fruit first came into Britain is entirely unknown. It is supposed to have been introduced by the Romans, as, in the time of Pliny, these people were acquainted with twenty-two varieties. But, however this may be, we have it, on the authority of Stow, that carp and pippins were brought to England by Mascal, who, in 1572, wrote on fruit trees. The apple tree never bears, except accidentally, upon young wood. It is on wood two or more years old, and on the stunted branches called "spurs," that its fruit appears. The fruit is principally grown as a standard, which should have a clean, straight, and substantial stem. Of the apple, there are upwards of 1,400 varieties enumerated in the London Horticultural Society's catalogue, of which about one-seventh, perhaps, may be good kinds. To attempt to give detailed descriptions of such a multitude of species would be vain; we shall, therefore, confine ourselves to giving a list of the sorts deemed most worthy of the attention of the grower.

| TABLE APPLES.—The earliest of these are the Juneating, or White Geniton, ripening about the close of July; the Red, or Striped Juneating; the White Crofton, an abundant bearer, and useful for the kitchen, as well as the table; the Arb-roath Pippin, or Oslin; the Early Julian, or Clydesdale; Summer Golden Pippin; Red Quarrenden, or Devonshire, and the Early Harvest. To succeed these, we have Hick's Fancy, or the Early Nonpareil; the Autumn, or Royal Pearmain; the Doonside; Baird's Favourite; White Astrachan; Red Astrachan; Shepherd's Fame; Pearl's Plate; Old Golden Pippin; Franklin's Golden Pippin; Pomme de Nige; Maclean's Favourite; King of the Pippins, or Hampshire Yellow, a valuable variety; Kerry Pippins, one of the best of the Irish apples; CoLo Apple, or Scarlet Perfumed; Leishman's Pippin, and Longville's Kernal.

Winter dessert apples being in great force, we can only enumerate a few of the best. The Ribston Pippin has long held a high character, not only for the richness but the highly aromatic flavour of its juice. Hubbard's Pearmain is of the finest quality; the Golden Harvey, or Brandy Apple of Forsyth, though a small, is a capital fruit, characterised by Mr. Lindley as juicy, rich, and finely flavoured. It has the quality of great hardiness, and is an abundant and a constant bearer; and no garden in which a dozen trees can be contained, ought to be without one. The Downton Pippin is also an excellent fruit, and a large bearer; it ripens at the end of October, and keeps till January; the Yellow Ingestre; the Berehamnell; Court of Wick Pippin; Wood's Transparent; Scarlet Crofton; Scarlet Pearmain; Dutch Mignonette; Fearn's Pippin; Paradise Pippin; Old Nonpareil; Brad-lick's Nonpareil; Scarlet Nonpareil; Pintas-ton Nonpareil; Kirke's Golden Kemnet; Sykehouse Russet; Cornish Aromatic, a famous apple; the Sam Young, an Irish fruit; and the Norfolk Beaufin, which is the best apple for drying and preserving, making an admirable winter fruit.

| Dessert Apples.—The Baddon Pippin, and Barton's Incomparable, are excellent; as are the following:—Ashmead's Kernel; Clara Pippin; Christie's Pippin; Cockle Pippin; Cornish Gillyflower; Creed's Mari- |
gold; Colonel Vaughan's White Crofton; Ellford Pippin; Forman's Crewe; Scarlet Golden Pippin; Golden Russet; New Golden Pippin; Winter Golden Pearmain; Claygate Pearmain; Herefordshire Pearmain; Lamb Abbey Pearmain; Scarlet Pearmain; Royal Pearmain; Keeping Russet; Reinette Franche; and Powell's Russet.

Of American apples, the most suitable for our climate is the Boston Russet.

KITCHEN APPLES.—Under this specification we mean such as are principally used for tarts or sauces; and they are so very numerous that the names of some of the best can only here be given. The Nonsuch, Hanwell Sourcing, Fulwood, Menshnul Crab, Alexander, Blenheim Orange, Wheeler's Russet, Cat's Head, Forman's Crewe, and the Hunthouse of Yorkshire, are all held in high estimation. The Bedford Foundling is a certain bearer, whilst it is a large and handsome fruit; and the Cellini is a good apple for November. Some of the best apples for keeping long are Scottish Gogar Pippin; Moncrieff, or Stone Pippin; the Wormsley Pippin; Baxter's Pearmain; Winter Strawberry Apple; the Yorkshire Greening; the Northern Greening; the Calvill Malinger; Winter Lud; Pentcarland Pippin; Cockle Pippin; Green Fulwood Alfriston; Beauty of Kent; London Pippin; Hawthornden; Glory of England; Pope's Apple; Royal Russet; Carlisle Codlin; and the Eastern Pippin.

STORING PEARS AND APPLES.

For this purpose there should be attached to every considerable garden, a well-ventilated, commodious fruit-room, fitted up with the necessary drawers and shelves, and such other conveniences as may be found requisite. Forsyth says—"The fruit on shelves should be turned two or three times during the winter; as delicate and tender fruit, by lying long without turning, is apt to rot on the under side, even if perfectly sound when laid up. Be particularly careful, however, to pick out all the damaged fruit. When the fruit is laid in, put the earliest sorts on the lower shelves or in the lower drawers, according to their time of coming in, beginning with the Nonsuch, Golden Rennet, and Junecating apples; and Bergamot and Beurre pears.

Thus, by proper management, you may have a constant succession of fruit from one season to the other." The best way of keeping fruit, however, is to pack it in glazed earthen jars. "The pears and apples must be separately wrapped up in soft paper; then put a little well-dried bran in the bottom of the jar, and over the bran a layer of fruit, then a little more bran to fill up the interstices between the fruit, and to cover it; and so on, a layer of fruit and bran alternately, till the jar be full; then shake it gently, which will make the fruit and bran sink a little; fill up the vacancy at top with more bran, and lay some paper over it, covering the top with a piece of bladder, to exclude the air; then put on the top or cover of the jar, observing that it fits as closely as possible. These jars should be kept in a room where you can have a fire in damp weather."

THE QUINCE.

This fruit is a native of Austria, and other parts of Europe, and, in 1573, is mentioned by Tusser; but it does not seem to have ever been much cultivated in this country. The tree is much branched, of low growth, and generally distorted. Two or three trees are usually sufficient to be planted either in the slip or the orchard. They may be propagated either by grafting, by layers, or by cuttings; and the two principal sorts are the Portugal Quince and the Pear Quince, the latter being the most productive, and serving for all culinary purposes equally well as the former.

THE MEDLAR.

The Medlar is a native of the south of Europe, but appears to have been naturalised in some parts of England, by birds which, in their migrations, have sown it in copses. This is the opinion of Mr. Loudon. The varieties most worthy of notice are the Dutch Medlar with broad leaves, and the Nottingham Medlar with narrow leaves. The fruit is gathered in November, and kept till it begins to decay, when it is served up in the dessert, and much relished by some. The tree is propagated by seeds, layers, cuttings, or grafting on seedlings of their own species. The plant,
however, is somewhat difficult to strike by cuttings.

THE SERVICE-TREE.

This tree is a native of the mountainous parts of Cornwall, and, though not much cultivated, must not be entirely overlooked. Its fruit has a peculiar kind of acid flavour, and is used only when thoroughly mellowed by keeping. There is both a pear-shaped and an apple-shaped variety, both of which may be propagated by layers, or by grafting on seedling plants of their own species.

THE MULBERRY.

This is a fruit but little known in Scotland, although, in old gardens, there are to be found some aged trees which, in favourable seasons, yield some berries. The plant is originally from Persia; and, in this country, requires to be cultivated in warm situations. During the months of August and September, the fruit is in request for desserts, possessing a rich aromatic flavour, and a fine sub-acid juice. Where it grows abundantly, wine is made from it: and, in Devonshire, a little of the juice added to full-bodied cider, produces a delightful beverage, known as Mulberry Cider, which preserves its flavour for several months. The tree is propagated by layers or by cuttings; also by branches of an inch or more in diameter.

THE Currant.

Under the general title of Small Fruits, the red, white, and black currant, the gooseberry, the raspberry, the strawberry, and the cranberry are usually cultivated in this country. Their uses in cookery, confectionery, as well as in making some wines, give them considerable importance. Besides our red and white currants, there are included, in the Ribes Rubrum, many sub-varieties. Among these may be noticed as the principal—the Ruby Castle, the Dutch Red, Knight’s Early Red, Knight’s Sweet Red, Wilmot’s Large Red, Goodwin’s Red, Champagne, Dutch White, Woolly-leaved Dutch, Victoria White, and Wilmot’s New White.—The Black Currants comprise the Common Black, Black Naples, and Ogden’s Black Grape.

Red and white currants are easily propagated by cuttings, and succeed in any sort of common garden soil. They thrive best, however, in warm moist situations, where they may have the benefit of plenty of air. When planted by themselves, in separate compartments, or trained as dwarf standards, or as bushes from single stems of about a foot high, they are best; but care must be taken that the principal branches do not cross each other. In winter, the young bearing-wood is shortened down into spurs of from one to two inches in length.—The Black Currant succeeds best in a shady situation, with a deep, moist soil. Its culture is much the same as that of the other currants, only the young shoots are not spurred.

THE GOOSEBERRY.

The bush which bears this exquisite fruit is a native of several parts of Europe; and, in the Vallais, abounds in copse-woods, where it produces a small, green, hairy, and highly-flavoured fruit. In England it has been naturalised in various places against old walls, among ruins, and in the woods and hedges about Darlington. In Lancashire it is cultivated in greater perfection than in any other part of Britain. The following are some of the sorts recommended by the London Horticultural Society. Of the Yellow Kind—the Golden Yellow, the Yellow Ashton, and the Yellow Champagne, the Smooth Yellow, Smiling Beauty, Rumbellion, Sulphur, and Yellow Smith.—Of the Red Kind—the Rob Roy, Ironmonger, Red Champagne, Keen’s Seedling, Small Red Globe, Lord of the Manor, Leigh’s Rifleman, Wellington’s Glory, Shipley’s Black Prince, and the Red Warrington.—Of the White Kind—the Cheshire Lass, White Champagne, White Crystal, Bright Venus, White Damson, White Smith, and the White Honey.—Of the Green Kind—the Green-gage, Pitmaston, Langley Green, Green Gascoigne, Green Laurel, Late Green, Gregory’s Perfection, Green Walnut, Copper’s Bonnie Lass, and the Jolly Tar.

The gooseberry-bush thrives best in a loose, rich soil, which readily absorbs, but does not retain much moisture. It may be propagated by all the modes of application to shrubs or trees; even by pieces of the roots; but the mode usually adopted is by cuttings for com-
tinuous varieties, and that by seeds for procur-
ing them.

THE RASPBERRY.

This is a native of Britain, and is very often
found in woods where the situation is low and
moist. The fruit is grateful; but sugar used
with it heightens the flavour, which helps to
make it much esteemed when made into sweet-
meats, jams, tarts, and sauces. The best
varieties are the Red Antwerp, Yellow Ant-
werp, Barnet, Cornish, Red Globe, Belle
de Fontenay, Cox's Honey, River's Large-
fruited Monthly, Roger's Victoria, Francheon
White Monarch, White Globe, and Falstaff;
which last is the most profitable.

In propagating the raspberry, "varieties can
be perpetuated by young sucker-shoots, rising
plentifully from the root in spring and sum-
mer. When these have completed one season's
growth, they are proper to detach with roots
for planting, either in the autumn of the same
year or the next spring, in February or March,
but not later than the middle of April. These
new plants will bear some fruit the first year,
and furnish a succession of strong bottom
shoots for full bearing the second season.
New varieties are easily raised from seed;
and they come into bearing the second
year."

THE STRAWBERRY.

This fragrant, delicious, and universally-
esteeved fruit, is a native of temperate or cold
climates, such as Europe and America. In the
catalogue of the London Horticultural Society,
no fewer than 112 varieties are given; but
the following are sufficient for any garden, as
they are the most worthy of cultivation:—
Cuthill's Black Prince, for its early ripening
qualities; Grove-end Scarlet, most suitable
for preserving, on account of its fine Carmine
colour; Elton, on account of its late ripening;
British Queen; Myatt's Pine; Deptford Pine;
Eleanor; Ingram's Prince of Wales; Keen's
Seedling; Princess Royal; Princess Alice
Maud; Trollope's Victoria; Nicholson's Ajax;
White and Red Alpine; Sir Harry Myatt's
Mammoth; Largo Flat Hautbois, and Comte
de Paris.

Scientific gardeners have different modes of
growing the strawberry; and among these we
believe that the experiments of Mr. Cuthill, of
Camberwell, have been very successful. The
present writer has been shown, by this excellent
grower, numerous medals presented to him as
prizes, for the various varieties he has produced
by his judicious mode of cultivating this fruit.
"The plants multiply spontaneously every sum-
mer, as well by suckers from the parent stem as
by the numerous runners, all of which rooting
and forming a plant at every joint, require only
removal to a bed where there is room for them
to flourish. Each of these, separately planted,
bears a fine fruit the following season, and
will bear in full perfection the second summer.
A plantation of the Alpine yields fruit the same
year that it is made. The wood and the al-
pine come quite true from seed, and bring a
finer fruit than from offsets. The other species
are uniformly propagated by offsets, except the
intention be to try for new varieties."

In reference to the soil and site most suit-
able for strawberries, Neil says that they are
generally placed in a compartment of the
garden by themselves, and it should be one
which is freely exposed to sun and air. They
are sometimes, however, planted in single
rows, as edgings to borders; and in this way
they often produce great crops. In either
case, care must be taken to re-plant them
every fourth or fifth year at the furthest. The
alpine and wood species may be placed in
situations rather cool and shady; perhaps as
an edging in the shrubbery. In such places
they produce their fruit perfectly well, and
late in the season, which is desirable.

THE CRANBERRY.

This plant is a native of North America,
and was known to Miller, who, of the tribe in
general, says—"They can only be cultivated
for curiosity in gardens, for they will not
thrive much, nor produce fruit out of their
native swamps and bogs." The culture of the
cranberry, however, need not now be
confined to swamps and bogs. Salisbury
says that it may be cultivated very suc-
cessfully in situations not positively wet, if
only planted in bog earth, which retains its
moisture longer than any other soil. Halley
found both the cranberry and the bilberry to
succeed perfectly in a dry bed of peat earth;
so that it may be cultivated in any garden
where that kind of soil exists, or can be procured.

THE ALMOND TREE.

This is a native of China, and may be noticed here, although its importance as a fruit tree in this country is very little. Every good garden, however, should contain a tree or two as standards. In very fine seasons they will yield a crop; and in spring they are always ornamental, from the beauty of their blossoms. The sorts most worthy of notice, are the Tender-shelled Sweet Almond, or Jordan; and the Common Almond, or Bitter. The tree is generally budded on seedlings of its own kind; but, for heavy soils, plum-stocks are preferable.

THE HAZEL-NUT.

Of nuts the hazel is indigenous to this country, and is the original parent of the Red and White Filbert, the Cob-nut, Cosford-nut, Frizzled, Spanish, and other improved varieties. The whole of these thrive best in a rich dry loam, carefully worked, and receiving from time to time a slight application of manure. It is the usual practice to plant them in slip; but they succeed best by themselves in an open quarter. The mode of propagating them is by suckers or layers; and where there are stocks of the common hazel, the other sorts may be grafted upon them. Preference is generally given to the Cosford, on account of the thinness of its shell, and its possessing a kernel of high flavour. If the Filbert or Cosford be grafted on small stocks of the Spanish nut, which grows fast, and does not throw out side suckers, small yet fruitful trees may be obtained. By pruning the roots in autumn the trees may be kept in a dwarfish state.

THE WALNUT.

The tree which produces the walnut is originally from Persia, or the south of Caucasus; it does not, therefore, arrive at complete maturity in this island, except in the warmer districts. The common walnut is well known; but, besides it, there are several cultivated varieties, which are held in much esteem. These are the Large-fruited, or Double Walnut; the Tender-shelled; and the Thetford, or Highflyer. This last is by far the best walnut grown. It is only by budding that the varieties can be propagated with certainty; but this operation being rather delicate, frequently does not succeed. Upon this subject, that great gardener, Knight, observes—"The buds of trees, of almost every species, succeed with most certainty when inserted in the shoots of the same year’s growth; but the walnut tree appears to afford an exception; possibly, in some measure, because its buds contain within themselves, in the spring, all the leaves which the tree bears in the following summer, whence its annual shoots wholly cease to elongate soon after its buds unfold; all its buds of each season are also, consequently, very weedy of the same age; and long before they have acquired the proper degree of maturity for being removed, the annual branches have ceased to grow longer or to produce new foliage.” Notwithstanding many difficulties with which Mr. Knight had to contend, he at length succeeded in propagating the walnut tree by budding; but, as we have said, it is a very nice operation. The tree has generally been propagated by the nut; and this mode is recommended both by Miller and Forsyth; probably, Mr. Loudon thinks, from their not having known that the tree may be continued by inoculation, as successfully practised by Knight.

THE CHESTNUT.

Some of the oldest trees in the world belong to this species, which is supposed to have been originally brought from Sardis, in Italy, by Tiberius Caesar. It is so common there, as well as in France, as to be considered native to the soils of each country. Some consider it to have been naturalised in England; but, however this may be, it is well known to have been long an inmate of our forests. Several varieties have obtained celebrity, especially Knight’s Prolific, the New Prolific, and the Devonshire. These are propagated by grafting upon stocks raised from nuts; and when grafts are taken from bearing-wood, fruit may be produced in a couple of years. It is on a dry sub-soil that the tree succeeds best.
CHAPTER VII.

FORCING; RESTING; BUILDING OF HOT-HOUSES; APPLICATION OF ARTIFICIAL HEAT; CONSTRUCTION OF BOILER; DIFFERENT MODES OF HEATING; SCIENTIFIC INSTRUMENTS; SOLAR HEAT; LIGHT AND AIR; THE VINESERY; THE PEACH HOUSE; THE FIG-HOUSE; THE CHERRY-HOUSE; THE PINERY; THE MELONERY; THE CUCUMBER.

FORCING.

In the science of horticulture, the term forcing signifies the art of raising, by artificial heat, plants, flowers, and fruits at an earlier season than that to which nature has assigned them. To what nation or people we are indebted for the discovery of this art, we believe no one has yet shown; at all events, it could not have been made in those Oriental countries where the genial warmth of the climate is such as to produce two or three harvests within the year, and to furnish, spontaneously, successes of the finest fruits and vegetables known to man. It must, therefore, have been made in some of the nations of Europe where the climate is always more or less variable and uncertain. From Martial we learn that the Romans were acquainted with the use of hot-houses; but whence they borrowed the idea of their uses and structure nowhere appears. Tiberius Caesar, being fond of cucumbers, erected houses in his garden, and had them heated by means of stoves throughout the year. Pliny informs us that they were grown in boxes, which were, in fine weather, wheeled out into the open air, and returned to their artificial abodes in the nights or in cold weather. With the construction of flues the Romans were well acquainted, so they possessed the knowledge of the means of heating the houses constructed for the artificial ripening of their fruits and vegetables. In England, hot-houses for the growing of pines do not seem to have been known in the beginning of the eighteenth century. We infer this from the fact, that Lady Mary Wortley Montague, on her journey to Constantinople, in 1716, makes the remark of pine-apples having been served to table in the dessert, at the Elector of Hanover's—a circumstance she had neither seen nor heard of before. Had pines been then raised in Eng-
cases, cold. In the tropics it is marked by coolness and dryness, while the summer is rainy and very hot; and in extra-tropical countries the two seasons vary in their character, in accordance with latitude and local circumstances.

The above is sufficient to lead to the conclusion, that "the natural resting of plants from growth is a most important phenomenon of universal occurrence, and that it takes place equally in the hottest and the coldest regions. It is, therefore, a condition necessary to the well-being of a plant, not to be overlooked under any circumstances whatever; and there cannot be any really good gardening where this is not attended to in the management of plants under glass. Rest is effected in one of two ways—either by a very considerable lowering of temperature, or by a degree of dryness under which vegetation cannot be sustained."

BUILDING OF HOT-HOUSES.

It is not necessary that we should recapitulate here what has already been written by many authors on this subject: it may be remarked, however, that the improvements in the construction of hot-houses have by no means kept pace with those which have, within these few years, taken place in other departments of gardening. In the *Annals of Horticulture*, a writer observes—"There is yet much which remains to be realised in the erection of houses for the cultivation of plants, not only as regards their number and dimensions, but also their arrangement and details. We seldom see more than the same kind of flat lean-to or gabled roofs; the same kind of formal stages where the plants are grown in pots; and the same kind of formal beds where the latter are planted out in borders of prepared soil. Even refinements or elegancies of construction fail to invest such buildings with any character of distinctness or novelty, owing to the sameness or monotony which forms the basis of the design." Since this was written, however, there have been improvements in the construction of hot-houses. This has, perhaps, been more especially the case in regard to the roofs. Among these, the ridge-and-furrow form, as it is called, may be considered the greatest. It was, in 1816, first suggested by the late Mr. Loudon, and afterwards admirably worked out by the late Sir Joseph Paxton, in the large house at Chatsworth and elsewhere; but more recently in covering in nearly twenty acres of ground for the Exhibition in Hyde Park. This, at the time, was the largest building ever constructed of timber, iron, and glass; and showed, with the most perfect clearness, the possibility of extending the same description of pillared covering over any space, however extensive.

In discussing the merits of this subject in his *Book of the Garden*, Mr. C. Mackintosh says, that "the greatest advantage of a ridge-and-furrow roof is, that any extent of area may be covered without internal walls. Indeed, no walls whatever are required, as the sides and ends may be glass close to the ground—the whole being supported on cast-iron tubular columns, with cast-iron valleys, or gutters. A good idea of the effect and practicability of roofing over a whole garden, may be obtained by a careful examination of some of our most extensive railway stations—that at Derby, for example, which, we believe, could be extended over a hundred acres, if required."

We do not wish to enlarge upon this subject; but it may not be amiss to give, in Sir Joseph Paxton's own language, an explanation of the *principles* of this improved sort of roof. In a lecture which he delivered before the Society of Arts, in London, he says—"In the construction of glass-houses requiring much light, there always appeared to me to be one important objection. In the plain lean-to or shed roofs, the morning and evening sun—which is, on many accounts, of the greatest importance to forcing fruits—presented its direct rays at a low angle, and, consequently, very obliquely to the glass. As, at those periods, most of the rays of light and heat were obstructed by the position of the glass and the heavy rafters, so that a considerable portion of time was lost both evening and morning, it consequently became evident that a system by which the glass would be more at right angles to the morning and evening rays of the sun, would obviate the difficulty, and remove the obstruction of the rays of light entering the house at an
early and late hour of the day." By this mode of reasoning, suggested by close observation, he was led to adopt the ridge-and-furrow principle for glass roofs, which places the glass in such a position, that the rays of light in the mornings and evenings enter the structure without "let or hindrance," and present themselves more perpendicularly to the glass at those periods when they are least powerful; whereas, at mid-day, when they are most powerful, they present themselves more obliquely to it.

APPLICATION OF ARTIFICIAL HEAT.

Hot or forcing-houses are heated by different means, and in various ways. The means are by flues and pipes; and the ways are in allowing the former to convey both smoke and air through the building; and the latter to conduct steam or hot water in any given direction. The other means are by constructing the forcing-house in such a manner as will enable the calorific action of the sun's rays to be increased; and, occasionally, by the heat which is produced by the process of fermentation of vegetable substances: this mode, however, is rapidly disappearing from amongst us. The smoke-flue is now pretty generally abandoned for the hot-water pipe, which possesses many advantages over the former. In the first, it is more lasting; in the second, it requires much less space; in the third, it admits of being placed in situations where the flue could not be placed; in the fourth, it yields a more uniform heat; in the fifth, it can rarely be over-heated—a great matter in a forcing-house; in the sixth, it is much more cleanly and elegant; and, in the seventh, it seldom gets into such a state of disrepair as to require mending. On the other hand, the flue is liable to burst by explosion from the ignition of the inflammable gases generated within. This, of itself, is condemnatory to the flue; and although the pipe is more costly than the flue at its first erection, it has usually been found the cheapest in the end. It must be remembered that noxious gases cannot be prevented from entering the structure, be the flue ever so well built; and when it is considered that these gases consist of sulphurated, phosphorated, and carburated hydrogen, besides various comparts of nitro-
gen and carbon—all of which are extremely injurious, not only to vegetable, but to animal life—it need excite no surprise that the preference has been given to steam over smoke, in the heating of the forcing-house. Besides, the bricks usually employed in constructing the flues, have, from the softness of their texture, the power of withdrawing from the air of the house much of the moisture necessary for the health of the plants—a power which the hot-water pipe, being unabsorbent, does not possess. Upon this subject, the Book of the Garden thus delivers its opinion—"Heating by hot water is, undoubtedly, the most wholesome form yet adopted; and, in its various modifications, it may be applied to all kinds of structures. The temperature it produces is uniform and moderate when compared with hot-air stoves, flues, or steam. There are a few cases, however, which should be noticed, where heating by hot water would be attended with more expense than is necessary; and these are small green-houses and nurserymen's plant-houses, where only half-hardy plants are kept, and where a well-constructed flue can be introduced without occupying much space. These only require heat sufficient to exclude frost; and they might be heated by an Arnott's, White's, or other stove, placed outside the building. In ordinary winters, it might not be necessary to use the stove above a dozen times; and as frost, in general, sets in pretty suddenly, these houses would, by such means, be heated in less time than by a hot-water boiler and pipe."

The length into which a complete consideration of this subject alone would lead us, would occupy more than the space allotted to us for the treatment of horticulture in this work: we must, therefore, content ourselves by referring the reader to the numerous systems which he will find explained, and illustrated by diagrams, in the Book of the Garden, by Mr. Charles Mackintosh. After all that has been said, written, and practically carried out in this matter, it would appear that we have still to be supplied with a proper heating apparatus for the forcing-house. In an excellent paper read by John Rogers, Esq., before the Horticultural Society of London, we find him declaring this fact. After alluding to the many and various modes which have been
PRACTICE OF HORTICULTURE.

adopted for heating forcing-houses, and acknowledging the decided superiority of the hot-water system over all other methods, he states that the saving of fuel is equal to 25 per cent. in well-arranged hot-water apparatuses, over flues, however well arranged or well managed they may be. He, however, at the same time, observes that many of the modes, even at present in use, are so defective, that they actually consume a greater amount of fuel than ordinary furnaces: he then adds that "this remark applies not merely to the earlier apparatus, when the power was inadequate to the work required, but even to the best-constructed modern ones; and the waste of fuel arises from a misunderstanding of the nature of a hot-water apparatus, and from an attempt to make it do that which, if it be properly constructed, it is impossible that it should do."

CONSTRUCTION OF THE BOILER.

Almost every variety of form has been suggested, and even practically carried out, in the construction of the boiler designed to heat water for the forcing-house. As a matter of course, many of these are of no value whatever; but in the Gardener's Magazine we find the rationale of the process of heating the conical boiler, invented by Mr. Rogers, of Sevenoaks, Kent, thus given:—"As fuel cannot be consumed without air, if a furnace be constructed of considerable depth, and filled with fuel, and air be admitted only at the bottom, that fuel alone is consumed which lies immediately on the bars, and first receives the draught of air. The fuel above, provided it transmits the air, becomes red-hot, or nearly so; but does not consume until that below it is destroyed. In this manner, one of these conical furnaces being lighted and filled with fuel, that portion in the upper part of the furnace which cannot burn, absorbs the heat of the burning fuel below, and radiates or transmits it to the water on every side. So perfect is this absorption of heat, that for several hours after the furnace has been filled up with cinders, though there may be a fierce fire below, little or no heat escapes up the chimney—the whole being taken up by the surrounding water. The economy, therefore, of fuel in such an apparatus is very great. It is evident that excess of draught must be carefully guarded against, so much only being allowed as will consume the fuel steadily; but this is easily learned by experience. The necessity, also, of keeping the aperture in front close, so that air enters the furnace only through the ash-pit, is, hence, evident. The water is (then) in close and immediate contact with the red-hot fuel on all sides, no black, smoking coals intervening, as in most kinds of boilers; hence the great power in proportion to size." In commenting upon these boilers, another writer says, that the economy in fuel is not their chief advantage; their great recommendation being a long and steady heat. When properly managed, this heat may be relied upon from fifteen to twenty consecutive hours. They have been successfully applied to all kinds of hot-houses; but for pits they are eminently useful, from the limited space they occupy. When fired with coke, gas-cinders, or anthracite, they give off very little smoke.

DIFFERENT MODES OF HEATING.

An ingenious method of heating has been exhibited by Mr. Fowler, in a tract written on an instrument which he terms the thermosyphon. By this contrivance, he shows how walls, as well as glass-houses, may be heated. He says, that any one may prove that hot water will circulate in a syphon, by taking a piece of lead pipe, say of half an inch in bore, and four or five feet long, bending it like a syphon; but one leg a good deal more bent than the other, in order to give the descending water time and space for giving out its heat; and then filling this tube with water, and placing one hand on each end to retain it full, immerse the extremities in a pot of water over a fire. Supposing the water of a uniform temperature in both legs of the syphon, no circulation would take place; but supposing it to cool sooner in the long leg than in the short one, then the equilibrium would be destroyed, and the water in the long leg would descend and draw up water through the short leg. This circulation would continue as long as the water was preserved at a temperature above that of the surrounding atmosphere.

Another invention is Mr. Kewley's adaptation of the syphon to heating purposes.
Mr. Perkins constructed an apparatus consisting of small tubes, hermetically sealed, in which water circulated at a temperature varying from 300° to 400° Fahrenheit. This invention, however, is unsuitable for horticultural purposes.

Besides these, there is a mode of heating, applied by Mr. Rendle, of Plymouth, in which tanks, in place of gutters or pipes, are employed, and which is designed to be adapted to the purposes of both surface and bottom heating. These tanks are built of brick or stone, or made of cast-iron or wood. When made of wood, the planks require to be good and sound, not less than a couple of inches thick, well jointed; and they are usually covered with slates. If they are built of brick or stone, the inside should be clothed with a thick coating of Roman cement; and their covers should consist of slate, stone, or brick pavement. The cast-iron tanks have covers of the same materials. In describing this mode of heating, a writer observes, that "when only one tank is fitted up in a house or pit, a division is made along the centre, leaving an opening at the end furthest from the boiler for the water to flow through; the hot water, or flow-pipe from the boiler, being fixed to the end of the tank on one side of the division; and the cold water, or return pipe to the boiler, being fixed to the end on the opposite end of the division. When two tanks are used, they are joined to the flow and return pipes respectively, and united at the extreme ends. In pits, the tanks may be carried round the sides and ends of the pit, with a division between the flow and return pipe." It would appear that the advantage to be gained by this plan of heating, consists in its adaptation to the production of bottom heat. It is necessary, however, that provision should be made for preventing no more of the steam or vapour rising from the hot water (into the house) than is required. If this precaution be not adopted, there will be too much damp, in the winter season, for the proper growth or preservation of the plants.

In closing this important branch of our subject, it should be remarked, that, in the management of artificial heat, it is necessary to exercise a considerable degree of care. All the operations of nature being in opposition to those of artificial force, and being gradual, the best plan is to follow them. The skilful horticulturist will, consequently, apply his heat, at first, very gradually. He will, for several weeks, slowly increase it by degrees; and, especially, he will watch that no sudden decrease of warmth occurs, as nothing more certainly insures success, than that the course of vegetation be continued uninterruptedly through foliation, inflorescence, and fructification. He will make the temperature increase by day, and decrease by night; to rise in summer, and to fall in winter. In short, the operations of the sun shall be his guide: by its natural and varying influence he shall be ruled.

**SCIENTIFIC INSTRUMENTS.**

The scientific instruments absolutely necessary to the horticulturist, are a Fahrenheit thermometer, which is not only an indispensability in the forcing-house, but is required in almost every department of his professional practice. Six's registering thermometer is also a convenient instrument for ascertaining the extremes of the temperatures of night and day. Besides the thermometer, the hygrometer is very necessary to the hot-house, as it measures the quality of elastic vapour in the atmosphere; and thus enables us to ascertain the degrees of its humidity. In the *Theory of Horticulture*, it is observed, that "skillful balancing of temperature and moisture in the air, and a just adaptation of them to the various seasons of growth, constitute the most complicated and difficult part of a gardener's art. An excess of dampness is indispensable to plants in a state of rapid growth, partly because it prevents the action of perspiration from becoming too violent, and partly because, under such circumstances, a considerable quantity of aqueous food is absorbed from the atmosphere, in addition to that obtained by the roots. But it is essential to observe, that when not in a state of rapid growth, a large amount of moisture in the air will be prejudicial rather than advantageous to a plant; and if the temperature is, at the same time, high, excitability will remain in a state of continued action, and that rest which is necessary will be withheld; the result of
which will be an eventual destruction of the vital energies. But, on the other hand, if the temperature is kept low, while the amount of atmospheric moisture is considerable, the latter is absorbed without it being possible for the plant to decompose it.”

SOLAR HEAT.

Perhaps it might be deemed an omission if we did not take notice of the solar rays, being a species of artificial heat, when reflected from other surfaces. Mr. Mackintosh, referring to this subject, says—“This species of heat is materially affected by the admission of the air necessary to the growth and healthy state of the plants. Solar heat, if properly regulated by ventilation, is of immense importance in the ripening of many of our finer fruits. In the orchard-houses, brought into notice by Mr. Rivers, fruits are ripened by the influence of solar heat alone. The idea is, however, by no means new. We have known many glass-houses in which peaches and grapes have ripened in the greatest perfection, without any other heat than that of the sun.

The management of the temperature consists solely in the proper regulation of the ventilators, securing as much solar heat during the day as possible, ventilating early in the morning, and shutting up early in the afternoon.”

LIGHT AND AIR.

Whatever may have been the nature of the experiments of natural philosophers in investigating the laws of light, and the effect which the different coloured rays produce upon the vegetable kingdom, the conclusion arrived at by Mr. Lindley is, that the white light which is natural to plants, is, therefore, the one best adapted to their constitution. Mr. Hunt, who has given much patience to experimenting upon this subject, has still, according to Mr. Lindley, failed in arriving at any valuable practical results in his investigations. “No advantage seems to have resulted from glazing the great palm-house, at Kew, with green glass, of a tint selected by Mr. Hunt himself.” In the Theory of Horticulture, it is stated, that “when a leaf is exposed to the direct influence of the sun, it gives off oxygen by decomposing the carbonic acid; whereupon the carbon remains behind, in the interior of the leaf, in a solid state. In the total absence of solar light, there is little or no extrication of gaseous matter; and what little is given off will be found to be carbonic acid, which plants exhale at all times in small quantities: oxygen, however, which was before expelled, is inhaled. Hence plants decompose carbonic acid during the day, and acquire it again during the night; and during the healthy state of a plant, the decomposition of this gaseous matter by day, and its recovery by night, is perpetually going on. The quantity of carbonic acid decomposed is in proportion to the intensity of light which strikes a leaf, the smallest amount being in shady places; and the healthfulness of a plant is, ceteris paribus, in proportion to the quantity of carbonic acid decomposed; therefore, the healthiness of a plant should be in proportion to the quantity of light it receives by day.” In times when the science of horticulture was less advanced, no great degree of attention was paid to the form of the roofs of those houses in which plants were artificially raised. Now, however, the minutest circumstances enter into the calculations of the scientific gardener. That the greatest possible influx of light might be secured, Sir George Mackenzie proposed hot-houses with curvilinear roofs; for he thought that “if we could find a form for a glass roof, such that the sun’s rays should be perpendicular to some part of it, not on two days, but during the whole year, that form would be the best.” Such a form is the sphere; accordingly, this shape of structure has been, by some, warmly advocated. But, however this may have been, the span and ridge-and-furrow roofs are now the prevailing forms; and any form is better than that of the lean-to, both for the convenience of internal arrangement as well as effect.

As the natural element of plants is the open atmosphere, where they are constantly surrounded with air in a state of continual motion, to arrive as nearly as possible at the circumstances of their natural conditions in the climates to which they belong, ought to be the aim of the gardener. “The atmosphere is the proper pasture of plants,” says Dr. Lindley; “and its ever-varying density is a natural phenomenon, most intimately con-
rected with the maintenance of vegetable health. It is a beautiful compensation for their want of locomotion; as plants cannot move to the atmosphere, the atmosphere is ever moving towards them. It is therefore certain, without inquiring into the exact philosophy of the matter, that free access of abundant air must be secured if the health of plants in glass-houses is to equal that in the open air." To remedy the defects felt to exist in the former modes of ventilation, what is termed aération, or subterranean ventilation, has now been adopted. The mode in which this is effected is by introducing supplies of fresh air through tubes or drains, placed at a distance of several feet under the surface of the borders, and having one end opening into the open air, while the other opens through various parts of the floor or border, and often, very properly, under the hot-water pipes. By this means fresh air is admitted, at almost the same temperature as that of the air close to the front of the house, and also charged with the moisture which it receives in passing through the damp pipes or drains. As plants, like animals, cannot long exist without their necessary supply of air, whether by night or by day, when it is admitted in this manner, it may often be allowed to act beneficially during the hours of natural darkness, as well as those of natural light.

THE VINYERY.

The vinery admits of almost every variety of structural form; for, of all the fruit trees cultivated under glass, the vine is the one which entails the least trouble upon its growers. If the design be to bring the crop to maturity chiefly by the natural heat of the sun, or by this alone, then the vinery may have any form, provided the trees are trained near the glass. If the crop is designed to ripen in July, it is recommended by Knight that the roof be at an angle of 35°; but both Miller and Wilkinson recommend an angle of 45°, which is the slope most generally adopted for both grapes and peaches. The angle of inclination in glass-work is not, however, of the very highest importance. Abercrombie says that the diagonal side of a glass case, designed for a short periodical course of forcing, beginning on the 21st of December, may be

55; 22nd of January, 50°; 21st of February, 16°; 21st of March, 43°. If the front and back wall of a vinery have shutters for ventilation, its roof may be fixed. The common trellis is as good as any for training vines.

In reference to the pruning and training of the vine, every horticulturist of eminence entertains an opinion of his own. It would, therefore, be the next thing to an impossibility for us to recapitulate even the half of what has been written upon this subject. McPhail, however, says, that "to have good crops of grapes, much more depends on the soil they are planted in, and the climate in which they are kept, than on any methods of pruning and training that have been, or ever can be adopted." Mr. Loudon coincides with this remark; but, according to a high authority, the great object is "the reproduction of bearing; that is, annual wood over every portion of the house. When this is accomplished, the next matter to be determined is the number of eyes or buds to be left on each shoot; that is, whether we shall adopt the short or the long system of pruning. The former is most allied to the practice of foreign vineyards, and has been most successfully employed in this country. According to this system all the lateral shoots are cut down to single eyes. The other it is unnecessary to describe." In estimating the merits of the different modes, however, Mr. Lindley says—"As the ultimate object of every method of pruning and training must be supposed to be the obtaining a large crop of good fruit, it is material to consider how and by what means this is to be effected; and whether it is desirable to grow a large number of bunches or a number of large bunches; the weight of the whole of each being the same. I have myself ever been an advocate for large fruit, or the largest size to which any particular fruit usually attains; being fully satisfied that the value of fruit is more to be estimated by its individual bulk or weight, than by the number of individuals composing that weight. I may illustrate this by taking, for example, any variety of either the grape or of any other fruit. For example, let the Muscat of Alexandria, the Black Hamburgh, or, indeed, any other sort, be selected, and compare fifty single berries, of the largest size, with a bun-
PRACTICE OF HORTICULTURE.

THE PEACH-HOUSE.

Peach-houses, constructed in what is known as the lean-to form, and intended to be heated by one furnace, have usually the dimensions of forty feet in length, ten or twelve in width, and a height of forty feet. These, however, may be considerably varied, according to the time at which the crop is desired to be brought into season. For early forcing, it has been suggested that twenty-five or thirty feet in length, and seven or eight in breadth, are sufficient; whilst a house in which the operations of nature are only to be slightly assisted, may be extended to fifty feet. For peaches, as for vines, the span-and-ridge and furrowed roofed buildings are equally adapted, as in them the trees can be treated as standards, which is their natural habit. Besides, the fruit obtains a more favourable position, in so far as respects air and light, than it can obtain under any other form of house-training.

In the forcing-house, the pruning and training of peach trees does not materially differ from the practice followed in the open air. "Fire-heat is commonly applied about the beginning or middle of February; but where there is a large suite of houses, and an extended succession is wanted, forcing, as it then truly becomes, may begin a month sooner. At first the temperature is kept at 45°; but it is afterwards gradually increased to 50° or 55° Fahrenheit. While the trees are in flower, and till the fruit be set, the house is occasionally steamed by sprinkling water on the warm pipes; but, much better, by placing shallow troughs of water so as partly to surround the lower or returning pipe, the lower pipes being less heated than the upper ones. After this period the foliage is washed, from time to time, with the garden engine. When the fruit has stoned, or the kernels have been formed, the temperature is raised to about 60°." Water is then plentifully supplied to the border, the fruit thinned out, the different operations of disbudding and tying are performed, and air admitted in abundance. After the end of April little fire is required for the peach-house.

The best soils for fruit trees, generally, are such as are open and well drained, in order that the air may get freely into the roots.
Loamy soils are generally preferred for peaches, nectarines, apples, and pears; but light gravelly or sandy soils are suitable for figs and apricots. Dr. Lindley says that the reason chopped turf forms the best of all soils for fruit trees, is, that the "roots penetrate the soil in all directions, forming myriads of fine tubes, which convey air and moisture through the whole mass of earth." The best soil for peaches and nectarines is the turf from the loamy soil of an old sheep-walk, or fine pasture field, pared off about three inches thick, and roughly chopped. The fresher it is used the better.

The sorts recommended as the best for forcing, are—Gross Mignonne, Royal George, Royal Charlotte, Red Magdalen, and Belle-garde.

**NECTARINES.**—Ebruge, Violet, and Hative.

**THE FIG-HOUSE.**

For the forcing of figs alone houses are but rarely built, as in most families there is no great demand for this fruit; and, perhaps, because figs are generally forced in flues or tubes in the peach or cherry-house, and managed in the same manner as the trees of these houses are.

**THE CHERRY-HOUSE.**

The cherry is amongst the most difficult of all fruits to force. This arises from its blossoms being apt to fall off before the fruit is set, and also from the fruit itself frequently falling off before it has attained to the size of a pea. The period of commencing to force the cherry is sometimes in December, but more generally in January or February. Newly-planted trees, says Nicol, will bear gentle forcing next spring, from the first or middle of March, which ought to be considered merely as preparatory to forcing them fully from about the 1st of February the third year. As cherry trees are trained against the back wall, the house should be narrow, and the roof steep. When the fruit is setting, the temperature is kept, as steadily as possible, at 50°; but after it is set, a plentiful supply of water should be given to both their roots and foliage. When the fruit is colouring, water is almost entirely withheld, and air freely admitted. During the whole process of forcing cherries, an excessive heat from the rays of the sun must be prevented, either by shading or a due admission of air. In the cherry-house the plum and the apricot may have a place, as their treatment is almost identical.

**THE PINERY.**

The pine-apple being a native of the tropics, naturally requires, in this country, all the light which our cloudy climate can afford it. It is rarely propagated by seed, but frequently by crowns, which grow on the top of the fruit; though often by suckers, which rise from the stem. The following may be taken as a choice list for propagation:

- Enville, Black Antigua, Old Jamaica, Globe, Russian Globe, Montserrat, Queen, Moscow Queen, Antigua Queen, Ripley's Queen, Smooth Queen, Prickly Cayenne, Smooth Cayenne, Providence, and Prince Albert.

Formerly it took about three years to bring the fruit of the pine to perfection in this country; but on the system of training practised now, that period is reduced to much less than one-half. In regard to the rearing of this luscious fruit, it would appear that it is only to be brought to its highest state of perfection by being grown in low pits, just sufficient for the full development of the foliage of the crown and the fruit. "So closely is this adhered to by Mr. Fleming, of Tretham, one of our most successful cultivators, that he has had occasion to take out a pane of glass to allow the crown of the fruit to protrude into the open air. A passage along the centre of such pits is exceedingly useful, particularly in the fruiting department." In order to obtain sufficient warmth for these plants, the pots in which they are placed are usually buried in a bed of tanner's bark, decaying leaves, or other kinds of fermenting matter. This bottom-heat, as it is called, is somewhat difficult to be properly managed; and it would appear to have been, by gardeners, universally kept at too great a height. "Perhaps the upper limit of its temperature may be fixed at blood-heat, or, at most, 100°, while the richer or winter limit may be brought down to 70° or 75°. The principles of the application of bottom-heat have, until lately, been little understood. In practice its value has been acknowledged for
ages, having been an element in Roman gardening in the days of Claudius. The roots of fruit trees, even of the hardest description, become paralysed whenever they descend too deep into the soil; and this paralysis is one of the evils of deep planting.” Although pine-apples have been usually potted, it is found that they succeed better unpotted, if planted freely in soil, and exposed to a proper amount of bottom-heat. In the Theory of Horticulture, we are told that a Mr. Martin Call, one of the emperor’s gardeners at St. Petersburg, was the first to assert this; and others have since proved it. In 1830, a pine-apple obtained by this treatment, weighing 9 lbs. 4 oz., was sent to the King of England by Mr. Edwards, of Rhela; and, in modern practice, all great pine-growers adopt this plan when circumstances permit them to do so. The following summary, by Mr. Lindley, in reference to the culture of this fruit, will serve to complete our notice of it:—“One of the best methods, without entering into any lengthened detail of operations, seems to be that which has been recommended by Mr. Sweet; which is, to put the young plants in a mixture of one-third loam, and two-thirds of half-decayed leaves; in which they root very freely. They may then be plunged in frames, or a stove; but not in too much bottom-heat, as that will injure their roots, as is often done by those who expect to force them on by bottom-heat; and who, by that means, kill their plants, or injure them so much that they never perfectly recover. They do not consider that giving plants a strong bottom is working against nature; for, in their native climate, it is the sun that warms the ground in which they grow; and this heat should not be exceeded here.”

THE MELONRY.

The melon has long been cultivated in Britain; but its original country is not thoroughly ascertained, neither is the period of its introduction into this island. The plant is a tender annual, demanding considerable attention and skill to bring to perfection, although it repays the labour of the horticulturist, by showing a large, and, to most persons, by being an agreeable fruit. The water-melon is seldom reared in this country, save as a curiosity; but the following species may be taken as a list somewhat select:—The Beachwood; Trentham high-bred, green-fleshed; Cuthill’s Early Cantalousse, remarkable for its earliness and hardiness; Broomham-hall; Green-fleshed Egyptian; Cassabar; Sweet Melon of Isipahan; and Green Valencia. The melon succeeds best in a strong rich soil, in a prepared compost, formed of two-thirds of rotted turf, and one-third of old cow-dung. This should be prepared some months before being used in the melon-bed. The average heat required for the successful growth of melons is about 70 Fahrenheith. In the common hot-bed, this is maintained by protecting it during the night, and by applying linings from time to time. In pits or houses heated by the circulation of hot water, this is easily effected at any season; and such pits are said to supersede the hot-bed frame altogether.

THE CUCUMBER.

This, like the melon, is a tender annual, which, in order to bring it to perfection, requires the assistance of artificial heat. It also requires great care and attention, although it is somewhat harder than the melon, and in summer requires less heat. In every other respect, however, it is managed precisely in the same way as the other. The leading varieties are—the Victory of Bath, Tilly’s Captivation, Cuthill’s Black Spine, Hunter’s Prolific, Lord Kenyon’s Favourite, Sir Colin Campbell, Canrobert, Snow’s Prize, Allen’s Victory of Suffolk, Duncan’s Victory, and several others; but, like the melon, they run into endless varieties if grown in the same structure. The prickly sorts of cucumbers are, in the summer months of the year, frequently raised under hand-glasses. To do this, a cavity is made in a border in front of a wall or rather warm place, and is filled with hot dung. This is covered with earth, and two or three plants are put into it, and sheltered with a hand-glass. They are, from time to time, watered and dressed; and by this means a sufficient supply of small cucumbers, or gherkins, is obtained for pickling. In the southern counties of England, pickling cucumbers are easily raised without any artificial heat, being sown in drills in the open ground.
CHAPTER VIII.

ANGELICA; ARTICHOKE (JERUSALEM); ARTICHOKE (GLOBE); ASPARAGUS; BROCOLI; BEET; BEANS (CLIMBING); BEANS (ROAST); BEANS (BRACH); BROOKES SPROUTS; CABBAGE; CARROTS; CALEST; CAULIFLOWER; CEREAL; CEREA; CHICORY, ETC.; CRESS; CRESS (AMERICAN); CRESS (NORMANDY); CRESS (INDIAN); ENDIVE; ESPALD; GARLIC; ICE PLANT; LEEK; LUTOUG; MALLOW (CURLED); MARROW-BEAN (KNOTTED); MELON; MUSHROOM; ONION; PARSLEY; PARSNIP; PEAS; POTATOES; RHUBARB; SAVOY; SEA-KALE; SPINACH; TURMIPS; VEGETABLE MARROW.

ANGELICA.

In treating of the plants of the kitchen garden, we shall adopt an alphabetical arrangement, as being simpler than that which would bring them before the reader in the order of their importance. Accordingly, the first is Angelica, a biennial, and a native of England, where it is found in moist situations, as it is over the northern countries of Europe. It grows freely in any soil and exposure. It should be sown in September, in drills a foot apart. When the seedlings have attained to a height of six inches, they should be transplanted to the spot where they are to remain for use. The stem may be blanched and eaten like celery; and the young green shoots may be gathered in May, candied or preserved in sugar, and used in confectionery.

ARTICHOKE (JERUSALEM).

This is a perennial, which flowers in August or September. It is a native of the south of Europe, and, in 1818, was introduced into England. The three varieties cultivated, are the Conical, French or oval Artichoke, with a green head; the Globe, or largest, with dusky-purplish head; and the Deersfoot Globe. It will grow in any soil in which the potato will grow; but light, friable, and loamy soils will always produce the best-flavoured tubers. It is useless, however, to plant on poor barren land. Trenching, to the depth of two feet, should be done, and a good dressing of manure given, if a fine crop is desired. Plant in rows, alternately two and four feet apart, allowing the tubers to be at least eighteen inches apart in the row, which should run north and south, so that the sun may shine freely on the soil. The tubers should be planted whole, any time from November until March. The former, however, is preferable, on various accounts. This root may be grown for years upon the same spot of ground, and the produce increased, provided the soil be annually well trenched, and afterwards kept loose and open by thorough surface-stirring.

ARTICHOKE (GLOBE).

About the last week in October this vegetable should receive its winter dressing, and its old leaves should be cut away close to the ground. This must be done without giving any injury to the centre or side shoots. The bed should then be forked over, the earth being thrown in a ridge about eight inches high over each row, at the same time putting it close round each plant, but taking care to preserve the heart from being touched by any crumbs of the soil. This accomplished, pile round each plant with some long litter or peahulm, four inches thick; and to prevent this from being carried away by the wind, as well as to help to preserve the roots from severe frosts, the litter should be covered over with coal ashes, to a depth of about two inches. In the spring the ashes may be turned into the soil, as they are congenial to the artichoke. Should the land be stiff and clayey, trench it to a depth of eighteen inches, filling in with a mixture of dung and mould; and in April plant out in this mixture. A plantation will last many years.

ASPARAGUS.

This perennial is found near the sea, in stony or gravelly situations; but it is not very common in such places. It grows in the Isle of Portland, near Bristol, and, not very abundantly, near Edinburgh. For growing first-class asparagus, the following plan is recommended by Mr. Arthur Henderson. After
having selected a piece of ground that has been well trenched, manured, and, for years, worked about for other crops, apply all the manure that can be got in the shape of decayed vegetables, and good, sweet, rotten dung. Then trench the ground three feet deep, and fork up the sub-soil. This should be done in February, allowing the ground to remain until the young plants (one or two years’ seedlings) have grown an inch, which will be the best time for planting. The rows should be six feet apart, and the seed sown four inches apart in each row. Where the ground is wet and damp, and no expense spared to have the best grass that can be raised, "it is advisable to have a drain right under each row, of any rough material; and a very efficient one can be made with bundles of rough stakes (not brushwood), which lasts ten or fifteen years. The finest asparagus has been raised in this way." To have asparagus in fine condition, the third season after planting, a few may be cut for use, but not too many; and all through the summer the berries should be gathered as they make their appearance.

**BROCCOLI.**

Mr. Loudon tells us that, in the time of Miller, the few broccoli then known, were supposed to have come from the cauliflower, which was originally imported from the Isle of Cyprus, about the middle of the sixteenth century. Miller speaks of the white and purple broccoli coming from Italy; and it is supposed that from these two sorts all the subsequent kinds have sprung, either by accident or intentional impregnations. To cultivate this plant successfully, it requires a deep, rich, and somewhat adhesive soil. The ground should be kept clean, and all weeds kept down. As broccoli is often cut off by the frost, as many as possible should be planted in sheltered situations. Mr. Henderson says that the following is an excellent plan for growing first-class broccoli:—"Prick them out from the seed-bed nine inches apart in July, choosing strong sturdy plants, discarding all that are doubtful. Let the bed or border be well prepared with plenty of manure. To get them strong and vigorous plants before they are finally planted on a dry clay, mark, with a spade or dibber, one yard away from their destined places. Take out the mould from each successive place, one foot wide and one foot deep; pass it through a coarse sieve, adding a teaspoonful of guano, or a cupful of horse-dung. The refuse clods or stones should be put in the bottom of the hole, well broken up; press the earth down firmly with the foot, and then plant the above sturdy, stout plants from the bed or border, taking up with each plant plenty of ball and earth. It is an excellent plan, in hot, dry weather, which often prevails when the Cape broccoli is put in the ground, to sow the seed thinly in drills, where a portion can be taken out, and the remainder left for the crop."

**BEET.**

Red Beet is a biennial, and a native of the sea-coast of the south of Europe. The white beet is also a biennial, and is a native of the sea-coasts of Spain and Portugal, and was introduced into this country in 1570. The sea-beet is a native of the shores of Britain, but is not common. The field-beet, or mangold-wurzel, is supposed to be a hybrid between the red and white species of beet. This root is best grown in a deep and somewhat sandy soil. For salad beets no manure need be used, as it is not requisite to have them large. Ground well pulverised, with plenty of the manure of former years, well worked and trenched three feet deep, is what this root likes. For early use, a little should be sown in the middle of February; but for general use, sowing should be done about the middle of May, twelve inches from row to row, and finally thinned out to about eight inches. When the crop is taken up, store it in a cool dry shed, covering it over with straw, after it has thoroughly dried, among dry sand.

**BEANS (CLIMBING).**

The climbing section of beans are natives of South America; and of late years there have been some valuable additions made to this class, excelling, both in tenderness and prolificness, the French beans, and even the Scarlet Runners. None of this section should be sown before the 10th of June, being strictly late summer and autumn kinds: notwithstanding, their growth is so rapid, and they
are so delicate and tender eating, that they demand a snug, warm, and sheltered situation in every garden, however small.

BEANS (BROAD).

For these the ground should be trenchied to a depth of two feet, with some good manure added through the top spit. If sown in rows parallel to each other, the rows (single) should be about three feet apart, and the beans six in the row, the large Windsor kinds requiring more room. As soon as a crop is insured, it is a good practice to pinch off the tops. This makes the pods swell better, and impedes the ravages of the dolphin fly, to which this family is peculiarly liable; it also concentrates the sap, and brings them forward a week earlier. Marshall's Dwarf Prolific is excellent for early work; and the Mazagan, though not so productive, is valuable because of its hardiness and early growth.

BEANS (FRENCH).

For the cultivation of this valuable and wholesome vegetable, choose a warm, snug border, taking care to earth them up in good time, in order to prevent the wind from breaking them. The hoe must be liberally used, and also watering, should the weather be very dry. Single-row culture is recommended; but if another mode is adopted, the rows should be two feet and five inches apart between the plants. Regarding the time of sowing, about the first week in May, in the open garden, is the best; and should the weather look suspicious, lend them a slight protection. One of the most prolific and finest flavoured sorts for forcing is the Yellow Canterbury, or Golden Dun; and, for sowing out-of-doors, the White Battersea is excellent. It should be placed in a warm, snug situation. Fulmer's Sion House, Newington Wonder, and the Early Battersea, are the best for forcing.

BRUSSELS SPROUTS.

This is one of the most valuable winter greens, and ranks also among the hardiest of vegetables. The seed should be sown in the middle of March, and again about the 15th of April. If sown in May, which is a very general and a very wrong custom, it is impossible for the plants to become tall and stout.

CABBAGE.

The common garden cabbage is too well known, and too universally used, to require any description here. In British gardens, by proper culture, it produces, from May to November, firm, compact heads, glaucous, green, or greenish-yellow externally, but blanched within; and varying, in different sorts, from three to twelve or fifteen inches diameter, and from two to fifteen or twenty pounds' weight. Its sub-varieties are numerous.

CARDOON.

This is a perennial, and a native of the south of France and Spain. It closely resembles the artichoke, but is larger. It prosperity in a light deep soil. The seed is sown annually, about the middle of May, in shallow trenches, like those for celery, and the plants are thinned out to ten or twelve inches from each other in the lines. During severe frosts, the tops of the leaves should be defended with straw or litter.

CARROT.

The best varieties of this root are the Early Horn and the Long Horn; the former for early, the latter for general cultivation. The Altringham is also a good garden sort. The Carrot delights in a light, deep, fresh soil, in which it may be free to push down its long spindle-shaped roots. On a bed moderately hot a few Early Horn carrots may be sown in February; and, in the beginning of March, the same sort may be sown in the open air. The other sorts may follow in April, as a general crop. The carrot succeeds best in drills. After sowing, it is only necessary to thin the plants, and keep them clear of weeds. They are stored in winter, after the manner in which turnips are done.

CAULIFLOWER.

This variety of the cabbage tribe is cultivated for the sake of the flower-buds, which form a large dense head, and yields one of the most delicate products of the kitchen garden. The sowing, for the first or spring crop, takes
place in the latter half of the month of August; and, in the vicinity of London, the growers adhere, as nearly as possible, to the 21st of that month. A second sowing takes place in February, on a slight hot-bed; and a third in April or May. As the cauliflower is a tender plant, when young, it requires protection in winter. A good method is to plant them thickly in the ground, under a common hot-bed frame, and to secure them from cold by coverings, and from damp by giving air in mild weather. A rich soil, and a warm situation, are the best conditions for growing cauliflower, of which the varieties are—Early London, White, London Particular, Early Dutch, Large Asiatic, Walcheren, and Wait's Alma.

CELEBIAC.

This plant, a native biennial, and inhabitant of ditches near the sea, is usually sown at three different times: on a hot-bed in the beginning of March, and in the open ground in March; and again in April. The seedlings, when about two inches high, are pricked into rich soil, in which they are allowed to stand till they have increased to four or five inches. The first crop is defended by frames, or hand-glasses, and is planted wide, to admit of being lifted with balls of earth adhering to the roots. As the plants advance in growth, earth is laid up about the stalks of the leaves—an operation which is repeated at the end of every ten or fifteen days, care being taken not to choke the plants. As the celery approaches maturity, scarcely anything but the tips of the leaves appear above the ridges; and, when lifted, the stalks are found to be completely blanched. Successional crops should be planted out from the 1st of June till the 1st of August, in a rich light soil, where there is plenty of moisture, in which this plant delights. The varieties are—Cole's Superb Red, Cole's Superb White, Lion's Paw, Seymour's White Champion, Nutt's Champion, Manchester Giant Red, Cole's Crystal White, Wall's White, and Cole's Dwarf Red.

CELERIAC.

This plant resembles celery in its flavour, and is, at first, treated like the early crop of that salad. In the beginning, or middle of June, it is planted out in a flat bed, in drills fifteen inches apart. Afterwards, a single earthing suffices. Its roots are used in soups; but it is not so much a favourite in Britain as it is in France and the Low Countries.

CHERVIL, AND OTHER PLANTS.

The chervil, Lamb's lettuce, marigold, and borage, are all used either as salads or in cooking, and may be sown in spring or in summer, in any light, fresh soils. The common sorrel, the French sorrel, and the horseradish are perennials, and are increased by parting their roots. They succeed best in any cool, shady situation. The capsicum, or chili, and the love-apple, are tender annuals, from tropical climates. Both are sown in hot-beds in spring; and after being transplanted, and nursed in separate pots, are planted out—the former in a warm border, and the latter against a wall. Dill has, for a long time, been cultivated in our gardens, though not extensively. It is easily raised from seed. Tarragon is a beautiful perennial, used in salads and sauces. It may be propagated either by parting the roots or by seeds, which should be sown in autumn, soon after they are ripe.

CRESS.

The common or curled cress may be sown in shallow drills, a little successively every week, in spring, summer, and autumn, by those who prefer it cut in the seed-leaf; but if it is not cut till in the fourth or fifth leaf, as many prefer it, one sowing will last many weeks, provided the outside leaves only are picked off. In winter it may be sown in pots kept in a window, or on moistened sponge or flannel. As it is not required to produce large or strong plants, air may be wholly dispensed with. Heat, darkness, and moisture alone are necessary to make it germinate. It should be always sown on the surface of the soil, and not covered with it; for the more rapidly it is grown, the more tender will be the crop.

CRESS (AMERICAN).

This is a very good autumn, winter, and early spring salad, in use from September till May. It is an excellent substitute for watercress, and may be cultivated in any corner of
the garden. The best time to sow it is in the first week of July.

CRESS (NORMANDY).

A hardy variety, succeeding well in the open air. If sown in a sheltered situation, about the beginning of September, it will produce leaves throughout the latter months of the autumn, the winter, and spring. Sow the seed thin, and keep the bed or edging well hoed up.

CRESS (INDIAN, OR NASTURTIUM).

This is a salad not much used in this country; but, when young, it is considered wholesome. Sow at intervals in heat, beginning as early as January, cutting it down in the same manner as Common Cress for use, or make use only of the tops. It soon sends out side-shoots, which produce many gatherings.

ENDIVE.

This is an annual, and a native of China, whence it was introduced to this country in 1518. It is the lettuce of winter, the blanched hearts being used for salads and soups. It prefers a very rich but light soil, and should be sown at various times, beginning in the middle of May, and sowing monthly afterwards; the last sowing for autumn and winter being made in the middle of July. Sometimes they are planted in drills, to facilitate the operation of blanching. The Batavian and the Curled are the most highly-marked varieties; and of these there are many sub-varieties.

THE ESCALOT, OR SHALOT.

This plant is originally from Palestine, and is much used in cookery, for highly-flavoured soups and gravies. It is also sometimes put into pickles. There are two sorts—the Common, and the Russian, which is much larger, and less pungent. It is propagated by offsets, which are commonly planted in September or October.

GARLIC AND CHIVE.

This is a common ingredient in continental cookery, but is not much used in this country. A few rows are quite sufficient for domestic purposes. It is propagated by offsets from the roots or by the bulblets, which grow on the flower-stem. The Chive is also occasionally used as a salad and alliaceous seasoning. A single row may be planted as an edging; and it is easily increased by parting the roots in spring or autumn.

ICE PLANT.

As a garnisher for the table, this plant possesses great elegance, and is easily cultivated. The seed should be sown in heat, about the beginning of April, potting them off singly as the plants acquire strength. They should be hardened off, and planted out about the end of May.

LEEK.

The Leek is originally from Switzerland; but, in all probability, has been cultivated in this island for many centuries. It is sown in beds in spring; and in June or July planted out in rows, fifteen or eighteen inches apart, and six inches asunder between the rows. When the weather is moist it is beneficial merely to lay the plant into the hole made by the dibble, without closing the earth upon it, the stem being, by this means, encouraged to swell out and fill the hole, as well as getting blanched at the same time. The varieties are—the London Flag, Dutch Flag, Musselburgh, Erfurt, and Ronen. Of these, the Musselburgh is the most hardy plant.

LETTUCE.

The native country of this plant is not known. There are two principal varieties—the Cos, or upright, and the Cabbage Lettuce. Its sub-varieties are numerous; and among them the following may be named:—The White Cos, Cilicia, White Cabbage, Early Forcing Cos, Dutch Cabbage, Imperial Cabbage, Grand Admiral, Paris White Cos, Green Paris Cos, Brown Cos, Wait's White Cos, Malta Cabbage, Neapolitan Cabbage, Tennis-ball, Hardy Green Hammersmith, and Black-seeded Grotto. By proper care fresh lettuce may be had throughout the year. The first sowing is made in January, in some sheltered situation; or in February, on a gentle hot-
bed: the second in the beginning of March; and the third in April. For winter sowing is made in August or September, and the plants are pricked out in October, along the bottom of walls, or under glazed frames.

MALLOW (CURLED).

This plant is a very hardy annual, and is used for garnishing, in the place of vine-leaves; but when the leaves of the vine can be obtained they are preferable. The plant grows to a height of about three feet, and flowers in common garden soil.

MARJORAM (KNOTTED).

The most suitable time for sowing marjoram is about the end of February, and during March. This should be done on a bottom-heat; and when up, it should be potted and gradually hardened off for planting out-of-doors, or forced for early use. When the demand for it is large, a portion of what is planted out-of-doors should be cut down before the flower-stems run to seed; and as soon as the ants begin to grow again, they should be taken up, potted, and placed in a pit or house, to cut as green marjoram during the winter. A light, deep, and friable soil is the best adapted for successfully growing of this plant.

MELOM.

We have spoken of this fruit in the forcing garden; but those who take pleasure in trying experiments, may be informed that melons are to be cultivated out-of-doors with success. The points to be attended to, are a south-east aspect bed, raised one foot above the level of the ground, only allowing nine inches for the plants to grow in; below them, to have a good drainage of rough bushes, straw, leaves, or other similar material. Plant under hand-glasses, and continue the use of them for some weeks, depending, of course, on the congeniality of the season. The plants intended for this purpose should be brought up very hardy.

MUSHROOMS.

This is one of those fungi with which it is dangerous for the inexperienced to deal. Those who desire to study the artificial production of their spawn may cultivate them; but for all other ends they are better left alone. However, small spare spots under stages, platforms, or at the ends of houses, can always be found for making a flat little bed, two feet in thickness, of droppings; soiled, and defended by a mat, taking care to beat the bed well down. By this means abundance of mushrooms will be produced with very little trouble; but "excessive moisture," says one of the first gardeners, "is not only apt to destroy the spawn, but it debases the flavour of such fungi as are produced under it," and such excess of moisture, he further observes, is supposed to render the "salutary sorts less, and to make the unwholesome kinds more acrimonious."

ONION.

This is one of the most precious inmates of the garden; and one sort differs far less from another than the degree of skill in different hands, or the degree of quality in different soils. "The best sort for keeping," says Mr. Paterson, "is the Strasbourg; and, for a large crop, the white Spanish; the silver-skinned is beautiful, and the dwarf-grown of that sort are the handsomest for pickles. The Blood-red and James' Keeping are excellent for pungency, and for the quality, which the latter name implies. The soil cannot be too light, if it be rich with old manure, incorporated by digging about the end of autumn." It is advantageous in the course of winter, after the manure has become amalgamated with the soil, to ridge up the earth like potato drills, which, by pulverising and drying, prepares for early sowing. Drilling is greatly to be preferred to broadcast, as the former admits of the hoe, which not only promotes the growth of the crop, but saves the trouble of weeding. One or two ounces of seed may be sown in August for a spring and early summer crop. At a medium elevation the middle of August is the proper season; and, sooner or later, from the beginning to the end of the month, according as the locality is near to mountains or the level of the sea. Some, in any condition, will shoot; but, by pinching off the early buds, good-keeping bulbs may be secured. The potato onion is very hardy, very productive, and of mild quality—equally
so with the Spanish; and it comes into use earlier than any other sort. Plant in the middle of October: it is as well to give them a slight covering of litter in severe weather. There is a silver-skinned variety of this underground onion, very excellent, and equally prolific as the old sort.

**Parsley.**

Sow this plant in lines one foot apart, the first sowing being performed in the last week of March, and the second in the first week of June. The soil should be deep and rich; and the plants should be thinned out to six inches. As an edging to borders it is very suitable. Perhaps the best variety is Myatt’s extra fine-curled, or the Enfield Market. The turnip-rooted parsley is treated in the same manner as the common parsley, sowing it in drills in the middle of April, and thinning out to four inches from plant to plant.

**Parsnip.**

The parsnip agrees with a deep and rich, but not recently-manured soil. It may be sown in March, either in drills a foot apart, or broadcast. It should be thinned out to half a foot from plant to plant. As the parsnip is not injured by frost, it may be taken up as required, or the whole crop may be gathered in October, and pitted like potatoes. The Hollow Crown and Large Guernsey are the sorts most in use.

**Peas.**

A deep, rich, and loamy soil is that in which the pea delights; but any ordinary garden soil, if dug deep, and well manured, will afford fair crops. Nothing is more idle than to study the almost endless varieties of peas; but we must recommend the following as among the best varieties:—The Champion of England, Mammoths, Knight’s Marrow, Epps’ Monarch, Ne Plus Ultra, British Queen, Bedman’s Imperial, Auvergne, and Kingwood Marrow. Thurston’s Reliance is also an excellent sort, superior in flavour, and keeping green much longer than the ordinary kinds.

**Potatoes.**

The management of this root is so well known that it supersedes the necessity of saying much about it here. We must, however, recommend the planting of early varieties, of which the crop is generally positively certain. The Ash-leaved Kidney is good eating, up, at least, to Christmas; and Martin’s Early Globe is a sure cropper, ripe and ready for use just before the disease makes its appearance in this country. It also possesses the excellent property of always eating like a new potato, even as late as April and May. Autumn planting, say from the middle of October to the end of November, is recommended for general and main crops. It is advisable to use whole sets of tubers of a moderate size, putting charred wood-ashes in with each set. This acts beneficially. Earthing up early, and keeping the ground clear of weeds, are the chief duties to be attended to, never making use of any manure to the ground, or at planting time. Fresh broken-up ground usually produces very good crops, and mostly free from disease.

**Rhubarb.**

This root is excellent for tarts and pies in the early part of the season, before the gooseberry has made its appearance. To have a good supply, set a dozen or more cuttings of the roots, reserving to each a part of the crown or top, on deep rich ground, in rows four feet apart, and three feet distant in the row, taking care to have none less than a yard from the walk, or box edging. The best varieties are the Prince Albert (early), Randal’s Prolific, and Myatt’s Victoria.

**The Savoy.**

This vegetable delights in a deeply-trenched soil; and the best sorts are—Dwarf Green, Curled, Dark-Green Globe, and Yellow Curled, more delicate than the greens. The celebrated Ulm comes into use in the middle of August; but the earliest sorts can be sown the second week in March; again in the middle of April; and, lastly, in the first week of May. Plant two feet and a-half between row and row, and about twenty inches from plant to plant, with the Dwarf and Early Ulm just half the distance. There are few vegetable plants more generally relished than the Savoy, when properly cooked for the table.
SEA-KALE.

This fine esculent is little inferior to asparagus, and a great deal more abundant, with less cost. The ground prepared for it should be well manured, and trenched to a depth of three feet. It should also be forked up, and the bottom spit of the trench loosened. Sow the first week in April, thinly upon a bed in an open part of the garden, or in straight lines three feet asunder; the plants in each row to be eighteen inches apart. During August and September, or earlier, should the young plants be in a vigorous state, a little salt and soot, dissolved with manure water, may be applied once a fortnight. The following spring, about the beginning of April, take them up, carefully shortening the roots to seven inches. Then plant them out in deep-trenched ground, as already stated, in rows four feet apart, and two feet from plant to plant, placing the crowns of the roots a couple of inches below the surface.

SPINACH.

This vegetable is not particular either as to soil or season; and it makes its appearance early in the spring, when there is no great abundance of culinary plants in the market. It is sown in shallow drills, with a width between each sufficient to allow the hoe to be worked. Sow in the latter end of March, and again in the middle of June, in order to ensure a succession of leaves, the size and succulence of which entirely depend on the richness and moisture of the soil. This is the only vegetable, in common use, that has the male and female flowers on different plants—a circumstance which gives no trouble in the raising of seed, as it is certain to happen, that, among a considerable number of plants, there will be some of both sexes.

THE TURNIP.

Mr. A. Henderson says, that turnips, to be tender and mild, must be grown rapidly, receiving no check of any kind from the day the seed is put into the ground. They delight in a generous, well-worked soil, abounding in manure, and thoroughly incorporated together—filled, in fact, with the vegetable manure of previous years. Under such circumstances the fly becomes unknown, and the flavour is delicious, the bulbs being tender and delicate. Perhaps the row system is the best for garden culture; and the distance between should vary from two to fifteen inches, and, in the row form, to six inches. Very clean culture, scaring and stirring the ground, with early thinning, is requisite. The fly must be averted; and charred ashes, and chimney or charcoal-dust, used in the dry state, is quite a preventative for this pest. Sow Early Dutch in a sheltered situation in the middle of March; the Early Stone monthly, till July, when a good breadth of a hardy sort (say the Orange Jelly) should be put in for winter use. There is another excellent variety, called the Chick Castle Black Stone, for winter use; and, for this purpose, should be sown about the latter end of July, and middle of August. The American Strap Stone is also very superior in quality and flavour, being quick in growth, and very white and crisp.

VEGETABLE MARROW.

This is both a valuable and a profitable vegetable. The celebrated green, long-fruitcd variety, named Prince Albert, and the long white one, are the best in cultivation. It is better to sow the seed in a gentle hot-bed, or under cover, about the middle of April, when they have four rough leaves. Plant them in a rich soil, and in a warm and sheltered situation, about the third week in May, taking care, at first, to cover the plants over with an inverted flower-pot at night, or other similar contrivance. When hot dung is to be had, about four barrowfuls, buried in the ground, greatly assists them; the earth that is taken out ridge up round the plants. This will protect them; whilst the hot dung will be of great benefit in giving the young plants a vigorous start; after which they will require no extra care. In dry weather they require an abundance of water; and, at the least, once a week, a thorough good soaking of liquid manure, washed in afterwards with clear water—always applied in the evening.

The pumpkin and the squash are treated in the same manner as the vegetable marrow; but they are not so generally esteemed.
CHAPTER IX.

STYLE: BRITISH FLOWER GARDENS; SOIL; GRASS-WALKS; THE SUCCULENT; MODES OF PROPAGATION; PERENNIAL PLANTS; BIENNIAL PLANTS; ANNUAL PLANTS; THE HYACINTH; TULIP; RANUNCULUS; ANEMONE; NARCISSUS; LILY; PAREIA; OTHER FLORIST'S FLOWERS; CALENDAR.

STYLE.

The great Condé, after spending half of the mature manhood of his life in war, strategy, politics, and intrigue, fell back upon the cultivation of a flower garden, as being the most delightful of all out-of-door amusements; and there are tens of thousands of men, who, although they have never had the chance of becoming Condé's, pass much of their recreative hours in the tending of flowers. It is, therefore, not altogether, as some think, an occupation only suited to employ the leisure of ladies; although there is no fairer sight than to see a beautiful Proserpine trimming her flowers beneath the golden beams of an early spring or summer morning. The principles of gardening, however, are both vague and evanescent. "As flower gardens," says Mr. London, "are objects of pleasure, the principle which must serve as a guide in laying them out, must be taste. Now, in flower gardens, as in other objects, there are different kinds of tastes. These, embodied, are called styles, or characters; and the great art of the designer is, having fixed on a style, to follow it out unmixed with other styles, or with any deviation which would interfere with the kind of taste or impression which that style is calculated to produce. Style, therefore, is the leading principle in laying out flower gardens, as utility is in laying out the culinary garden. As objects of fancy and taste, the styles of flower gardens are various. The modern style is a collection of irregular groups and masses, placed about the house as a medium, uniting it with the open lawn. The ancient geometrical style, in place of irregular groups, employed symmetrical forms; in France, adding statues and fountains; in Holland, cut trees and grassy slopes; and in Italy, stone walls, walled terraces, and flights of steps. In some situations, these characteristics of parterres may, with propriety, be added to or used instead of the modern sort, especially in flat situations; such as are enclosed by high walls; in towns; or where the principal building or object is in a style of architecture which will not render these appendages incongruous. There are other characters of gardens, such as the Chinese, which are not widely different from the modern; the Indian, which consist chiefly of walks under shade, in square grass; the Turkish, which abound in shady retreats, boudoirs of roses and aromatic herbs; and the Spanish, which are distinguished by trellis-work and fountains: but these last gardens are not generally adapted to this climate; though, from contemplating and selecting what is beautiful or suitable in each, a style of decoration for the immediate vicinity of mansions, might be composed preferable to any one now in use."

BRITISH FLOWER GARDENS.

In Britain two varieties of flower gardens have principally prevailed; one in which the ground is composed of turf, and the pattern, so to speak, exhibits a variety of figures cut out on the turf, and planted with shrubs and flowers: the other when the flower beds are separated by walks, usually covered with gravel, without having any grass whatever. As a matter of course, situation should, in a great measure, determine which of these is to be chosen; but when the garden is to be viewed from the windows of the house, or any other elevated point from which the whole or a considerable portion of the design may be perceived at once, preference should be given to the former. Where the surface is irregular, and the situation more distant, and particularly if the flowers are to be taken as the primary objects of interest or admiration, the choice should be given to the latter. The situation of the flower garden must be governed by the nature of the lawns, and the site of the house or mansion to which it is attached. As to form, the flower garden
may take any shape; but if it is large, its boundaries ought not to be continuously visible.

SOIL.

The soil of a flower garden is one of the principal things to be attended to, as it should be varied in such a manner as to meet the requirements of the species of plants designed to be grown in it. For example, earth varying from boggy peat to pure sand, is required for American plants. The best sort is alluvial, or that kind of boggy earth which has been washed away and incorporated with white sand. Peat, cut from its natural bed, and only partially decomposed, is valueless, if not really prejudicial to plants. "In collecting soil from the surface of a moor," observes a practical writer on this subject, "it is proper to take no more than the upper turf or sod, with the peat adhering to it, and only from the driest parts of the ground, where, besides the common heath, rescue-grasses occur. When this cannot be procured, a good substitute is found in vegetable mould; that is, decayed leaves, swept from lawns or woods, and allowed to lie in heaps for a year or two. For the general purposes of the flower garden, a light loamy soil is advantageous; and where the natural covering is thin, or requires making up, recourse should be had to the surface-earth of old pastures, which, especially when incumbent on trap-rocks, is found to be excellent. It is expedient to have a large mass of this material in the compost yard. The turf, and the surface soil adhering to it, should be laid up in a rough state, in which way it is continually ameliorating by the decomposition of the vegetable matters, and the action of the air."

GRAVEL-WALKS.

The principal walks of a garden should never be made narrower than to admit of, at least, three persons walking abreast upon them. It is a very common practice to see gravel-walks so contracted as scarcely to admit of two persons walking arm-in-arm upon them. We would therefore recommend that, even in small gardens, a considerable breadth of walk should be given, not only for the sake of convenience and pleasure, but on account of the much better effect such an arrangement has upon those who contemplate the garden. As a great deal of the neatness of walks depends upon the material of which they consist, gravel from an inland pit is preferable to any other. In the neighbourhood of the sea-coast, this is, in some parts, to be obtained of very good quality; but the gravels of Blackheath and Kensington, in the vicinity of London, have been much celebrated for the beauty of their colours, and have been transported to various parts of the kingdom for the purpose of being applied to the walks of gardens. Where the walks are covered with gravel, hoeing and raking, from time to time, is necessary in summer, to destroy the weeds with which they are apt to be disfigured. After this, or even after they have only been swept, they should be rolled down with a hand-roller, and this repeated as often as the surface is ruffled. Nothing has a greater tendency to heighten the beauty of garden-walks than the operation of frequent rolling.

THE SHRUBBERY.

The beauty of a garden greatly depends on the choice which is made of its trees and shrubs, and the mode in which they are artificially disposed. Of the many excellent species of these with which Britain is now enriched, it would be impossible for us to speak, in the space to which we are limited. In this department of horticulture, we can therefore only mention a few; but these few will be introduced on the authority of one of the best practical gardeners of the present day. We will, as far as possible, avoid the Latin names. —Besides the Common and the Portugal Laurels, there are other evergreens which merit especial notice, as suitable to be disposed in large masses. Among these we may notice the American Arbor Vitae, and the Chinese Arbor Vitae, which last is well adapted for small compartments. The different varieties of Ihamnus Alaternus, and the species of Phillyra and Junipers, have long enjoyed favour in the eyes of the admirers of evergreens. "The Sweet Bay," says Mr. Mackintosh, "in favourite situations, rises into a handsome shrub or low tree, and may convey to the student of the classics, the idea of the Delphic
Laurel." Besides these there are the Strawberry tree, the Irish Yew, the Cypress, Larusimmus, Swedish and Irish Junipers; different kinds of Daphne; the Andrachne, the Broad-leaved Myrtle; the Acuba Japonica, the Cistus and Helianthemum. Among the shrubs requiring a peaty or, at least, a moist and shady situation, are the Rhododendron, the Azelia, the Andromedas, and several others more recently introduced. Among these, some of the hardy heaths should find a place. Of deciduous flowering shrubs, there is not a finer object in the vegetable kingdom than the Flowering Lilac, which, from the deliciousness of its fragrance, and the pendent graces of its foliage, should always find a place in a garden. Of climbing shrubs, the Clematis and Honey-suckle may be first mentioned; but, independent of them, it may be observed, that there are numerous varieties of Fuchsia, Escallonias, and Ceanothus, which, when planted against a wall, or even in the open ground, and shaded, in winter, with an occasional covering, convey to us a better idea of the riches of Chilian vegetation, than when they are restricted to the shelves of the green-house. Many roses are also well adapted for walls, such as the varieties of Noisette, Boursault, and the different species from China.

**MODE OF PROPAGATION.**

"Nearly all shrubs may be propagated by layers; some by budding or grafting; many by separating the roots. In planting, shrubs may be arranged either singly or in masses. The latter method is the most efficient in the production of effect; but it should not be very servilely adhered to, as it is apt to begat monotonr. Some kinds should never appear in masses; the white Portugal broom, for instance, when so arranged, gives a limy tint to a garden. Perhaps it is better that groups should contain a predominance of one shrub, set off by a few others of a contrasting figure or colour, than that they should be entirely homogeneous."

**PERENNIAL PLANTS.**

The principal plants employed for floral decoration are the common perennial flowers, whether strictly bulbous or herbaceous in their character. In planting these, they should be arranged according to their height, otherwise many of the most charming flowers of lower proportions will be entirely lost sight of. It is essential, therefore, that the lowest plants stand first, or next to the border or margin of the parterre—to be succeeded by the next highest, and so on backwards. The flower-pots should present a regular bank of foliage and blossom, ascending gradually from the front: "but as this might convey an idea of too great precision, a few starry plants, on the same principle as those employed in green-houses, should be thinly scattered over the surface." Most herbaceous or perennial plants are propagated by parting the roots, or by cuttings; but some, most conveniently, by the sowing of seed. For the names of those showy flowers best adapted to the British climate and garden, we must refer our readers to the catalogues of practical horticulturists and nurserymen.

**BIENNIAL PLANTS.**

Plants which have been designated biennials are such as have an existence only of two years, when they wither and decay. Many of them are invested with great beauty; and by the casiness which they are propagated, and the rapidity of their growth, they furnish a ready means of ornamentation to garden borders. Where a very desirable variety is obtained, attention should be directed to the striking of cuttings during the summer, as the only way of continuing it. The end of spring is the proper time for sowing biennials, which is done in beds; and, in the course of the following autumn, they are generally transplanted into those places designed for them, and where they are intended to stand. The object of this is to enable them to get confirmed before the winter, that they may readily shoot into flower in the following summer.

**ANNUAL PLANTS.**

Annuals, besides being easy of culture, possess great beauty and elegance of form. All that is necessary to be done to have a crop, is only to throw the seeds into the bed or spot where they are wished to grow, and in due season they will make their appearance as plants, without care or trouble. They are
divided into three classes—the hardy, the half-hardy, and the tender. The first are sown at once in the ground assigned to them; the second, if wished to succeed well, should be, at first, assisted by a slight hot-bed, and then transplanted into the open air. The tender should be kept in pots, and cherished, as store or green-house plants, which is the treatment more properly belonging to them. It is hardly necessary to remark that the two former may be grown either in patches or in beds, and should be subjected to all the rules which apply to the disposition of common border flowers. Many new annuals have, within a few years, been introduced into this country; and doubtless, at no distant period, this will be the case with many more.

FLORISTS' FLOWERS

The flowers of the practical florist are, as might be expected, certain favourites to which that class of gardeners have devoted a large share of their attention. They comprise the Hyacinth, the Tulip, the Ranunculus, the Lily, Anemone, Narcissus, Dahlia, Auricula, Polyantbus, Carnation, and some others. We will devote a few remarks to each of these.

THE HYACINTH.

This flower is originally from the Levant, where it grows abundantly; and is possessed of great beauty, associated with a delightful perfume. In form, it bears some resemblance to the common harebell; and in the East it has long been a favourite. It is scarcely credible what an enthusiasm in particular flowers will give for a single bulb of his favourite. The catalogues of the Haarlem florists were wont to enumerate 2,000 sorts of hyacinths, some of which have been bought at £200 per bulb. They have now, however, diminished in variety, as well as in price; and are either single, semi-double, or double. A perfect flower of this sort is thus described by Mr. Glenny, in his work on The Properties of Flowers and Plants:— "Each pip or flower should be round, and not ragged. The petals should be broad, thick, and round at the ends, not pointed, and reflex enough to throw up the centre well. The foot-stalk should be strong, and hold the flower out stiff in a vertical position, and by no means weak, to allow the pip to hang with the face sloping downwards. The foot-stalk should be of a length to make the pips touch, and no more. The pips should be large, and the flowers close on the stem. Double flowers should have the rows of petals above each other very regularly imbricated, so as to throw up the centre. The spike should be bold, round, compact, and pyramidal. The flower should be very strong, and diminishing to a single flower at top. The flower-stem should be very strong and upright, and no part of it should be seen, in consequence of the closeness of the pips to each other. The colours should be bright, clear, and dense, whatever the shade; and any better approach to scarlet, blue, or yellow, than those shades we now possess, would be highly esteemed."

The proper soil for the culture of the hyacinth is one that is rich, light, and sandy. The best compost is, perhaps, that used by the Dutch, which consists of one-third of coarse sea or river sand; one-third of rotten cowdung, without litter; and one third of leaf mould. The natural soil is removed to an extent of, at least, a couple of feet deep, and the vacant space is filled up with the compost, previously well mixed. It is said that these ingredients retain their nutritive properties for six or seven years, although the Dutch do not plant hyacinths in the same place two years successively. In the alternate years, they plant it with the crocus and narcissus. About the 25th of October is the best time to plant the bulbs.

THE TULIP.

This gorgeous flower is, also, a native of the East, and was introduced into Europe about the middle of the sixteenth century. The properties of a fine late tulip, as given by Mr. Glenny, are these:— "The cup should, when quite expanded, form from half to a third of a hollow ball. To do this the petals must be six in number; broad at the ends, smooth at the edges, and the divisions between the petals scarcely to show an indenture. The three inner petals should set close to the three outer ones, and all being so close as to show no openings between them. The petals should be smooth, thick, and stiff, and should keep their form well. The ground colour should be clear and distinct, whether white or
yellow. The least stain, even at the lower end of the petal, would render a tulip comparatively valueless. Whatever be the disposition of colours or marks upon a tulip, all the six petals should be marked alike; and be, therefore, perfectly uniform. The feathered flowers should have an even, close feathering, forming an unbroken edging all round. If the flower have any marking besides the feathering of the edge, it should be a beam or bold mark down the centre, but not to reach the bottom of the cup; the mark or beam must be similar in all the six petals. Flowers not feathered, and with flame only, must have no marks on the edges. None of the colour must break through to the edge. The colour of the petals should not descend too close to the bottom. The height should be from eighteen to thirty-six inches; the former being right for the outside row in a bed, and the latter for the centre or highest row."

The proper soil for tulips is similar to that suitable for hyacinths, and the season for planting the same.

THE RANUNCULUS.

This flower is from the Levant, where it is in great favour with the Turks. The existing varieties in this country are now mostly of British origin. The properties of a fine double ranunculus are, according to Glenny, the following:—"The flower should be the form of two-thirds of a ball, two inches in diameter, and the upper part of it square or horizontal. The outline of the bloom should form a perfect circle. The petals should be thick, smooth on the edges, and gently cupped; they should lie close, so that little but the edges should be seen. The flower should be symmetrical to the centre, which should be close, so as perfectly to conceal the seed-vessel. The colour should be very dense, whatever be its hue. If an edged flower, the edging should be well defined, and the marking even and uniform. In no case should the ground-colour break through the edging; but spotted flowers, with one spot on each petal, are allowable. The stem should be strong, and long enough to raise the flower clear six inches above the foliage. Striped flowers are not perfect, nor are flowers speckled at the edges."

The ranunculus requires a stronger and moister soil than most other flowers. It is generally sown in boxes, in the autumn or the spring; and no florist's flower is more readily propagated from seed.

THE ANEMONE.

This beauty of the flower garden comprises two species, called the Anemone Hortensis, from Italy, and the Anemone Caronaries, from the Levant. In a double specimen the stem should be erect, strong, and not less than nine inches high. The soil and culture are so similar to those of the ranunculus, that it is unnecessary to specify them.

THE NARCISSUS.

This is an extensive genus, which rather belongs to the botanico-florist than to the florist proper. The polyanthus narcissus gives the varieties principally cultivated by florists; and they succeed best in a rich, light soil, containing a little dung.

THE LILY

Of this flower there are numerous species; and the old White Lily, after furnishing the poets with so much imagery, has sunk into the humble station of a modest border flower. The Orange Lily, and the Lily Mortagan, may follow its example; but the Scarlet Turk's Cap is worthy of more care, as being more beautiful and more tender. The Tiger Lily—a splendid specimen—flourishes best in a peaty soil; and the same remark applies to the Lily Canadense and Superbam, both of which are magnificent specimens. In the Lily Japonicum and Longiforum, the genus attains its greatest magnificence; but the climate of Britain is unfavourable to them out-of-doors. They must, therefore, be grown in pots under glass.

THE DAHLIA.

This splendid flower is a native of Mexico, and was, in 1789, introduced into this country, but was afterwards lost by our cultivators. There are two species, the Dahlia Variabilis, and the Dahlia Coccinea; but the varieties are endless. In 1804, it was re-introduced to this country, and the results have been very favourable to the flower garden, from the
magnificence of its appearance. The plant succeeds best in an open situation, and in rich, deep soil; but there is hardly any garden soil in which it will not thrive with manure. Dahlias, however, should not be repeatedly planted in the same spot; and they generally flower till checked in autumn by the frost. The roots are then taken up, dried, and stored in a cellar, or some other place, where they may be secured from frost and moisture. Old roots often throw up numerous stems, which render thinning necessary.

OTHER FLORISTS’ FLOWERS.

It would lead us greatly into detail to speak fully upon Calceolaria, Chelone, Pilox, Pentestemon, Pansies, Roses, Cinarrias, Lobelias, Verbenas, Chrysanthemums, Picotees, Hollyhocks, Fuchsia, Petunia, &c., notwithstanding all of them enter into the category of florists’ flowers. We may observe, however, that the Auricula is a native of the Alps and the Caucasus; that the Polyanthus is supposed to be a seminal variety of Primula Vulgaris; that the Carnation is a native of Germany; and that the Pink is merely one of its varieties. These are all favourites of the garden; more especially the Carnation, not only on account of the delightful fragrance of its blossoms, but also for the beauty it possesses.

CALENDAR.

JANUARY.

Fruit Garden.—Open weather in autumn is the proper season for planting; but if it has not then been done, do it now, watching over the roots to protect them from any draughts which may occur in spring. All sorts of fruit trees should, in mild weather, be pruned; nailing only in fine weather. Any trees which may be infested with insects, should be washed with tobacco liquor, or with soapsuds and flower of sulphur.

Forcing Department.—Shrubs to be forced should be taken to the green-house or to a warm pit first, to prepare them, and their roots thoroughly soaked, as they are often very dry; see also that they are not heavily laden with flower-buds, and that they are in proper trim as to training, &c. Hard-wooded plants must have fire-heat during frosty weather; but it must not rise above 40° at night, and 50° by day. Soft-wooded plants may be kept growing freely, but not at high temperatures.

Kitchen Garden.—Sowing of peas, beans, two-bladed onions, collards, York cabbage, horn carrot, and parsneps, may, at any time, be made this month. There is, of course, a certain amount of risk in early sowing; but in mild and tolerably dry seasons, there is sufficient compensation for losses at other times in the earlier production or increased bulk and excellence of the crop. Rhubarb, in the open ground, may be forwarded by covering the crowns with sea-kale pots, or a lot of old boxes.

Flower Garden.—Evergreens should not now be planted, but deciduous trees may be, during open weather. It is a good time to make alterations, and to stack up turf, and mix composts. Tulips and hyacinths require protection from severe frost, but must be allowed as much air and exposure as possible. Those in beds, exposed to the morning sun, should be watered with cold water very early, when the foliage has been frozen in the night. Prepare beds for anemones and ranunculus. Roses may be planted, and after planting, layed out on a heavy mulch of half-rotten dung.

FEBRUARY.

Fruit Garden.—Vines should be pruned, and laid in. This should be done only with the ripest of last year’s shoots, at a distance of about eighteen inches from each other, and not more than four eyes in length. The walls should be cleared, and the plants nailed up firmly, making use of as narrow shreds as possible. Netting for espalier and wall trees should be prepared, and employed whenever the buds begin to swell, especially if north-west winds prevail. If strawberry beds be early formed this month, on rich firm ground, they are likely to bear well. Bush fruits should be planted and pruned. Grafting, if the weather be favourable, should be begun; and scions put into the earth in bunches, with a tally to each, will keep a month, if necessary, and take better than if put on as soon as cut.

Forcing Department.—Fire-heat may be used more liberally now; and cinerarias, primulas, and other soft-wooded, early bloom-
ing plants, placed as near the glass as possible. Abundance of water should be given to every-thing that is growing freely. Hard-wooded plants, that have been kept dry all the winter, very possibly need to be plunged to the rim of the pot in a vessel of tepid water, to soften the ball of earth, and allow water to pass through freely. Old plants of bedders should be started for cuttings; and these put in as soon as they can be taken, in order that the bedders may be brought forward in time to plant out strong. All store plants from boxes and cutting-pan should be potted off. Look to the under sides of the leaves of the cinera-riases, calceolarias, pelargoniums, &c.; and, if any fly be there, put these together in a box and fumigate, or fill the house with smoke, and syringe next day. All hard-wooded plants coming into leaf should be freely syringed. Temp. 45° at night, 55° to 60° by day. Bot-tom-heat for cuttings, 60° to 70°.

*Kitchen Garden.*—Prepare immediately every inch of ground intended for summer crops. Where peas, beans, onions, cauliflowers, and broccoli are to be put in, the ground must be liberally manured and deeply stirred. Mark out the soil for onions into four-feet beds, and raise the beds six inches above the general level, leaving the surface rough. Choose, for potatoes, ground on which cabbage, broccoli, or celery has been grown, and which was well manured in the preceding year. Make up sloping borders under warm walls and fences, for early horn carrot, onion, radish, lettuce; and to prick out cauliflower and broccoli from seed-pan, &c. Plant, on dry ground, potatoes as soon as possible; sets should be of moderate size, and with short, stubby, hard sprouts upon them when the sprouts are long and white, a sound and abundant crop can hardly be expected. Sow *in the open quarters*, peas, beans, parsnips, spinach, leeks. Sow *on warm slopes*, radish, hardy lettuce, cabbage, parsley. Plant potato, garlic, shallot, chives, onions for seed.

*Flower Garden.*—Deciduous trees should be planted without delay. Mixed borders forked over, where it can be done without fear of damaging paonies, bulbs, &c.; but if these are not tallied, it will be better to leave the borders alone till the plants appear above ground. Walks, rockeries, edging, rosaries, peat-beds, and lawns, may all be formed and planted this month; and the sooner the better. Herbaceous plants should, also, be parted and planted. Also ranunculusses and anemones. Sow hardy annuals in pans for planting out. Californian annuals, such as escholtzias, godelias, Clarkia, candytufts, nemophila, viscarias, &c., may be sown in the borders where they are desired to bloom.

**MARCH.**

*Fruit Garden.*—Cuttings of bush fruits may still be planted, and grafting should not be delayed. Pruning and cleaning ought to have been completed some time ago. All the prunings and clippings of trees and hedges should be burned, and the ashes used as a top dressing for quarters of bush fruits. Mulch raspberries with half-rotten dung, and they should not be dug between. Plenty of manure should be laid down between straw-berries.

*Forcing Department.*—There must now be no delay in shifting on all subjects that require increased root-room, for vegetation is fast becoming active; and if plants make new roots in old exhausted soil, their vigour and their beauty are both deteriorated. Pot gladioli, lilies, Cape bulbs; shift cicas; start fuchsias, and take cuttings. Camellias, which are done flowering, should be started into growth in a moist atmosphere and genial temperature. Plenty of water should be given, alternating with liquid manure, to cinerarias, calceolarias, pelargoniums, and other subjects advancing into bloom. Temp. 50° night, 60° to 65° day.

*Kitchen Garden.*—The plots to be sown or planted this month and next, should be manured, and the ground dug pretty deep, and left rough. Should the soil be well drained, the principal crop of potatoes may be planted at once; but if the soil is damp, it will be better to wait till next month. Plant horseradish in any spare corner, digging the ground pretty deep, manuring the sub-soil, that the roots may come finer. Onion-beds should be marked out, and the soil liberally manured. Prepare for all crops that are to succeed each other, so as to have the ground well sweetened in time to receive them. Sow turnip, long radish, main crop of parsnips,
broccoli, savoy, cabbage, cauliflower, horn carrot, main crop of onions, parsley, leeks, beans, peas, lettuce, spinach, and small salads.

Flower Garden.—Herbaceous plants for summer and autumn bloom can now be planted, though it is always better to do so in autumn. Hardy annuals in the borders should be sown, and thinned to each patch; as soon as large enough to handle, thin the patches, and plant out the thinnings wherever necessary, or pot them for blooming in the window. Strike chrysanthemums in heat, for planting out in May. Set dahlias, and take cuttings. Give sufficient air to carnations, p Ansies, auriculas, &c.; and water freely during bright weather. Weak liquid manure should be given once a week. Plant dielytra spectabilis from pots in rich deep loam. Finish planting roses, and stake them at once. Examine tulip beds, and remove, with a knife, every particle of canker. Keep beds of pansies clean, and peg down the branches at equal distances, covering them with soil up to about two inches of the ends of the shoots. Lay down turf, turn gravel-paths, make box edging, and use the roller freely on lawns and walks. Train and trim ivy at the close of the month, reducing the growth on walls, &c., to one regular felt or layer of shoots; and removing all the leaves, so as to expose those shoots to view.

APRIL.

Fruit Garden.—Protect wall trees from the east winds, and with something that may be easily removed, so that the trees have free air night and day, weather permitting, and be covered with the least possible trouble if the wind shifts to the east or the north. Pruning and grafting, in the exposed quarters, must be completed quickly. Abundance of water should be given to fruit trees in pots, and the orchard-house kept in an orderly state.

Forcing Department.—A moderate heat only should be given to general collections, and a strong healthy growth should be promoted by the admission of abundance of air, with a view of dispensing with the fires for the season. Many of the less tender things may be transferred to cold pits, to give room for other things that want continued protection to be brought to fine plants. Young stuff from the propagating-house should be potted as fast as rooted, and kept close till started afresh, and then gradually inured to air and light, so as to be vigorous by the middle of May. All tropical plants required for summer blooming should be hastened, and a quick growth promoted, so as to give them as long a season as possible for blooming, and ripening their buds for next year. Average temperature this month. 55° by night, 60° to 65° by day.

Kitchen Garden.—Sowings may now be made of all leading kitchen crops that are to succeed each other; and where the work of the last month has been delayed, seeds should be got in early. Windsor, longpod, and Johnson’s Wonderful beans may be sown; Marrow, Auvergne, and dwarf mammoth peas, and a few rows of the earlier sorts to come in before the late peas are ready. Brussels sprouts, broccoli, cabbages, cauliflowers, horn carrot, Scotch kale, and savoy, for autumn use, should be put in. Among cabbages, Atkin’s Matchless, Early York, and Shilling’s Queen, and West Ham, are excellent kinds to sow now; but the principal crop of cabbages should be up by this time, and they should be hoed between when the ground is in a fit state. In ground deeply dug, but not manured, beets should be sown in the second week. The main crop of celery should be sown on a rich warm border, with the surface made light and fine; sow thin, and merely dust the seed over. Sow also asparagus, lettuce, onions, radish, sea-kale, and small salad—the two last in drills, one foot apart, and one inch deep for asparagus, and two inches for sea-kale. To raise seedling rhubarb plants, sow about the middle of the month in shallow drills, eighteen inches apart, dropping the seeds in patches, six inches from each other. Potatoes not yet got in should be planted without delay; and towards the end of the month, scarlet runners and French beans sown. The principal crop of carrots should be planted about the middle of the month; and there is still time for a crop of parsneps, but they must be sown directly. Slips of kitchen herbs will do any time this month, but will root quicker if planted in a rather dry sandy border.

Flower Garden.—Hardy annuals and pe-
Perennials are to be sown early; and towards the end of the month the more tender sorts may be put into the ground; but very small seeds of choice plants need not be sown till next month, as heavy rains may wash them down into the soil, and cause them to be lost. Perennials may be planted out, and old stools of chrysanthemums, lycnchus, phlox, &c., may be parted. Dahlia roots may also be planted; and if the shoots rise before the night-frosts are over, they should be protected by inverted flower-pots, and the holes covered with pieces of tile. Tigridia bulbs may be planted two inches deep; walks should be turned and rolled, and grass-plots dressed.

**May.**

**Fruit Garden.**—Plums and pears, and all bush and pyramid fruits, will require to be pinched in to the third or fourth leaf from the base. Strawberries should have plenty of water. If raspberries have not been mulched, give them at once a top-dressing of half-rotten dung. Do not dig it in. In the orchard-hose renew the mulchings, if needful, giving abundance of water.

**Forcing Department.**—Plenty of air ought to be given to hard-wooded plants, and specimen plants in flower should have shade. Allow nothing to form seed, unless seed be specially desired. All kinds of bushes that are out of shape should be cut back, and kept somewhat close afterwards, to obtain good breaks, so as to bring them into decent shape, and get the wood well ripened for next year’s bloom. All soft-wooded plants advancing in growth should be shifted, stopped, and tied out; but if required to bloom shortly, they must not be disturbed, but merely kept in shape, and plenty of water and free ventilation allowed. Continue to strike bedding stock for late blooming. Fuchsias, geraniums, petunias, and verbenas make charming specimens for pot-blooming in the autumn, if struck now, and kept regularly stopped till July. The temperature should not be high for fuchsias especially, which like shade and moisture. Azaleas and camellias that have made their young shoots should have a little more ventilation, to prepare them for the open air next month to ripen their wood. Pelargoniums out of bloom should be cut in and allowed to break before repotting them, and the syrinx and fumigator kept in use, as may be necessary, to destroy the red spider and green fly. Fire-heat should be dispensed with as far as possible, before clearing and cleaning out the house.

**Kitchen Garden.**—Aim now at high culture with all vegetable crops; stir frequently between the rows with the hoe, to keep down weeds, and supply an abundance of water and liquid manure. Rows of peas should be staked, and those that are formed well banked up. Thin parsnips and carrots to eight inches apart, and go on transplanting from seed-beds as fast as the plants are of sufficient size to handle, leaving the smallest to become more vigorous before removing them. For transplanting choose showery weather, if possible, or else give shade for a few days, and gentle watering. Flat-hoe potatoes, and draw but little earth to their stems. Thin out celery, and make up small beds for the plants on very rich, hard ground. Trenches with about six inches of rotten dung forked into the bottom of each, should now be made for celery. Look to seed-beds, and transplant; well hoe and clear the ground as may be necessary. Sow beans and peas for succession, and savoy for a late crop. Beet-root, broccoli, cabbage, kale, kidney beans, both runners and dwarfs, cucumbers, lettuces, marrows, spinach, and turnips, may now be put into the open ground for a late supply.

**Flower Garden.**—Sowings should be made of all hardy annuals required to succeed those sown in March; and tender kinds, such as asters, zinnias, &c., may now be sown in the open ground. This is a good time to sow hardy and half-hardy perennials of all kinds. The Chinese primula should be now sown for the next spring. Late-planted roses should have an abundance of water, and the surface mulched; and similar treatment should be given to hollyhocks and chrysanthemums put out last month. Carnations and picotees should be staked without delay, and their shoots thinned. Part and plant polyanthuses and primroses done blooming, and give them a rich loam and a shady aspect. Roll and now grass turf frequently; to promote a fine close growth; and make everything look clean and tidy, which greatly adds to the beauty of the garden.
CALENDAR.] PRACTICE OF HORTICULTURE. [CALENDAR.

JUNE.

*Fruit Garden.*—Snails are now harbouring on the stalks, and among the side-shoots of raspberries. Look for them every morning. If large fruit is wanted, thin the blooms at once, and disperse liquid manure. Disbud and nail in. Put trees to have plenty of water; and, if weakly in their new growth, give pretty strong doses of liquid manure at intervals of a week each. Pinch, regulate, and, where the fruit grows thick, thin it out.

*Forcing Department.*—If plants in flower are desired to be prolonged in their beauty, a shading of Shaw's tiffany or Haythorn's hexagon net should be used; the latter will also exclude bees and wasps; for flowers on which bees have settled, perish sooner than those to which they have no access. Cinerarias having ceased to bloom, may be propagated by suckers and side-shoots; if the plants are turned out on a border, and heaped round the collar with sandy loam, they will give out suckers, which may afterwards be slipped off with a portion of root attached.

*Kitchen Garden.*—By this time the ground will be, for the most part, entirely occupied, and everything in full growth. The hoe must never be idle. Next to keeping down weeds, give plenty of water; but do not drench to excess plants lately put out, lest a chill should check their growth. Cucumbers, gourds, tomatoes, and capsicum may be put out in a rich soil, giving a sunny aspect to the tomatoes. Manure-water should be freely given to all crops in full growth, especially to strawberries; but there should be two or three waterings with plain water, to one with liquid manure. Sow beet, cabbages, cauliflower, endive, early horn carrots, French beans, lettuces, radishes, spinach, scarlet runners, turnips, and peas and beans. Salad plants should have a shady situation, or they may run to seed. In sowing peas and beans, depend on the earliest sorts at this time of the year, as they are soon off the ground; but Knight's Marrow and Bedman's Imperial are excellent peas to sow now for late supply. Dress asparagus and sea-kale beds with one pound of salt to every square yard, and give the asparagus powerful doses of liquid manure from horse-dung.

*Flower Garden.*—Newly-made lawns require a little special care at this season. Carnations, pinks, and picotees, may now be propagated by pipings on the north side of a fence, or in pots half filled with sandy loam. Ranunculus require water frequently; and beds of valuable kinds must be screened in the same way as tulips, with netting or canvas. Pansies strike readily from short side-shoots; the old hollow stems will also strike, but never become good plants; the new growth is that to be depended on. Dahlias should be immediately staked, if not done at the time of planting, so as to avoid damage to the roots when they have begun to grow. Perennials should be sown for next season's blooming, that strong plants may be obtained. So thin in nursery beds, and prick out the plants in rows as soon as they make rough leaves.

JULY.

*Fruit Garden.*—Gooseberry and currant bushes should be kept open in the centre; and leave on the bush-fruits only as much wood as will bear a fine crop next season. Cuttings of gooseberries and currants may be struck now in a moist shady border. Mulch raspberries with half-rotten dung. Strawberry beds should be well attended to. Strong-rooted runners should be taken off to form new plantations, and be pricked out into well-manured beds, pretty close together. After three years, strawberry beds cease to pay, and should be broken up, and the ground trenched for winter crops.

*Forcing Department.*—All green-house plants require shifting for late blooming, and they should be grown to a good size before allowed to blossom. Cinerarias for winter blooming must have good culture and shifts as required, and camellias may be shifted if necessary. Erics generally require to be pruned, and cleared of seed-pods and dead flowers. All the ventricosas should be put into the open air in a north aspect, and sheltered with spare lights during heavy rain. All those with woolly leaves should be put in cold pits, and kept shaded at mid-day. Any not shifted in the spring should be cut in at once, and as soon as they break re-potted. Re-pot leschenaultias. Every kind of hard-wooded plants may be re-potted now if out of bloom.
Kitchen Garden.—Clear the ground, and dig it over at once, from which early crops have been taken. Brussels sprouts, kale, savoys, cabbages, broccoli, &c., should be planted out in ground deeply dug. For winter spinach, seed-beds should now be made up and well manured, and the seed put in without delay. In gathering French and runner beans, all should be taken or none. If seed is desired, a row should be left untouched. Never take green pods and seeds from the same plants. Take up garlic, onions, and shallots as they ripen, and store them for winter. Give asparagus beds plenty of liquid manure. Earth up celery for early use, and plant out the main crop as soon as the ground is ready. Artichokes should be cut down. Hoe between all growing crops, and especially potatoes. Top runners, and keep them well staked. Sow the last succession of runners and French beans; also endive, lettuce, peas, radish, small salads, spinach, Stadtholder and Mitchell’s cauliflower, and turnips. High and dry land may be planted with potatoes now, for use early next spring.

Flower Garden.—The most important operation this month is budding. Out of doors, cuttings of all kinds may be struck; including, besides the bedding of every sort of plant, most kinds of hardy evergreen shrubs, the young shoots of which soon make roots in the shade. Dahlias want special attention as they come into bloom. Another lot of pomegranate chrysanthemums should be struck this month, under hand-glasses, to make dwarf plants for the window and greenhouse in autumn. Layer carnations, picotees, and pinks; and put pipings of the same into a gentle bottom-heat.

August.

Fruit Garden.—To keep off the birds, nets should be thrown over the fruit-bushes, and a little shade given to keep a few bunches hanging for a late supply. Nail in all good shoots on wall trees, that they may have the heat of the wall to ripen them. In dry weather gather fruit; and, as a rule, not till quite ripe. Plant strawberries.

Forcing Department.—Such pelargoniums as have been pruned back and rested, should be re-potted as soon as they have broken regularly. Place them in the smallest pots into which their roots can be got, so as to allow of a series of shifts till they are once more in their blooming-pots. Young plants and green-house shrubs should be well hardened now before going to their quarters for the winter. Camellias and azaleas should have plenty of sun, and little water. Summer-struck geraniums, achimenes, and fuchsias, may be got into bloom now, in order that a display may be kept up till Christmas.

Everything that requires potting should be so done at once, as all plants get through the winter best when their pots are full of roots.

Kitchen Garden.—Brussels sprouts, broccoli, savoys, Scotch kale, &c., ought now to be strong; and where they have been planted between rows of peas, to stand the winter, they should now be looked over, and every other plant taken out, to make fresh rows if they are crowded. Most sorts of cabbages may be sown in the second week of August; Red Dutch, Shilling’s Queen, Sprotborough, and West Ham, ought to have a place in every garden. Prickly spinach should be sown on slopes in rich soil, and plenty of hardy green Hammersmith and black-seeded cos lettuce. Cauliflower should be got in from the 7th to the 20th, to keep over winter in frames. The summer-sown endive will now be strong enough to plant out on slopes or raised beds. Leeks should be carted up, and the rows of parsley thinned out, so as to get rid of every plant not well curled.

Flower Garden.—Bedding plants should be propagated for stock. Strike verbenas and petunias from the points of young shoots; and strike calceolarias in chopped moss or peat. Herbaceous plants, such as pansies, die-lytras, double wall, double Canterbury bells, double feverfew, and hollyhocks, may also be struck in quantities to keep over winter in frames. Dahlias and hollyhocks should be kept well fastened, and put stakes to chrysanthemums before their heads get heavy, as a protection against storms. Pompones may still be struck for blooming in pots. Pinks and carnations may be planted out in nursery beds, in well-manured loam. Give plenty of water to chrysanthemums, with occasional doses of strong liquid manure. Pansies may be sown, as may also most hardy.
annuals, to stand over winter for early blooming next spring. Roses and fruit trees should be budded in damp, dull weather; they take best just after heavy rain. In budding on the manetti stock, enter the bud just above the collar, close to the ground.

**September.**

**Fruit Garden.**—When the pips of apples and pears have become dark in colour, it is usually taken as the signal for harvesting the crop; but in looking for this sign a sound fruit must be taken, not one that has been pierced by an insect. Have all fruit gathered with care, and stored without bruising.

**Forcing Department.**—The growth of all hard-wooded plants should be well ripened while there is plenty of sun-heat. Bedding plants should be got into small pots as speedily as they make good roots in the borders, or can be spared from the decorative grounds, if worth keeping. Keep the houses gay with amaranthus bicolor, balsams, cockscobs, colcums, fuchsias, gladioli, heliotropes, liliums, and plants with fine foliage.

**Kitchen Garden.**—Winter stock which was sown last month may now be sufficiently forward for planting out. The ground from which onions have been cleared is usually the best for cabbages for spring use. Winter spinach should be thinned to six inches from plant to plant; also the rows of lettuce that are to stand the winter. Celery should be earthed up as the rows require it in dry weather. Sow saladings, and gather seeds as fast as they ripen. Potatoes should be taken up as the tops wither; but carrots and beet-root may remain till the frost cuts off the foliage, no longer. Parsneps may be left in the ground, to be trenched out as wanted for use, unless the space is required, in which case store them in sand.

**Flower Garden.**—Plant out pinks and carnations, and rooted cuttings of herbaceous plants. The season has now commenced for planting bulbs, but tulips should not be put into the open ground till next month. This and next month are the best times for striking calceolarias.

**October.**

**Fruit Garden.**—Gooseberries, currants, and raspberries may be moved towards the close of this month; and new plantations made on ground deeply trenched and manured. Gooseberries and raspberries need a richer soil than currants; and black currants and raspberries will thrive in more marshy ground than any other of the bush-fruits. Root-pruning and planting may be commenced in the last week of the month; but root-pruning should only be resorted to in cases of over-luxuriant, unfruitful trees.

**Forcing Department.**—House at once whatever is to be wintered under glass. Chrysanthemums ought now to be in such bloom as to keep the house gay for a while; and, as they go off, fuchsias and geraniums, from summer cuttings, should be got into bloom by giving the plants good places and shelter from draughts.

**Kitchen Garden.**—In getting ready for next year's crops, first trench over the ground intended for root crops; and choose for potatoes, carrots, parsneps, and beet, plots that have been well manured this year. Plant out the August-sown cabbage; leaving the weakest in the seed-bed for future planting. Also plant out lettuce in a warm situation; taking up potatoes, carrots, beets, and parsneps. Earth up celery; lay cabbages and broccoli that are forward with their heads to the north. Asparagus beds should be forked over, and all litter cleared away. Remove the stems with a knife, and dress the crowns with manure, and a little fresh mould over all. This is the best time to make plantations of rhubarb for next season's produce. Tomatoes, not ripe, should be cut with a length of stem, and taken into a warm green-house, where they will soon ripen.

**Flower Garden.**—Chrysanthemums should now be securely staked; plants in pots trained out, and made neat and tidy, for blooming; give plenty of water. The bulbs to be planted this month are crocuses, crown imparials, hyacinths, irises, liliums, narcissus, jonquils, daffodils, scillas, and early tulips. For late tulips, next month is sufficiently early; and anemones and ranunculuses are best kept out of the ground till February, except in places where autumn planting has been proved to be congenial to them, in which case it is preferable. Herbaceous spring-flowering plants may be got into the borders, to bloom
at the same time as the bulbs, such as aliums, arabis,aubretia purpurea, diantras, iberis, pansies, polyanthus, primulas, wallflowers, &c.

**November.**

**Fruit Garden.**—Prune and plant as weather permits. Prune bush-fruit, and fork the ground over between the rows. Burn the prunings, and strew the ashes over the newly-forked surface. Red and white currants should be cut back to skeletons. Old apple trees should be scrubbed, if infected with blight, with a strong brine, and the holes stopped with a mixture of clay, sulphur, soot, and cow-dung, beaten together into a tenacious paste.

**Forcing Department.**—Begonias, camellias, chrysanthemums, fuchsias, late-struck geraniums, and salvias, will now contribute greatly to the gaiety of the conservatory.

**Kitchen Garden.**—Wherever trenching and digging are required, let it be done without delay. Turf should be stacked, and the clippings gathered for burning, to make dressings of manure for beds and borders. The general work of the kitchen garden is only a continuation of last month.

**Flower Garden.**—Get under cover, without delay, whatever is too tender to bear the frost. Get up dahlias, tally, and stow them away, out of the reach of frost, moisture, and heat. Obtain a supply of rose stocks at once, if you intend to graft or bud for yourself next season. Plant in good loam, and stake them securely. Plant bulbs as soon as possible, both in beds and borders.

**December.**

**Fruit Garden.**—Old fruit trees should be dug round, and a layer of old dung, six inches thick, laid down in a ring, three feet round the stem of each, to improve the size of the fruit against next season. Any trees that grow too luxuriantly to bear well, should be pruned at the roots. Protection to any tender fruit trees should be given, and boards, in a slope, laid over vine borders to shelter them from excessively cold rains. Strawberry beds may be made this month; but it is not a favourable period for strawberries. Bush-fruits should be planted, potted, pruned, and manured. Gooseberries and currants may be lightly forked between, to amalgamate the manure with the soil; but raspberries should have three or four inches of dung, not very rotten, laid over the piece, and the soil between them should not be dug at all. Orchard-house trees may be pruned; and it is recommended that they be washed with a solution of eight ounces of Gishurst to a gallon of soft water.

**Forcing Department.**—Till after Christmas chrysanthemums will keep this department gay, when the first lot of forcing shrubs, especially azaleas, will be ready to take their place. Hard-wooded plants in the green-house must have as much air as the weather will permit, and as little water as possible, from the expectation of frost setting in. The thermometer should not descend below 38°. Ericas should have air at every opportunity; and if forced with other flowering shrubs, must have the coolest place in the forcing-pit, and be very gently stimulated. Green-house temperature, 10° to 15°.

**Kitchen Garden.**—Plantations of asparagus, horseradish, rhubarb, and sea-kale should be made. Roots of dandelion, packed together in leaf-mould, and put into gentle heat, will, in five or six weeks, furnish a delicate salad. Early peas and beans should now be sown on warm dry slopes; and broccoli heeled over, with their heads to the north.

**Flower Garden.**—Bulbs ought to be all planted by this time; but if any remain out of the ground, they should be got in without delay. Fuchsias to remain out all the winter should be cut down, and their roots covered with litter or coal-ashes. Pansies, pinks, and other choice things in open beds, should have a little light litter sprinkled over them in frosty weather, or be protected with canvas on hoops. Protect tulips in the same way.
INTRODUCTORY.

Addison, in his 200th Spectator, translates some of the iambics of Simonides, and tells us that this poet was famous in his generation, and that he is the author of the oldest satire now extant. The subject of this satire is woman; and we find him stating that the souls of one kind of women were formed out of those ingredients which compose a swine; a second were formed out of the same materials that enter into the composition of a fox; a third were made up of canine particles; a fourth were made out of the earth; a fifth were composed of the sea; a sixth were manufactured of the ingredients which make an ass, or a beast of burden; the cat supplied the materials for a seventh species of women; the mare with a flowing mane, which was never broken to any servile toil and labour, composed an eighth species of women; the ninth kind were taken out of the ape; and the tenth, and last, sort were made out of the bee. In reference to this species, Simonides says—"Happy is the man who gets such an one for his wife! She is altogether faultless and unblamable. Her family flourishes and improves by her good management. She loves her husband, and is beloved by him. She brings him a race of beautiful and virtuous children. She distinguishes herself among her sex. She is surrounded with graces. She never sits among the loose tribe of women, nor passes away her time with them in wanton discourses. She is full of virtue and prudence, and is the best wife that Jupiter can bestow on man." Simonides lived about 400 years after the siege of Troy; and, as Addison remarks, "shows, by his way of writing, the simplicity, or rather coarseness, of the age in which he lived." But, whatever may be the simplicity or the coarseness of his manner of writing, he has certainly been highly complimentary to the virtues of the bee, if we are to consider that such women as his tenth species could be composed of the forms, qualities, and instincts of that notable insect. If so, we trust that every kind and careful bee-master may have the happiness of falling in with a bee-wife.

INTEREST ATTACHED TO THE BEE.

"The bee is little among such as fly; but her fruit is the chief of sweet things." This is the language of the Scriptures; and from the ancients this insect has claimed a greater interest than it has done among the moderns. No nation upon earth has had so many historians as this remarkable creature. De Montfort, who drew "the portrait of the honey-fly," in 1646, enumerates the authors up to his time who had written upon the same subject; and they amount to between five and six hundred. Varro, Columella, Celsus, and Pliny have each given in their contributions to the subject; and some idea may be formed of the minuteness with which they extended their investigations from a passage in Columella, who, in speaking of the origin of bees, says that Euhemerus maintained that they were first produced in the island of Cos; Euthronius, in Mount Hymethus; and Nicaner, in Crete. The subject of the fourth book of the Georgics of Virgil, is the management of bees. Their habits, economy, polity, and government are described with great fidelity, and with all the charms of poetry. In David-
son’s translation, the invocation runs—"Next will I set forth the heavenly gift of aerial honey. Vouchsafe, Macenas, thy regard to this part, also, of my work. I will sing spectacles to you marvellous of minute things; the magnificent leaders, the manners and employments, the tribes and battles of the whole race in order. My labour is upon an humble theme; but not mean the praise, if the adverse deities permit one, and Apollo invoked, hear." Virgil, however, in this Georgic, has proved himself a better poet than a well-informed naturalist.

Besides the multitude of authors who have written express treatises on bees, periodical works have been published, confining themselves entirely to their management and economy; whilst learned societies have been established with the sole view of conducting researches upon this subject. The most distinguished association of this kind is the Société des Abeilles, founded upwards of half a century ago, in Little Bautzen, a village in Upper Lausatia, under the auspices of the Elector of Saxony. The labours of this society have greatly added to the general stock of knowledge on the subject of bees.

FUNCTIONS OF BEES.

Every reader of the Scriptures knows that the Supreme Being has, in many senses, supplied the houseless and the wanderer with "wild honey," and "in a piece of honeycomb," and "honey out of the stony rock;" whilst, "a land flowing with milk and honey," has, from the first, been the type of another and a better country. The little honey-maker, too, is, in itself, one of the most marvellous proofs of the goodness and power of the Almighty. "Wise in their government," observes Kirby, "diligent and active in their employments, devoted to their young and to their queen, the bees read a lecture to mankind that exemplifies their Oriental name, Deborah, she that speaketh."—"That within so small a body," says another writer, "should be contained apparatus for converting the virtuous sweets which it collects into one kind of nourishment for itself; another for the common brood; a third for the royal; glue for its carpentry; wax for its cells; poison for its enemies; honey for its master; with a proboscis almost as long as the body itself, microscopic in its several parts, telescopic in its mode of action; with a sting so infinitely sharp, that, were it magnified by the same glass which makes a needle’s point seem a quarter of an inch, it would yet itself be invisible, and this, too, a hollow tube;—that all these varied operations and contrivances should be enclosed within half an inch of length, and two grains of matter; while, in the same small room, the large heart of at least thirty distinct instincts is contained, is surely enough to crush all thoughts of Atheism and Materialism," wherever such opinions may be held.

The leading feature in the history of bees, and one which gives them a marked distinction from almost all other insects, is the different kinds into which they are distributed, and which, to all appearance, constitutes so many different modifications of sex. First of all comes the drone, who may readily be known from the heavy noise which he makes, and from which he has received his name. He is the "lazy, yawning drone" of Shakespeare; and is, indeed, all over the world, a by-word, applied to those who are more lazy than active—more sleeping than awake when performing any duties that may be assigned them in the several positions they may have been called to occupy in life. "The drone," says Butler, "is a gross stingless bee, that spendeth his time in gluttony and idleness. For howsoever he brave it with his round velvet cap, his side gown, his full paunch, and his loud voice, yet he is but an idle companion, living by the sweat of others brows. He worketh not at all, either at home or abroad, and yet spendeth as much as two labourers: you shall never find his maw without a good drop of the purest nectar. In the heat of the day he fleeth abroad, aloft and about, and that with no small noise, as though he would do some great act; but it is only for his pleasure, and to get him a stomach; and then returns he presently to his cheer." This lazy member is distinguished by a thicker body, a more flattened shape, a round head, and more obtusely terminated abdomen, within which are contained the male organs of generation, as he is admitted to be the male of the species. The queen-bee is the next and the most dis-
tungished character in a hive. In fact, she reigns over her people. She is—

"First of the throng, and foremost of the whole,
One stands confess the sovereign of the soul."

Her embrace is said to be fatal to the drones, and her power was acknowledged long before her sex was known. Greeks, Latins, and Arabs invariably designate her as the king; and so does Shakespeare.

The queen-bee is, however, not a king-bee; and she is said, by an old author, "to differ from the vulgar, both in shape and colour." Her abdomen is of greater length, and she is provided with a sting and two ovaria of considerable size. The working bees compose the third class, and are marked by the smallness of their size, the length of the proboscis, the singular structure of their thighs and legs, and by the seeming want of generative organs. These are now set down as undeveloped females. Mr. Scherach, of Little Bautzen, and secretary to the Lausanian Society, has proved this. It is on these creatures all the laborious duties incident to the community devolve. They are the working classes, who construct the interior of their habitation; explore the fields in search of food and other materials; bring them to the hive, and apply them to the purposes for which they are adapted. They are also the constant attendants of the queen, whose wants they supply; besides being the soldiers of the hive, which they defend against the attacks of enemies; so that their whole lives is a scene of constant and busy occupation, from early dawn till close of day, when the weather and season are congenial to their employments. The lives of the females are chiefly occupied with laying eggs, and conducting the colonies, which, at certain periods, emigrate from the parent hive; so that the drones seem to be the only encumbrances upon the state. They have, however, their uses, as everything in nature has. They perform the important duty of impregnation; but they perish the moment they have fulfilled their purpose.

NUMBERS IN A HIVE.

In a hive there is usually only one perfect queen existing at a time, and she receives all the honour, deference, and affection to which she is entitled by the dignity of her station. The number of labourers, however, vary considerably in different hives. In a strong hive there are about 15,000; and of drones about one to ten of these. This proportion, though seldom exact, is rarely very much exceeded or fallen short of. According to Dr. Bevan, a single family, where swarming is prevented, will sometimes amount to 50,000 or 60,000. A writer observes, upon the strength of a hive, that the drones, even in the spring, seldom compose more than one-thirtieth or one-fortieth of the whole; and at other seasons there are none to be found in the hive. "In order to form an estimate of the number of bees which can occupy a certain space, Mr. Hunter counted what number of drowned bees could be contained in an alehouse pint, and found it to be 2,160; so that if a swarm were to fill two quarts, their numbers would be nearly 9,000. Reamnur, with the same view of ascertaining their numbers, employed the more accurate method of weighing them. He found that a collection of them weighing one ounce, consisted of 336 bees; and, therefore, that sixteen ounces, or one pound, would consist of 5,376 bees."

ATTACHMENT AND HOMAGE TO THE QUEEN-BEE.

The sole province and occupation of the queen of a hive is to lay eggs, which, in the height of the season, she does at the rate of 200 a day. If the weather be particularly warm and favourable, she will lay even more than that; and continue to do so, though at a gradually diminishing rate, till the approach of cold weather in October. "So early as February she resumes her labours in the same department, and supplies the great blank made in the population by the numerous casualties that take place between the end of summer and the commencement of spring. Her great laying of the eggs of workers begins generally about the fifth day of her age; and she continues to deposit eggs of the same kind for the succeeding eleven months; after which she commences laying those of males." In the operation of laying the queen puts her head into a cell, and remains in that position not more than a couple of seconds; after which she withdraws her head, curving her body
downwards; inserts her abdomen into the cell, and turns half round on herself. In a few seconds the egg is safely deposited in the cell, when she withdraws her body, and thus passes on from cell to cell. Whilst she is making this progress she is the subject of the most marked attention of the workers. They show their affection for her by caressing her with their antennae, and occasionally supplying her with food from their proboscides. "On one occasion," says the writer of the article on the bee, in the Naturalist's Library, "we gave her subjects an opportunity of testifying their courage in her defence, as well as their affection and zeal. Observing her laying eggs in the comb next to the glass of the hive, we gently but quietly opened the pane, and endeavoured to seize her. But no sooner did the removal of the glass afford room (while shut, it was almost in contact with her back), and before we could accomplish our purpose, they threw their bodies upon her, to the number of, at least, a hundred, and formed a cone over her of such magnitude, that she could not be less than two inches distant from any part of the surface. We dispersed the mass with our finger, and got hold of her precious person, and kept looking at her for some minutes before we restored the captive to her alarmed defenders. It is remarkable that this violence was not resented by them; though they coursed over our hands in scores while we kept hold of their mistress, not one individual used its sting. The all-engrossing object was the queen." The same writer remarks, that bees may be even roughly handled without danger of being stung when they are swarming. Then, being only intent on securing a habitation for themselves and their sovereign, they seem incapable of entertaining, at the same moment, two different ideas, and their natural irritability is not awakened to exertion. There is one striking feature in the natural history of queen-bees; and that is, the hatred which they hate for each other. Queen Elizabeth's to Mary, Queen of Scots, was as nothing to it, notwithstanding that it stimulated the English lady to take off the head of her fairer cousin. When two queen-bees in a hive happen to emerge from their cells at the same time, a pitched battle takes place, which is only terminated by the death of one of the combatants. This mutual enmity is an inborn disposition with them. No sooner has the queen-bee in a hive thrown off a second swarm, and escaped from her own frame, than she hurry's away in search of her rival, and, with the most impetuous eagerness, uses every exertion to destroy her.

To rehearse the many stories which have been told of the attachment and homage which the working bees show to their queen, would be endless. One or two must suffice. In the notes to Dr. Evans' poem of The Bees, we find the following affecting anecdote:—

"A queen, in a thinly-peopled hive, lay on a honeycomb, apparently dying; six workers surrounded her, seemingly in intent regard, quivering their wings as if to fan her, and with extended stings, as if to keep off intruders and assailants. On presenting them honey, though it was eagerly devoured by the other bees, the guards were so completely absorbed in their mournful duty, as entirely to disregard the proffered banquet. The following day, the queen, though lifeless, was still surrounded by her guard; and this faithful band of attendants, as well as the other members of the family, remained at their post till death came kindly to extinguish both their affections and their grief; for though constantly supplied with honey, not a bee remained alive at the end of the four days." This is an extraordinary instance of bee devotedness; and, we presume, is not common. We can give, from another writer, an instance of an opposite kind. It is in the case of a hive which, having early exhausted its store, was found, on being examined one morning, to be utterly deserted: the comb was empty; and the only symptom of life was the poor queen herself, "unfriend'd, melancholy, slow," crawling over the honeyless cells—a sad spectacle of the fall of bee greatness. The writer thinks that Marius among the ruins of Carthage, or Napoleon I. at Fontainebleau, was nothing to this. In reference to the homage which they show their queen, if we are to believe Syderell, it would appear, that "whenever the queen goes forth to take the air, as she often does, many of the small bees attend upon her, guarding her before and behind. By their sound I have known when her majesty has been coming forth, and have had
time to call persons who have been desirous of seeing her." These are human rather than insect characteristics; although similar anecdotes are well attested by other authorities.

THE PASTURAGE OF THE BEE.

For the physiology of the bee, we must refer the reader to such works as specially treat upon that branch of the subject, our space being insufficient to enter upon it at length: we must, therefore, confine ourselves to the more practical management of the bee, and such portions of the subject as may be supposed to be more desired to be known by the common keeper of a hive or an apiary. In noticing what is necessary to the nourishment of bees, we may observe that their food consists chiefly of two kinds—the fluid secretions of vegetables contained in the nectar of the flowers, and the dust of the anthers, which has been designated by botanists, the pollen; but which, when collected by the bees, has received a variety of names, such as farina, raw wax, bee-bread, and others. Occasionally, however, we find bees feeding upon other saccharine substances besides honey, such as honey-dew, treacle, syrup, &c. A large quantity of ink has been consumed by writers who have treated of the poisonous effects of some plants, not only upon the honey, but sometimes upon the bees themselves. Every classic schoolboy will be able to recall the narrative which Xenophon gives of the effects produced upon the Ten Thousand, by the honey of which they partook in the neighbourhood of Trebizond. The soldiers were affected in proportion to the quantities they had taken. Some seemed drunk; some mad; and some even died the same day. This quality in the honey has been referred by Pliny, and some others, to the poisonous nature of the rhododendron, of which there is an abundant crop in those parts. But this is not to be believed; for it has been found that the honey in this country is not affected in districts where the rhododendron abounds; nor, indeed, is the common bee ever observed to settle on its flowers.

If we are to nourish or cherish bees, of course the pasturage on which they are to feed ought to be one of our first considerations. Yet we have heard of a man who kept bees on the top of his house in Holborn; and wishing to find out where they pastured, he sprinkled them all with a red powder as they came forth from the hive in the morning. He then set off to Hampstead, deeming it the nearest as well as the best bee-pasture in the neighbourhood of London; and what was his delight at beholding, amongst the crowds of other bees, some of his own, carrying upon their industries persons the marks of his own ingenuity, by which they were to be singled out from the others. The apiary of Bonner, a great bee observer, was placed in a garret, in the centre of the city of Glasgow; and that of Mr. Payne, the author of The Bee-keeper's Guide, was placed in the middle of a large town. It is conclusive, then, that the industrial populations of these hives would have to fly over the chimney-tops in order to get to the fields; and if there was plenty of Dutch clover (sometimes called honeysuckle) in them, they would be sure of making a good honey year. This is one of their favourite flowers, the red clover being too deep; for the proboscis of the common bee is not so useful to it as it is generally thought to be. There have been made many lists of bee-flowers, and of such as are deemed suitable for planting round the apiary. It has been suggested that mignonette, borage, bugloss, rosemary, lavender, the crocus for the early spring, and the ivy flowers for the late autumn, might assist in making up a pretty bee-garden. Pliny recommends thyme, apiaster, violets, roses, and lilies. There is no doubt that the prevalent flower of a district will flavour the honey. The fine honey of the Isle of Bourbon will taste for years of the orange-blossoms, from which, we understand, it is gathered; and, on opening a bottle of it, the room will be filled with the perfume. The same is the case with the honey of Malta. Corsican honey is said to be flavoured by the box-tree; and honey has been pronounced utterly valueless, from its having been gathered in the neighbourhood of onion-fields. Dr. Bevan suggests that lemon-thyme should be used as an edging for garden-walks and flower-beds, instead of box, thistle, or daisies; but we think, on the whole, it little matters to the bee what flowers are placed in the garden, as it is too much of a wanderer to confine itself to such an artificial spot. It is in the wild tracts of heath
and furze, the lime avenues, the clover meadows, and the broad acres of bean-fields in which it finds its delight, and from which it culls the sweets with which it stores its cells.

**CONSTRUCTION OF THE COMBS.**

Bees almost invariably commence building their combs from the top, continuing it downward, as far as they have room; and finishing it off at the bottom in a somewhat irregular curved line. Each comb possesses a double set of honey-cells, dos-à-dos, in a horizontal position. These are the receptacles of the eggs which the queen lays, and which are constructed, not with propolis, but with wax. To sustain them in common straw hives, cross-sticks are employed, round which the labours of the bees are carried on, so that the comb is often almost laid in ruins in detaching it from these wooden supports. This circumstance, however, has, in a great measure, been obviated by fixing a small piece of comb under several removable bars, and inducing the bees to work upon them. Huber, we believe, was the first to accomplish this. He fixed a small piece of comb under each of the bars, exactly parallel. The bees then followed their leader, so that any one of the pendant combs could be lifted upon the bar; this again replaced, and the bees once more set to work. This point, from which they commence their operations, is called the guide-comb; and the hive itself, though somewhat modified, is the same as that of the Greek islands. In constructing the combs, it is observed, in the *Naturalist's Library*, that the two classes of *wax-workers* and *nurse-bees* have their separate and distinct provinces. "That of the former is to supply the rough materials, and attach them coarsely together; and that of the latter to finish and perfect the edifice. And while these last are occupied in this more refined operation of finishing and polishing, the former, like industrious labourers, are continually bringing forward additional loads of materials. One comb is scarcely begun, or contains not more than two or three rows of cells, when the busy architects proceed to lay the foundations of two others, one on each side of that already founded; continuing their operations in this manner till they have taken in the whole range of their building-ground; and with such diligence do they ply their labours, that in one day they will construct no fewer than 4,000 cells. A comb measures, in thickness, generally one inch; and the interval between them is about one-third of an inch, affording a passage for two bees, back to back, without obstruction or inconvenience. These dimensions, however, are varied according to circumstances."

**THE FORMATION OF SWARMS.**

The breeding season of the bee begins about the end of January, or early in February; and continues throughout the summer with constantly augmenting progress and activity. The population, therefore, increases with amazing rapidity; and the heat of the hive rises to such a degree, as to be frequently above 100°. This, doubtless, coupled with the want of accommodation, hastens the swarming, although the jealousy and outrageously destructive propensities of the royal mother is said to be another of the principal causes. The commencement of the swarming season is in spring, as no swarm will ever take place while the weather is cold, or until the hive is well stocked with eggs of every description. The queen, in consequence of the vast number of eggs she has parted with, is now more slender than she was, and better adapted to make an excursion through the air. "Her aversion to the royal brood which she seems to foresee will in no long time become able to dispute the throne with her, and the vain attempts she makes to destroy them in the cradle, in which she is invariably repelled by the bees who guard them, produce in her a constant restlessness and agitation, which, as Huber represents it, rises to a degree of delirium." This frenzy acts upon the workers; a tumultuous noise resounds through the hive, and everything gives token of a change. This occurs a few days before the swarm actually takes wing, whilst provisions are being collected in larger quantity by the workers. Mr. Knight, in the *Philosophical Transactions*, gives a curious account of their manoeuvres about this time. In the cavity of a hollow tree, which, by the application of a board, had been fitted up for the reception of the swarms, he constantly observed, "that about fourteen days previous to their arrival,
A small number of bees, varying from twenty to fifty, were every day employed in examining, and, apparently, in keeping possession of the cavity; for, if molested, they showed evident signs of displeasure, though they never employed their stings in defending their proposed habitation. Their examination was not confined to the cavity, but extended to the external parts of the tree above: every dead knot particularly arrested their attention, as if they had been apprehensive of being injured by moisture, which this might admit into the cavity below; and they, apparently, did not leave any part of the bark near the cavity unexamined. A part of the colony which proposed to emigrate, appeared, in this case, to have been delegated to search for a proper habitation; and the individual who succeeded, must, apparently, have had some means of conveying information of his success to others; for it cannot be supposed that fifty bees should each accidentally meet at and fix on the same cavity, at a mile distant from their hive, which Mr. Knight has frequently observed them to do, in a wood where several trees were adapted for their reception; and, indeed, he observed that they almost uniformly selected that cavity which he himself thought was the best adapted for their use. It not unfrequently happened that swarms of his own bees took possession of these cavities; and such swarms were, in several instances, followed from his garden to the trees; and they were observed to deviate very little from the direct line between the one point and the other, which seems to indicate that those bees who had formerly acted as surveyors now became guides.

The first settlement of a swarm is, doubtless, merely a spot, or place of rendezvous anterior to the emigration that is to establish them. If they are not hived they will soon take flight, and in a direct line, for some locality which their instinct has previously marked out as suitable for their accommodation. They have been known to make straight for an old hollow pollard, the only one to be found within a mile or two of the hive. The first swarm is invariably accompanied by the old queen, who, on this occasion, looks out for a fine day, as she has a strong aversion to leaving home in bad or disagreeable weather. For after-swarms, it would appear, she is not so particular. If the first swarm sends forth a colony the same year, it is the same queen who places herself at the head of her wandering subjects, in the settlement of which she takes a truly parental interest. In descending on this part of our subject, a writer says, that "there seems to be an unerring method by which the exact time when the first swarm will leave the hive can be determined—their hanging from the entrance being very fallacious—except by watching the general state of things within. With the after-swarms, however, there is a most curious and certain sign in the 'piping' or 'trumpeting' of the queen and the princesses. About the ninth day from the issue of the first swarm, if another colony is about to leave the hive, this singular duct, in most regular intonation, between the emerged queen and the princess still a prisoner in her cell, is heard; and extravagant as the account may seem, and confused and embellished as it has been from the times of Aristotle and Virgil, till recent days, it is now the practical sign by which every attentive bee-keeper judges of the time of emigration of the after-swarms. The second swarm is called a 'cast; the third, a 'smart; and the fourth, a 'squib.' A swarm from a swarm is called a 'maiden' or 'virgin' swarm, and the honey is reckoned more pure. It seldom, however, happens that there are more than two from the same hive, except in some very fine bee-years; and there are, on an average, two good years in every ten."

The Apiary.

The objects which ought to be chiefly attended to in the construction of an apiary are various, and should be constantly kept in the view of the bee-master whilst engaged in the important task of making a domicile for his insects. The first is the security and multiplication of colonies; the augmentation of their productive labour; the obtaining of their products with ease and certainty, and with the smallest possible injury to the stock. Besides these primary objects, the apiary should give to its inmates the best possible shelter against moisture and the extremes of heat and cold; but more especially against sudden changes of temperature. It should also be a principal means of protection against
their enemies, and furnish them with every facility for the construction of their combs, and the rearing of their juvenile broods. It should, likewise, admit of every part of the combs being occasionally seen, and be capable of being removed when required; and it should be made of materials that are durable. In the construction of hives, much ingenuity has been, from time to time, exerted by apiculturists, who have laboured to unite, in the greatest possible degree, all these advantages; but success to that extent, so far as we are aware, has not yet been attained. It would be impossible, as, indeed, it is unnecessary, for us to describe all the different sorts of hives which have been constructed for the bee; but those made of straw, we believe, are generally preferred, on account of their being less liable to over-heating by the solar rays, and likewise of easier purchase, from their lowness of price. They also possess the merit of keeping out the cold better than other hives of greater pretensions. Of straw hives, notwithstanding the imperfections of those of the common bell-shape, there are many in use, because they cost little, and are easily made; and because there is no great skill required in the handling of them. They ought, however, to be globularly shaped, having the third of their diameter cut away. This would make them concentrate, and retain the heat better, and thereby accelerate the hatching of the eggs, on the success of which so much depends.

DIFFERENT SORTS OF HIVES.

Wildman's storeedy straw hive is, by many, preferred to modern hives made on the same plan. It consists of two or more storeys, each seven inches in height, and ten in diameter. There is a hoop of about half an inch in breadth in the upper row of straw; and to this hoop are fastened six or seven wooden spars, each one-fourth of an inch thick, and one-and-a-quarter of an inch broad, and half an inch apart from each other. To these bars the bees attach their combs. That greater steadiness may be given to the combs, to prevent their being broken or deranged when the hive is moved, a rod is run through the middle of it, in a direction across the bars, or at angles with them. A flat cover of straw, worked of the same thickness as the hives, and twelve inches in diameter, is applied to the uppermost story, made fast to the hive with a paper-needle and thread, and carefully luted. Before it is put on, a piece of clean paper, of the same dimensions as the top of the hive, should be laid over the bars, to prevent the bees from working in the intervening spaces.

Besides the above, there is the Grecian hive, as used in the Greek islands, and sometimes called the Candiote hive. It is shaped like a flower-pot, and has a flat cover, adapted to the same purpose as that described in Wildman's hive. Hulin adopted it, with some additional apparatus. There is also Lombard's hive, which is, to some extent, a storeyed one, but differing from others of that kind in having its upper storey less than half the capacity of the body of the hive. Whatever may be the merits of these hives, however, a decided preference has been given to Wildman's, both as regards the material of which it is made, and the mode of its construction. It is said to preserve a constant equability of temperature, and to enable the operator to practise the method of partial deprivation. Into the respective merits of bee-boxes and straw hives we will not enter; but we may briefly describe the hive invented by the celebrated Huber, and called by him the book or leaf-hive. In the bee volume of the Naturalist's Library, it is spoken of as possessing "more valuable properties, taken as a whole, than any other we are acquainted with." It is thus described—"The leaf-hive consists of eight frames, each eighteen inches high (English measure), and ten inches wide inside, having the uprights and top cross-pieces one-and-a-half inch broad, and one inch thick; so that the eight frames, when placed close together, constitute a hive eighteen inches high, twelve inches between end and end, and ten inches between back and front—all inside measure. The frames are held together by a flat sliding-bar, on each side secured by wedges and pins. To the first and eighth of these frames is attached a frame with glass, and covered with a shutter. The body of the hive is protected by a sloping roof, and the entrance is made through the thickness of the floor-board. . . . In taking honey from this hive, the bee-master has the whole interior completely under his
eye, and at his disposal, and can choose what combs best suit his purpose, both as to quantity and quality; taking care, however, to do so only at such periods as will leave the bees time to replenish the vacancy before the termination of the summer season. It is also well adapted for artificial swarming. By separating the hive into two halves, the honey, brood-combs, and bees, will, generally speaking, be equally divided; and by supplying each half with four empty frames, we shall have two hives (one half empty), equal in number of bees, of brood, and even of stores. One of the new hives will possess the queen; and if the operation has been performed at the proper time—that is to say, a week or ten days before the period of natural swarming—the probability is, there will be royal brood coming forward in the other; at all events, there will be plenty of eggs and larvae of the proper age for forming an artificial queen." For descriptions and diagrams of other hives, we must refer the reader to more extended treatises on this part of our subject, and also to the bee volume of the Naturalist's Library.

SITUATION OF THE APIARY.

The "house of bees" should face the south, with perhaps a slight turn towards the east, and should be protected from the north and prevailing winds. It should not be placed at too great a distance from the dwelling, lest its inhabitants become wary of man; nor should it be too near, lest they feel themselves disturbed by him. Its entrance should be crossed by no paths, nor should the homeward flight of the laden bees be intercepted by bushes or high trees. A quiet, retired spot, in low ground, is better than an elevated situation. Dr. Bevan says—"Excepting in peculiarly sheltered nooks, an apiary would not be well situated near a great river, nor in the neighbourhood of the sea, as, in windy weather, the bees would be in danger of drowning from being blown into the water. . . . Yet it should not be far from a rivulet or spring: such streams as glide gently over pebbles are the most desirable, as these afford a variety of resting-places for the bees to light upon. . . . Water is most important to them, particularly in the early part of the season. Let shallow troughs, therefore, never be neglected to be set near the hives, if no natural stream is at hand." In the Isle of Wight, the people have a notion that every bee goes down to the sea to drink twice a day; and they are often seen to imbibe of the farm-yard pool, although clearer water may be near. It is then supposed that a small piece of rock-salt might be of service to these winged insects, on the same principle that it acts favourably upon the bovine stock of the grazier.

THE DESTRUCTION OF BEES.

In order to obtain possession of the hoarded treasures of the bee, it was long deemed necessary to destroy it. The following simple method, however, has been adopted, as it is described by a writer in the latest edition of the Encyclopaedia Britannica:—"Uncover the hole in the upper centre of a flat-topped straw hive or box, and place a glass vessel over it in such a way that no bee can get either in or out, except by the ordinary opening of the lower hive. The glass hive must be covered with an empty hive, or with a cloth, that too much light may not prevent the bees from working. As soon as they have filled the straw hive or box, they will begin to work up into the glass hive." Mr. Thorley made the addition of a glass window to his hives, that he might witness the progress which his bees made; and which was of some consequence, particularly if one hive was to be taken away before the season was over for their collecting honey; for when the combs are filled with honey, the cells are sealed up, when the bees forsake them, and live mostly in the hive where their operations are carried on.

For the purpose of uniting swarms, and also for artificial swarming, chloroform has been applied with success. It is also used for the purpose of taking the honey from the hive. A quarter of an ounce, placed in a saucer, covered with a perforated card, or with wire gauze, should be placed on the board of the hive, and all apertures carefully closed. In about half a minute the bees will have fallen completely under its influence; and, on the admission of air, after fifteen or twenty minutes have elapsed, they will be restored to their functions, and the capacity of using their wings.
DIVISION XII.

ANGLING.

ANGLING APPARATUS: RODS; LINES; HOOKS; ARTIFICIAL FLIES; BAITS FOR ANGLING; THE SALMON; THE COMMON RIVER TROUT; THE GREAT LAKE TROUT; THE GRANLING; THE PIKE FAMILY; THE CARP FAMILY; THE COMMON CARP; THE BREAM; THE TENCH; THE BARREL; THE GUDGEON; THE DALE; THE ROACH; THE BLEAK; THE GUDGEON; THE MINNOW; THE LOACH; THE EEL FAMILY; THE COMMON EEL; THE PERCH; CONCLUSION.

ANGLING APPARATUS.

An angler, to be well equipped, requires to carry many things about him. The most necessary articles consist of rods, lines, reels, hooks, baskets, and landing-nets. Besides these, he must have a stock of different kinds of feathers, such as those which are denominated hackles, and which are taken from the necks and backs of common poultry, as well as from the wings of woodcocks, rails, snipes, plovers, grouse, partridges, chicks, and others. He must also carry with him some of the furs of animals. The most useful of these are such as are taken from squirrels, hares, martins, moles, mice, and water-rats. The hackles which anglers hold in highest favour are the duns; but since the introduction of Spanish poultry, black hackles have come into use. Christmas is the most suitable time to pluck the hackles from their owners; but, indepenent of these, the feathers of the peacock, and of other showy birds, are sometimes useful. The sea-trout and the salmon are attracted by the gaudy plumage of the parrot, and those of other tropical birds, deeming them, under the deceptive forms of flies, no doubt, exotic morsels of great delicacy. Silks are another necessary with which the angler cannot dispense. The first of these is what is called Barber’s silk, which is used double for splicing the top-pieces of rods; the second is not so strong, its use being to fasten on the rings through which the line on the reel runs; the third consists of fine netting silk for dressing flies and whipping hooks. Besides these the angler should carry with him a pair of scissors with fine points, small pliers, wax and needles, as all these are necessary to his thorough equipment for practising his art with pleasure.

RODS.

Numerous are the kinds of rods which have been invented for angling; but, in purchasing this instrument, the nature of the fishing intended to be pursued should enter first into consideration. To show the necessity of this, we may mention that there is a special kind of rod for fly-fishing, bottom-fishing, and a trolling-rod; there are also the single and double-handed rod, the bag-rod, the cane and the wood, and the walking-stick rod, with a great many more smaller varieties. The general rod, however, is the most convenient for the young practitioner, or for use when travelling in localities where there is no certainty as to the sort of fish that may be taken. According to Colonel Hanker, a trout rod should be about twelve feet three inches long, and about fourteen ounces in weight. It must not be top-heavy, nor must it have too much play in the lower part; but the play should be just in proportion to the gradual tapering, by which there will be very little spring till after about the third foot of its length. It is difficult to determine the exact degree of pliancy which a fly-rod should have; but a stiff rod is worse than a pliant one, and never can be used advantageously. The fly-fishers, both of Scotland and Ireland, use more flexible rods than those of England; and many of the sportsmen of these countries are famous for their piscatory feats. Christopher North is one example.

1003
LINES.

The lines of the angler are either composed of the gut of the silkworm, or of silk and hair combined, horsehair, cow-hair, and also of Indian and other grasses. They are either purchased or made by anglers themselves; but the lines of the tackle-makers are generally reputed the best. The hair-line is described, by Mr. Daniel, as requiring much knowledge in procuring the materials of which it is to be composed. The hair should be taken from "a young, healthy, grey, or white stallion," from the middle of the tail, and it should be of "a pale, transparent, water colour." He adds, that hair must not be touched with oil, or it will become hollow and rotten. This, however, is doubted; but who would take all this trouble, when a better line could be purchased for half the value of even the time it would take to make one ourselves? Many artists, however, prefer making their own tackle, not with the view of saving time and expense, but from the pleasure which it gives to fish with that which is of their own manufacture.

The single-hair line is used by many of our best anglers, at bottom, for roach, dace, and other fine fishing. On the advantages of this sort of line, Mr. Salter, in his Angler's Guide, speaks at large; but we may state, that, as a general rule, of whatever material a line is made, if it is not already of the colour of the water usually fished in, it should be dyed to that colour.

HOOKS.

The principal hooks made use of by the practical English angler, come under the denominations of the Limerick, the Kendal, the Sneakbend, and the Kirby. To trace the progressive history of these little instruments, from the primitive simplicity of their invention up to their present perfected state, might be interesting, but it could not be useful. We will, therefore, briefly state, that upon the quality of the material of which they are made, much of the success of the angler depends. Mr. Blaine observes, that "every fish-hook should be manufactured of a proper temper:" by which he means, that it should be capable of resisting all ordinary force applied, without snapping, and be tempered so equally that it will not snap. Each hook should be kept separately in the flannel with which the hook-book should be furnished, whether the hook be gimped, or gutted, or naked.

ARTIFICIAL FLIES.

To describe all the artificial flies used by the angler would occupy a large space; but a few of the most popular must not be omitted. Those who wish for a fuller list, may consult the Fly-fisher's Entomology, by Alfred Ronalds; or Blaine's Encyclopaedia of Rural Sports. The first we shall speak of is the Black Gnat, which appears about the end of April. It should be made of the light part of the wing-feather of any dun-coloured bird, and should be dressed thick and short. The tail should be of mohair, or black ostrich, which is preferable. Trout, as well as grayling, will occasionally rise to this fly, even so early as February and March. Besides the Black Gnat, there are the Alder, or Red-fly; the Dark Dun; the Blue Dun; the Black Palmer Hackel; the March Brown, and several others. The wings of this last are formed from the mottled feathers of the tail of a partridge; the body consists of the fur of a hare's ear, mixed with a little yellow worsted; the legs are a grizzled hackle. This fly continues to the end of April. According to Mr. Bainbridge, author of the Fly-fisher's Guide, this fly may be used during mild weather in February. It is made from the dull feathers of a mallard's wing; the body of mole-fur, mixed with a little dark-brown mohair; and a dark grizzled hackle composes the legs. Salmon often rise to this fly, which may be successfully used early in the morning throughout the fishing season. The Hazel-fly is famous for May and June fishing, where bushes are plentiful. It is made of black and purple ostrich hard, twisted together; the wings should be of the light-brown feathers taken from under the wings of a thrush; and a bluish hackle should be taken for the legs. Some of the flies, as enumerated for April, by Mr. Blaine, are—The Red Dun, Orange-bodied Dun; Ashy Dun; Large Spider, or Crane-fly; the Oak-fly, and the Stone-fly. Those for May are—The Later Willow-fly;
the Bright-yellow Dun; Cream-coloured Dun; Dun Cat; Green Drake; Grey Drake, or May-fly; Land-fly; Wasp-fly; White Moth, and Brown Moth. For June—The Oil-fly; Ephemeral Red Spurness Humble-bee; Hazel-fly (already mentioned); Horn-flies; Large Blow-fly, and Blue Gnat. For July—The Large Black Ant-fly; Large Red Ant-fly, and the Blue-blow. For September—The Golden Dun; Dark Dun; Alder, or Red-fly; Late Dark-bodied Willow-fly, and the Cinnamon, or Petid Brown-fly.

In reference to the artificial flies used in salmon-fishing, there are certain writers who recommend different sorts of salmon-flies; and among these are Bainbridge; Sir Humphry Davy, in his Salmonia; Taylor, Captain Williamson, and the Rev. R. Lescelles, in his Letters on Sporting. In this last work, seven flies are enumerated and described as applied to fishing in North Wales; but to insert them here would occupy too much space. He says, however, that all the salmon flies of North Wales, with the exception of the wasp and hornet, should be made to imitate dragon-flies, being the only large ones that are seen playing about the rivers there.

BAITS FOR ANGLING.

Baits are numerous, but the best for trout are well-scoured earth-worms. The garden, the dew, and the lob-worms are all of the same species, notwithstanding that they vary considerably in the points of size, form, and colour, in accordance with their ages, and the season and soils in which they are found. According to Daniel, there are two kinds of lob-worm—the old, which is knotted, and the young, which is destitute of knots, and which is sometimes called maiden lobs—as well as red worms. The latter is in highest esteem among anglers. These, with other sorts of worms, are obtained in fields and gardens, but more abundantly in such places as contain soil recently mixed with vegetable or animal remains. Another worm, called the brandling, is, from its head to its tail, streaked with red and yellow in alternate circles, but darker at its anterior than at its posterior portion. It is usually found among rotten tan bark, heaps of rich vegetable mould, and old dung-hills.

The palmer-worms, or wool-beds, are the hairy caterpillars of certain moths which fly about in the night. They are taken by trout, and are capable of preservation for many weeks, in a box with damp earth, covered with some of the bush leaves on which the insect is known to feed. Bees and wasps are, also, bait for the angler. The roe of the salmon is greatly praised by Barker, who seems to have been the first to discover its merits as a bait. Pastes, too, are of great value to the fisher; among which the following have been recommended as good sorts:—A red paste is made with a large spoonful of fine wheat-flour, moistened with the white of an egg, and worked with the hands until tough. A small quantity of finely-powdered loaf-sugar should be added, with some cotton wool spread over the paste when flattened by the hand. The cotton should be well mixed with it, and the whole dyed with a little vermilion. It will keep good for a week, if a piece of fresh butter be added to it. By omitting the colouring matter, white paste may be composed of the same ingredients; yellow, also, using a little turmeric as a colouring. To make a salmon-paste—Take one pound of salmon-spawn, in September or October; boil it about fifteen minutes; then beat it in a mortar until sufficiently mixed with one ounce of salt, and a quarter of an ounce of salt-petre. Pick out the membrane in which the spawn is contained, as it is disengaged from it. After it has been beaten to a proper consistence, put it into gallipots, and cover it over with bladders, tied down close, and so preserve it for several months. Minnows are frequently used by anglers as a bait for trout, and the tackle employed is both lighter and finer than that used for the salmon, with a single line of gut at the bottom. With this, very large fish are frequently captured.

We shall now describe some of the principal kinds of fish, the snaring of which form the chief object of the angler's art.

THE SALMON.

This is the king of fresh-water fishes; and the family to which it belongs is, in an economical point of view, the most important in the eyes of the angler. It embraces the grey trout, salmon trout, common trout, Loch
Leven trout, Great Lake trout; the char, smelt, grayling, groniad, vendan, poman, pollan, and the argentine. It would occupy too much space to do more than thus notice the whole of these; but some of the principal of the species must be described. The most characteristic feature of the family is the peculiar form of the posterior dorsal fin, which is fleshy and adipose, or destitute of rays. The enumeration we have given, however, does not constitute quite one-half of the family, when viewed in relation to Europe. Both America and Africa produce other forms; but these, to some extent, deviate from the typical structure. The most characteristic members are the most northerly fresh-water fish with which the naturalist is acquainted. According to the opinion of some anglers, the salmon bites most frequently from about six o'clock in the morning to eleven in the forenoon; and from three in the afternoon till sunset. The best months are those of March, April, May, and June. Sometimes this noble fish measures four feet in length, and weighs upwards of seventy pounds. The capture of such a piece is a prize indeed. The most successful bait to take it with is the artificial fly, made in imitation of butterflies and dragon-flies of various kinds. At the foot of a strong stream, where there is an eddy or a whirlpool, salmon are most frequently found when feeding; and old Walton observes, that you shall find he does not usually stay long in a place, as trout will, but covets still to go nearer the spring-head. In trolling with the minnows or other small fish, the foot-lengths ought to be about three yards, and provided with one or two swivels, to prevent the line from twisting, as well as to allow the bait to have free play.

THE COMMON RIVER TROUT.

This is the salmo fario of Naturalists; and although, perhaps, the best known of our fresh-water fishes, it is among the most beautiful of the species. It is generally distributed not only throughout Great Britain, but over the whole of Northern Europe, and that, too, in such abundance that there is hardly a collection of water of any extent, whether running or stationary, in which it is not to be found. It is pre-eminently the angler's fish, as it is always open to the temptation of bait, and may be taken by the rod, at almost any time of the year, not even excepting the winter months in favourable weather; but during the proper fishing season, when the river or lake is in good condition, it is almost certain to afford plenty of sport. It would appear that there are some strange and unaccountable differences to be seen in several of the same species of fish, but more particularly in trout. This was observed by Isaac Walton, who says—"I tell you, that you may the better believe that I am certain, if I catch a trout in one meadow, he shall be white and faint, and very like to be lousy; and as certainly, if I catch a trout in the next meadow, he shall be strong, and red, and lusty, and much better meat. Trust me, scholar," he continues, "I have caught many a trout in a particular meadow, that the very shape and the enamelled colour of him hath been such as joyed me to look on him; and I have then, with much pleasure, concluded, with Solomon, 'Everything is beautiful in his season.'" This fish is generally supposed to rise more freely during gloomy weather, succeeding clear, bright nights; as, when the moon is clear, they confine themselves to shadowy places. It is, therefore, supposed that in the following day they are hungry, and more ready to snap at bait.

THE GREAT LAKE TROUT.

This is the salmo ferox of Natural History, and sometimes weighs two pounds; though its usual weight is under one. In the first volume of the Naturalist's Library, it is said that "some varieties spawn about Michaelmas, ascending, for a short way, the rivers that feed their native lakes; others spawn in the end of December, and deposit their ova in the shallow parts of the lake. The charr occurs in all the three kingdoms, although it is by no means generally distributed. The northern lochs of Scotland yield it in tolerable plenty; it is also found in Orkney, and has been long known in some of the Welsh lakes. As it haunts deep, cool water, and is seldom found at the surface till late in the autumn, it is not frequently made an object of sport with anglers. In the Cumberland and Westmoreland lakes, however, it may be taken.
sometimes in tolerable plenty, by trolling, and occasionally it rises to a fly. The different states and varieties are known in England as Case charr, Gill charr, Red charr, Silver charr, &c." Returning to the Great Lake Trout, we find it stated, by Mr. Wilson, in his article on "Angling," in the last edition of the Encyclopædia Britannica, that “the ordinary method of fishing for this king of trouts is with a powerful rod, from a boat rowing at the rate of from three to four miles an hour—the lure a common trout, of from four to eight inches in length, baited upon six or eight salmon hooks, tied back to back upon strong gimp, assisted by two swivels, and the wheel-line coarse and strong.” Yet all this, he adds, is, in the first impetuous efforts of the fish to regain its liberty, frequently carried away for ever into the crystal depths of Loch Awe!

**THE GRAYLING.**

In the Silmonica of Sir H. Davy, an opinion is expressed that the grayling has been introduced to our rivers; but it is not a common fish in some parts of this island. In the Silmonica its localities are stated to be the Avon, in Hampshire; the Severn and its tributaries, in North Wales; the Wye and its tributaries; the Lug, in Herefordshire; the Dee, Dove, Trent, and Blithe; the Ribble, Erne, Wharf, Humber, Derwent, and Rye, in the north of England; and in the Esk and Eden, in Cumberland, it is also occasionally caught. These are considered its most northern localities on the mainland; but Lowe affirms that it is very frequent in the Orkney Islands. It has neither been found in Scotland nor in Ireland, notwithstanding that it is common in much colder parts, being abundant in Lapland. Mr. Wilson, also, says that he has killed it readily in Switzerland, with a moor-fowl wing and hare-car body.

**THE PIKE FAMILY.**

The representatives of this family in the British favour are the Pike, Garfish, Savory Pike, Half-beak, Flying Fish, and the Great Dr. The common pike is designated by Lacépéde as "the shark of the fresh waters;" and by Walton as "the tyrant of fresh waters." The voracity of this fish is enormous; and one which was kept in the preserve of Bushy Park, Mr. Jesse tells us, possessed an appetite almost insatiable. He threw to him one morning, one after another, five roach, each of about four inches in length, four of which he swallowed, keeping the fifth in his mouth for about a quarter of an hour, when it also disappeared. In this preserve there were eight pike, of about five pounds each; and, out of 800 gudgeons which were counted into the reservoir, there were, at the end of three weeks, hardly any to be seen, though some barbel and perch probably had their share. The fish is in season from May to February, and is angled for by trolling with a strong-topped rod. The fresher and cleaner the bait is kept for this fish, whether for trolling, snap-fishing, or line-bait, the more likely is the angler to succeed in taking him. The fish delights in the bends of rivers and the bays of lakes, where there is no great depth of water, and where reeds, weeds, and water-lilies are plentiful. In trolling for him, it is advisable to keep as far from the water's edge as possible, and to begin by casting close by the near shore, with wind blowing against the bank; but when the weather is bright, and the water clear, there are some anglers who prefer fishing against the wind. It is said that the largest pike ever taken in Britain was done with a peacock-feather fly, in Loch Ken, near New Galway. Its weight was seventy-two pounds. According to Mr. Colquhon, the most deadly way of catching the pike is by set lines; and the best time “is on one of those delicious evenings with scarcely a breath of air, when the shadow of the mountain becomes more imposing on the unrippled loch, and twilight begins to steal over the scene.”

**THE CARP FAMILY.**

This is a numerous family, but it has not a large number of representatives in the British fauna. Among these are the Common Carp, the Bream, the Tench, the Chub, the Barbel the Roach, the Dace, the Blean, the Gudgeon the Minnow, and a few others less generally known in this country. To each of these we will devote a few lines.

**THE COMMON CARP.**

To angle for this fish, old Isaac says a very
large amount of patience is required. In the winter months it haunts the broadest and least disturbed parts of rivers, where the bottom is muddy and soft; but in summer it usually occupies deep holes beneath hollow banks, under the roots of trees, or in the neighbourhood of beds of aquatic plants. On account of its being a wary fish, it is difficult to deceive it when it has "come of age." The best months to take it are May, June, and July; and the best times of the day are from sunrise to eight in the morning, and from sunset throughout the time of twilight, and onwards through the night. Mr. Daniel says that "three rods may be employed, one with the bait at mid-water, another a foot or less from the bottom, and the third to lie upon it when the line and lead are not discovered, as in the two former. The places intended to be fished in should, the night before, be ground-bated with grains, blood, and broken worms, incorporated together with clay; the hook bait should be red worms taken out of tan, flag or marsh-worms, green peas, so boiled as to soften, but not to break the skin, and throwing some in now and then. When this bait is used (which should be with one on the hook to swim a foot from the ground), in ease of a bite, strike immediately; a large carp, upon taking the bait, directly steers for the opposite side of the river or pond."

THE BREAM.

The carp-bream is called by Walton a large and stately fish, which thrives best in large pieces of water, and in deep, quiet rivers. It is to be found in the Mole and the Medway; and also in the Cumberland lakes. In those of Ireland it has been caught of such a size as to weigh from twelve to fourteen pounds. In Scotland it is little known, Lochmaven being its only recorded habitat. May is the time for spawning, when they feel rough to handle. This, however, according to Mr. Yarrell, "is nothing more than a periodical assumption, which, as in the other Cypriads, disappears when the season of reproduction is passed." A well-conditioned earth-worm is said to be the best bait for bream; but wasp-grubs, grasshoppers, and paste made of bread and honey, will all lure them to their destruction. For angling this fish Walton gives very minute instructions. He tells us carefully to study the selected spot; advises an abundant supply of ground-bait, and a visit, with fitted tackling, to the water-side, about three or four o'clock in the morning. The angler, however, is not to venture too near the water, as bream "have a cunning sentinel, and are watchful themselves too." Mr. Daniel gives the following account of a day's sport in Essex with this fish: "The weather was cloudy, and the wind brisk; there were seven rods used by the party, and very frequently were there biters at them all at the same time. When a fish was hooked, and played at the top, or near the surface of the water, numbers were seen to follow him; and as soon as the hooks were fresh baited, were alike greedily taken. They averaged at least two pounds a fish; and of these, from six in the morning till dusk in the evening, some hundredweights were taken."
ANGLING.

ANGLING.

THE CHUB.

This fish is common both in England and Wales. It is also found in the waters of Annan, Scotland, and in many parts of the neighbourhood of the English lake country. It is called the Skelly, because of the largeness of its scales. In the deep holes of rivers it is found; and, during the summer months, commonly lies on the water's surface, enjoying the shade of some bush or tree. Timidity being one of its principal characteristics, it sinks to the bottom on the slightest alarm, although it will soon again resume its position.

THE BARBEL.

This "bearded fish" (so called from the cirri at its mouth) is pretty common throughout Europe, although it is not known in Scotland. Mr. Jesse tells us that it is an extremely sly fish; although in the spring, when supposed free from observation, it will roll itself about, and exhibit a considerable degree of playfulness. He also remarks, that, in very cold weather, it appears to be in a perfectly torpid state. "They make their hybernaculum amidst tufts of weeds at the bottom of the Thames, apparently either asleep or insensible. Indeed, so torpid are they, that they may be taken up by the hand. In very cold weather, the fishermen provide themselves with a net fastened to an iron hoop, having a handle to it, which they place near the fish, and, with a pole, put it into the net, so perfectly inanimate are they at this season." The barbel is rather particular in the baits he will take; they must, therefore, be kept clean and sweet, and be untainted with the scent of musky moss. The angling season begins in May, and continues till September; and the best hours are from daylight till ten in the morning, and from four in the afternoon till sunset.

THE ROACH.

This fish is known in some parts of England under the designations of the dare and the dart: it bears a strong resemblance, both in its appearance and habits, to those of the roach. It is gregarious, and frequents the deep waters close by the piles of bridges, or beneath masses of collected foam caused by rapid eddies, or in shady pools. They are taken with the red-worm, brandlings, &c.; but will rise at a variety of flies. In the Thames, above Richmond, as soon as the weeds begin to rot, they will rise freely from the shallows to a grasshopper, used as an artificial fly in hot weather.

It will rise at a fly, and feeds generally on worms and insects. The baits employed are beadles, maggots, grasshoppers, salmon-roe, &c. It is called by Pennant a coarse fish; but one of the best ways of preparing it for the table is by boiling it with the scales on.

THE DACE.

This fish is common to many parts of England, as well as to the temperate parts of Europe. It is rather in Scotland, and haunts still rivers and lakes, confining itself, during the day, to the deeper parts, and, in the night, feeding in the shallows. During the winter it seeks other haunts, and in the months of May and June ascends the shallows to spawn. The proper season for roach fishing in the Thames, where it grows to a larger size than in any other river, begins about the end of August; and Walton tells us to fish for it in winter, with paste or gentle; in April, with worms or caddis; in the very hot months, with little white snails, or with flies under water. In many of the hot months roaches may also be caught thus:—"Take a May-fly, or ant-fly; sink him, with a little lead, to the bottom, near the piles or posts of a bridge, or near to any posts of a weir; I mean, any deep place where roaches lie quietly; and then pull your fly up very leisurely, and usually a roach will follow your bait to the very top of the water, and gaze on it there, and run at it and take it, lest the fly should fly away from him." This is from old
ANGLING.

Isaac, who further states, that in the Thames many have been taken weighing two and a-half pounds; and Mr. Jesse mentions that the largest he had known taken, weighed three pounds; but if we are to credit Mr. Pennant, the London fishmongers sometimes see them as large as five pounds.

THE BREAM.

The bleak, or blink, is common throughout England, and abounds in the Thames, and over rivers in the vicinity of London. Libbald says it is a native of Scotland; but whether this opinion has received due confirmation we are not aware. It is gregarious, swimming in large shoals, and spawning in May, when its scales are rough to the touch. It is a small and active fish, and may be taken with a small red worm, gentles, or a fly. In angling for it, the tackle must be very fine.

THE GUDGEON.

The common gudgeon abounds in the European continent, as it also does in the southern parts of England. Like many of its compeers, however, it is unknown in Scotland. Its usual length is from five to six inches; but it is stated by Mr. Pennant, that those caught in the Kennet and Cole are three times the weight of those taken elsewhere. The largest he ever heard of was taken near Uxbridge, and its weight was half a pound. The gudgeon frequents the shallows during the hot months; and before the winter finally sets in, retires into deeper waters. It is angled for near the ground, with a small red worm.

THE MINNOW.

This is a pretty little fish, and is common to the continent of Europe, to England, and the southern parts of Scotland. Isaac Walton tells us that this fish is "a sharp biter at a small worm; and, in hot weather, makes excellent sport for young anglers, or boys or women that love that recreation; and in the spring they make of them excellent minow-tansies; for being washed well in salt, and their heads and tails cut off and 'gutted, and not washed after, they prove excellent for that use; that is, being fried with yolks of eggs, the flower of cowslips, and of primroses and a little tansie. Thus used, they make a dainty dish of meat." It may be so; but speaking for ourselves, we are by no means admirers of some of the piscatory dishes recommended by the enthusiasm of old Isaac.

THE LOACH.

This fish we have often heard called the "Beardie" in Scotland, where it is common, as it is in both England and on the continent of Europe. It has six cirri on the snout, and its nose is destitute of spines. It haunts streams with gravelly bottoms covered with large stones, under which it lurks. It does not often exceed four inches in length, and it feeds upon worms and aquatic insects. It is very prolific, spawning in the spring. It is considered a nutritious food for man, and is an excellent bait for eels.

THE EEL FAMILY.

Of this family there are given, in the Naturalists Library, eleven species as the representatives in British fauna. "When it is stated," says the writer on fish in that work, "that the type or most characteristic representative of this family is the common eel, one of the most familiarly known of our native fishes, little more need be added to convey an idea of the general appearance of the species. Differing considerably from each other in the details of their structure, they possess in common, a long, narrow, serpent-like body, which, owing to the conformation of the vertebral column, is extremely flexible; the greater part of the body surrounded by a low, nearly continuous fin; scales so minute as to be, for the most part, almost invisible, and the surface frequently invested with a slimy mucus. The ceca are wanting; but all have an air-bladder, which sometimes assumes a very peculiar form." The common eel being the type, we will confine ourselves to a brief notice of it.

THE COMMON EEL.

The sharp-nosed eel is regarded as the common one, although the broad-nosed is in many parts equally abundant. It is found in all the fresh waters of this country; and, with the exception of the Arctic regions, and a few of the rivers, such as the Wolga and some of
the tributaries of the Danube, which have their source in very cold regions, abounds throughout Europe. It also occurs in Asia, in the great islands of the Pacific Ocean, and in North America. Strictly speaking, it is a fresh-water fish, in which it can permanently subsist. Its habits are nocturnal, and the largest and finest are usually caught with night-lines. They give little amusement to anglers accustomed to the more elegant branches of their art, as they are a troublesome fish, and from their great tenacity of life, and their tortuous motions, often destroy the tackle of the fisher.

THE PERCH.

This is the last fish we shall here notice. When it attains to three pounds in weight it is considered of a large size. It thrives well, both in lakes and rivers, in the latter of which it prefers the sides of the streams to the more rapid parts of the current. It is very common in temperate climates, and generally abounds throughout Europe. In the south of England, Wales, Ireland, and in the lowlands of Scotland, it is common. Mr. Selby says that it is a rare fish in the north of England, and still rarer in the northern parts of Scotland, being met with only sparingly in the lochs north of the Forth; and, in several instances, when found in these localities, its introduction can be traced to no remote period.

"In all the almost countless waters," he adds, "of the northern counties, it is wanting." It is gregarious in its habits, and is angled for with a worm or minnow. In the winter it is very abstemious, but in the summer it is a bold biter. When the weather is cool and cloudy, with a rolling breeze from the south, perchs will bite the whole of the day. The best fishing-hours, towards the end of spring, are from seven to eleven in the morning, and from two to six in the afternoon. In warm and bright summer weather, a good time is from sunrise till six or seven in the morning, and from six in the evening till sunset.

In closing this, the last division of Rural Life, we think we cannot do better than quote the following lines, from a fishing poem nearly two centuries and a-half old, and respectfully recommend them to the perusal of the angler.

"The lofty woods, the forests wide and long,
Adorn'd with leaves and branches fresh and green,
In whose cool bowers the birds, with many a song,
Do welcome with their quire the summer's Queen;
The meadows fair, where Flora's gifts among
Are intermixed with verdant grass between;
The silver-scaled fish that softly swim
Within the sweet brook's crystal watery stream.

"All these, and many more of His creation,
That made the heavens, the Angler oft doth see;
Taking therein no little delectation,
To think how strange, how wonderful they be,
Framing thereof an inward contemplation,
To see his heart from other fancies free;
And whilst he looks on these with joyful eye,
His mind is rapt above the starry sky."
